There has been growing interest in the roles of the n-3 polyunsaturated fatty acids (PUFAs) docosahexaenoic acid (DHA) and the precursor eicosapentaenoic acid (EPA) as potential treatments for ADHD symptoms. The longest-chain n-3 PUFA DHA is the most abundant PUFA in brain membrane phospholipids; it has an important role in membrane fluidity and associated metabolic and neural activities. DHA appears to be particularly concentrated at synapses, influencing dopaminergic, serotonergic, noradrenergic, and gabaergic neurotransmission [25]. Recent meta-analyses [26–28] suggest that omega supplementation may improve ADHD symptoms to a modest degree, with an effect size of about a quarter as large as that seen for pharmacological treatment; whether sub-normal blood concentrations should be an indication for treatment is still not clearly established.

In summary, evidence from meta-analyses investigating RCTs of non-pharmacological interventions indicate that non-pharmacological treatments should not be recommended as the *only* interventions for core ADHD symptoms. The wider adoption of such approaches requires better evidence reported using blinded assessments [17]. This does not mean that pharmacological therapy necessarily represents the first choice for all subjects; in some children, psychosocial interventions alone are associated with recovery [29]. However, consistent evidence across studies confirms the utility of adding appropriate pharmacological therapy to existing psychosocial therapy, while only small benefits emerge from the addition of current psychosocial therapy to an ongoing drug treatment.

Pharmacological treatments

Drug treatment for ADHD represents an intervention of specific value and relevance to patients within multimodal treatment. Methylphenidate (MPH), dexamfetamine, or amphetamine (AMP), derivatives, and 'noradrenergic' medications atomoxetine (ATX) and guanfacine are the most effective psychopharmacological treatments for ADHD. As a class the first three are usually referred to as stimulants. As explained in Chapter 11, terms based on mechanism of action are much preferable. This is especially true in this case because the objective of treatment in ADHD is almost the opposite of stimulation.

Drugs for ADHD

AMP and MPH have been proved to be the most effective drugs for ADHD; their use is well established and consistently recommended in evidence-based clinical guidelines across the world [1–9], with a response rate of around 70%, rising to 95% when non-responders are treated with a second drug [30]. It is a significant problem that amphetamine is a controlled substance as a result of the United Nations decree in 1971. In a number of countries, it is classed along with drugs like heroin, which has inevitably retarded its adoption for the treatment of children.

Molecular mechanism of action of drugs for ADHD

AMP and MPH enhance the efflux and function of noradrenaline (NA) and dopamine (DA) in the CNS, with a rapid onset of action; they act by blocking (or even reversing) reuptake in their respective monoamine transporters [31]. AMP also increases catecholamine release from synaptic vesicles [32]. The therapeutic effects on behaviour and attention are presumed to be related to the enhanced neurotransmission of these catecholamines, especially in the prefrontal cortex [33].

Racemic AMP (α -methylphenethylamine) contains equal amounts of d-(dextroamphetamine) and l-amphetamine isomers. *In vitro*, the affinity of AMP is higher for noradrenaline transporters (NETs) in the prefrontal cortex than for DA (in the striatum) [34].

MPH is significantly less potent than AMP at inhibiting vesicular accumulation of DA or NA, but a similarly potent inhibitor of synaptic reuptake of DA and a slightly less potent inhibitor of NA reuptake.

At therapeutic doses, DA and NA have a complementary effect on the firing rate of catecholamine neurons, which results in improved signalling, especially in the prefrontal cortex [35]. During cognitive tasks, MPH has been shown to increase cerebral blood flow in dorsolateral prefrontal and posterior parietal cortices in healthy controls [36] and in the prefrontal cortex in adults with ADHD [37], with a significant decrease in other regions. This suggests decreased metabolic activation in task-irrelevant brain regions, with, in turn, more focused activation in task-relevant areas and improved performance [38].

More recently, drugs for ADHD have been shown to modulate functional connectivity; MPH normalizes activation and functional connectivity deficits in the brain networks supporting attention and motivation. This has been shown in medication-naïve children with ADHD during a rewarded continuous performance task, together with normalization of fronto-cingulate under-activation during error processing [39]. In adolescents with ADHD, the drugs demonstrated effects on the functional connectivity of fronto-parietal networks, with beneficial effects on working memory performance [40]. During inhibitory tasks, children with ADHD exhibit a raised motivational threshold at which task-relevant stimuli become sufficiently salient to deactivate the default mode network (DMN); treatment with MPH normalizes this threshold [41].

Pharmacokinetics

Absorption of AMP is rapid, with peak plasma levels about 3 hours after oral administration. AMP is metabolized through the liver by various P450 enzymes. Food does not affect total absorption but can delay it.

Consistently with its pharmacokinetic profile, the onset of action of AMP is rapid, within 1 hour after administration. For immediate-release preparations, the duration of action is slightly longer than for MPH (around 405 hours), but still requiring at least twice-daily administration to ensure adequate coverage. Mixtures of different d-AMP and dl-AMP salt formulations (that is, Adderal[®]) are available in the United States, but not in Europe.

Lisdexamfetamine (LDX) is dextroamphetamine (DEX) covalently attached to the essential amino acid L-lysine. LDX itself is not pharmacodynamically active nor does it result in high DEX levels when injected or snorted, thus having a lower abuse potential. Following oral administration, the amide linkage between the two molecules is enzymatically hydrolysed, releasing active DEX. Most of this hydrolysis takes place within red blood cells. Pharmacokinetics of d-AMP after single-dose oral administration is linear; in adults, there is no accumulation of DEX at steady state nor accumulation of LDX dimesylate after once-daily dosing for 7 consecutive days. The mean plasma half-life of d-AMP is about 11 hours.

Oral MPH is rapidly absorbed from the gastrointestinal tract, with peak plasma concentrations occurring about 1.5–3 hours after administration. The elimination plasma steady half-life of *d-threo*-MPH is about 3–3.5 hours. Because of this short-half life, steady state for MPH is not achieved during regular treatment, although there is a theoretical possibility of steady state developing with high doses of extended-release preparations or in poor metabolizers. Classroom studies suggest a close relationship between the pharmacokinetic profile and pharmacodynamic properties [42]. Optimal clinical effect appears to be associated with rapidly increasing levels in the morning, followed by a steadily increasing plasma level across the rest of the day.

Concerta XL[®], Matoride XL[®], Equasym XL[®], Medikinet Retard[®], and Ritalin LA[®] all provide a mixture of immediate- and extended-release MPH; they differ in the mechanics of the delayed-release system and in the proportion of immediate-release to delayed-release MPH. Concerta XL[®] and Matoride XL[®] effects last 10–12 hours, while Equasym XL[®], Ritalin LA[®], and Medikinet Retard[®] can be considered mid-release formulations lasting between 6 and 8 hours.

Transdermal patches (Daytrana[®]) allow about 12 hours of effect if worn for 9 hours and are available in the United States. This formulation exhibits minimal first-pass metabolism, resulting in high bioavailability of MPH. Quillivant XR[®] (5 mg/mL) is a recent long-lasting liquid preparation of MPH. Peak plasma levels occur approximately 5 hours after dosing, with effects marketed to last for up to 12 hours.

These differing delivery profiles provide the clinician with increased options when choosing which preparation to use. They allow a more flexible and sensitive individualized adjustment, while retaining the benefits of an extended-release preparation. Pharmacokinetic profiles may, however, show considerable inter-individual variation, and caution should be observed when generalizing from aggregated profiles to individual cases.

Interaction with other drugs

Drugs for ADHD show little interference with the metabolism and pharmacokinetics of other medications. There is, however, a potential to inhibit the metabolism of anticonvulsant drugs, such as phenobarbital, phenytoin, and primidone, and of tricyclics. Drugs

for ADHD may potentiate stimulating effects of other drugs on the cardiovascular or central nervous system and can increase pressor response to vasopressor agents. There are potentially dangerous interactions with substances of abuse like cocaine and other sympathomimetic agents, including ATX.

Clinical efficacy

Strong evidence supports the efficacy of drugs for ADHD in reducing ADHD core symptoms over treatment periods of up to a year, and numerous placebo-controlled randomized trials confirm their effectiveness in the short term, with effect sizes of between 0.8 and 1.1 on hyperactivity symptoms [2].

Drugs for ADHD reduce restlessness, inattentiveness, and impulsiveness markedly and rapidly, but they also have an important role in improving the quality of social interactions and decreasing aggression. Beneficial effects also extend to a broad range of associated functional impairments and comorbidities, including increased academic achievement [43], reduced risk of emergency admission to hospital for trauma [44], lower risk of depression [45] and suicidal events [46], and decreased rates of substance abuse [47] and criminality [48], although effect sizes are generally somewhat smaller than for symptom reduction per se.

Knowledge about the effectiveness of medication in ADHD children and adolescents has also been expanded in specific populations.

Within the Preschoolers with ADHD Treatment Study (PATS) trial, 160 children younger than 6 years were randomized to placebo or immediate-release MPH. The magnitude of MPH effect (dose range 2.5–7.5 mg) was lower than typically observed in school-aged children, with an increased frequency and severity of adverse events (that is, greater mood lability or reduced growth rate and treatment discontinuation in about 11% of cases) [49].

Positive results, but with more frequent and severe adverse effects have also been observed in ADHD children with comorbid autism spectrum disorder (ASD). A meta-analysis showed MPH to be effective (effect size 0.67) for treating ADHD symptoms in children with pervasive developmental disorders, but its relatively lower tolerability must be taken into account [50].

Although early studies suggested that children with comorbid anxiety or internalizing symptoms displayed lower response rates on ADHD symptoms, more recent studies, including the MTA study, do not support this. Drugs for ADHD at a group level show a beneficial effect on anxiety [51], and several recent studies showed that they are quite effective in controlling ADHD in the context of Tourette's disorder.

A recent meta-analysis also shows that MPH is clearly an important potential therapeutic option for comorbid disruptive behavioural problems and aggression in patients with ADHD and conduct disorder. Studies of MPH efficacy on aggression in conduct disorder without ADHD are still lacking [52].

LDX has been shown to be more effective than placebo on ADHD symptoms (effect size 1.8). LDX was also effective in treating day-to-day problems associated with ADHD, significantly improving quality of life [53]. The randomized withdrawal of treatment after 24 weeks of open-label treatment indicated the continued benefit of LDX treatment, with treatment-emerging adverse events generally consistent with those associated with the MPH preparation, used as the active comparator [54].

Long-term efficacy of drugs for ADHD

Although the short-term benefit of drugs for ADHD has been repeatedly confirmed within several studies, its long-term effects have been less well investigated. The MTA study still represents the most valid source of information on the long-term effects of MPH. Within this large-scale, random-allocation, non-blind trial, a comparison was made between careful medication management, intensive behaviourally oriented psychosocial therapy, a combination of the two, and a simple referral back to community (usually medication) [10]. The main conclusions after 14 months were that careful medication was more effective than behavioural treatment. The combination of behavioural therapy and medication did have some benefits: better control of aggressive behaviour at home, improved overall sense of satisfaction of parents, and possibly reduced medication dosage.

The follow-up at 36 months, by which time parents and children were free to choose the actual treatment, showed that all four original groups had a similar outcome; similar results were observed at up to 16 years' follow-up [55]. Various explanations are possible—the effects of more intensive therapy disappear when intensive treatment is stopped; self-selection of patients to treatments at the end of the randomization phase may lead to similar outcome (many children assigned to behavioural intervention started medication, and a significant percentage of those on intensive medication management actually withdrew medication). The most favourable overall development was found in children initially randomized to the MTA medication regime, whether or not they were taking medication at 36 months, thus suggesting some lasting benefit for some children with ADHD.

Non-dopaminergic medications

Currently, two classes of non-dopaminergic agents are approved for ADHD treatment: the selective NA reuptake inhibitor ATX and the α_2 agonists guanfacine and clonidine. The main clinical differences between these agents and dopaminergic drugs are their more favourable legal status, their potential for a long (up to 24 hours) duration of clinical efficacy, and a generally slower onset of action (at least several weeks).

Mechanism of action and pharmacokinetics

ATX is a selective inhibitor of NA synaptic reuptake. *In vitro*, it shows high affinity with NETs, and *in vivo*, it induces an increase in NA extracellular concentrations in the prefrontal cortex. In this region, despite its low affinity for its transporters, it also results in a strong increase in the extraneuronal concentration of DA, which remains stable in the nucleus accumbens and striatum [56], making abuse or triggering of tics by ATX unlikely.

ATX is metabolized mainly through the hepatic cytochrome P450 2D6 enzymatic system (CYP2D6), resulting in metabolites with clinically significant activity. Once-daily ATX is associated with a decrease in 3,4-dihydroxyphenylethylene glycol (DHPG), which is the main brain metabolite of NA and a biomarker of central NET inhibition, persisting for at least 24 hours. Interestingly, there also appears to be a dissociation between the pharmacokinetic and pharmacodynamic profiles for ATX, with evidence that, despite the relatively short half-life, even once-daily dosing can result in clinical effects lasting throughout the day.

Guanfacine is a selective α_2 noradrenergic agonist, with 15–20 times higher affinity for α_2A adrenergic receptors than for α_2B or α_2C receptors. Extended-release guanfacine (matrix-s tablets, GXR) is well absorbed; after oral administration, the time to peak plasma concentration is approximately 5 hours. GXR half-life is 16–17 hours, allowing once-daily administration. The pharmacokinetic profile of guanfacine is linear (first-order) and dose-proportional. The profile of GXR differs from that of immediate-release (IR) guanfacine, with GXR resulting in 60% lower C_{max} and up to 43% lower area under the curve (AUC), compared to IR tablets [57].

Clonidine is an α_2 receptor agonist, which modulates adrenergic transmission. Reducing sympathetic activity can give rise to hypotension, sedation, and irritability. Clonidine appears to be less efficacious than conventional drugs in the treatment of ADHD. The effectiveness in reducing tics in children with ADHD is comparable to dopaminergic drugs. In addition to the effects of sedation and symptomatic hypotension, clonidine can cause bradycardia and dry mouth.

Clinical efficacy of non-dopaminergic medications

The clinical efficacy of ATX has been well documented in short- and long-term studies, with an effect size of approximately 0.7 across studies [58, 59]. The onset of clinical effectiveness of ATX is slower than that of dopaminergic drugs, varying between 2 and 4 weeks. Full therapeutic effect can take up to 6–8 (or even 12) weeks, but responders typically show some degree of improvement by 4 weeks [60]. Some patients may continue to improve for 36 weeks [61].

Guanfacine showed significant improvement of clinician- and teacher-rated symptoms, functional impairment, and positive continuous performance outcome measures in a series of controlled trials [62]. A recent randomized withdrawal trial showed long-term maintenance of efficacy [63]. In adults, guanfacine modulates the influence of emotion control on cortical activation for cognitive control [64].

Other drugs

Bupropion acts as a weak inhibitor of presynaptic reuptake of NA, DA, and 5-HT; it has been licensed for depression and smoking cessation. It showed better efficacy than placebo in reducing ADHD symptoms in children, although lower than dopaminergic drugs. Bupropion can cause nausea, insomnia, and palpitations; it can also trigger tics and cause dermatological reactions, at times severe enough to lead to discontinuation of the drug. Three head-to-head trials found bupropion had efficacy comparable to that of MPH, although a large double-blind, placebo-controlled multi-centre study found smaller effect sizes for bupropion, compared to MPH. In terms of tolerability, a head-to-head trial found that headache was more frequent in the MPH group than in the bupropion-treated group, with no difference in other adverse events [65].

Tricyclic antidepressants: the mechanism of action of tricyclics involve inhibition of presynaptic NA reuptake, with poor selectivity. None of them is approved by the FDA or European Medicines Agency (EMA) for the treatment of ADHD; they were prescribed off-label for children with ADHD, but after the introduction of ATX, they are rarely used because of concerns about their potential cardiovascular toxicity.

Modafinil is a ‘wakefulness-promoting agent’ marketed for the treatment of narcolepsy; it has been occasionally used for the

management of inattention in adults. Its mechanism is poorly defined as a non-dopaminergic activating action on the frontal cortex. A recent meta-analysis on five RCTs showed an effect size of 0.7 on ADHD symptoms and a significantly higher incidence of decreased appetite and insomnia, but non-significant cardiovascular adverse events, compared to placebo [66].

Medication safety and management of adverse effects

Medications for ADHD are generally safe and well tolerated; adverse effects are mild, transitory, reversible, and easily manageable by the ADHD specialist [3, 4]. The most common side effects of dopaminergic agents include sleep difficulties, irritability, appetite and weight loss, headache, tachycardia, and increased blood pressure (BP) and heart frequency. Side effects of non-dopaminergic drugs mainly include nausea, sedation, and appetite loss, dry mouth, insomnia, constipation, and mood swings. Additionally, urinary retention and sexual dysfunction have been observed in adult patients. Most of these adverse effects diminish over the first months of treatment, with no significant differences between normal and poor metabolizers [2].

More severe adverse reactions, like psychotic symptoms or allergic reactions, have rarely been observed in association with dopaminergic or non-dopaminergic medications [3, 4]. Despite this, the tolerability and safety of medications used to treat ADHD have recently been raised as a concern to some regulatory authorities. In January 2009, the European Union (EU) Committee for Medicinal Products for Human Use (CHMP) concluded that the benefit of MPH outweighs the risk when prescribed to ADHD children over 6 years and recommended to standardize prescribing and to provide safety information across all EU members. They further concluded that research was needed on the long-term effects of MPH [67]. As a result of these recommendations, the Attention Deficit Hyperactivity Disorder Drugs Use Chronic Effects (ADDUCE) consortium was established to confirm MPH safety; it included experts in the fields of ADHD, drug safety, neuropsychopharmacology, and cardiovascular research (<http://www.adhd-adduce.org>).

Cardiovascular effects

MPH, AMP, and ATX are sympathomimetic agents that increase noradrenergic and dopaminergic transmission; an effect on heart rate (HR) and BP is therefore an intrinsic feature of their pharmacological activity [68, 69]. MPH and ATX may be associated with generally small elevations of BP (≤ 5 mmHg) and HR (≤ 10 beats/minute (bpm)) at a group level; a subset of children and adolescents (around 5–15%) may experience greater treatment-related increases in HR or BP, over the 95th centile, or may report a cardiovascular-type complaint during drug treatment [69].

The 10-year follow-up of the MTA study [70] found no effect of treatment on either systolic or diastolic BP; however, use of dopaminergic drugs was associated with a higher HR at years 3 and 8. A recent meta-analysis conducted in ADHD children and adolescents treated with MPH, AMP, or ATX, including 18 trials with data from 5837 participants (80.7% boys) and an average treatment duration of 28.7 weeks, revealed that all three medications were associated with a small, but statistically significant, pre-post-increase of systolic BP (SBP). Compared to AMP and ATX, MPH did not show a pre-post-effect on diastolic BP (DBP) and HR. Only 2% of patients

discontinued their medication due to any cardiovascular effect. In the majority of patients, the cardiovascular effects resolved spontaneously or with medication dose changes [71]. A meta-analysis in adult patients with ADHD reported that treatment is associated with small, but significant, increases in SBP (+2.0 mmHg) and HR (+5.7 bpm), but no effect on DBP [72]. No changes in ECG parameters, including PR, QRS, and QT intervals, have been associated with the use of MPH and ATX [69]. However, it is a concern that even small, but persistent, BP and/or HR increases may increase the risk for serious cardiovascular events, including sudden cardiac death, acute myocardial infarction, and stroke, in the long term. The magnitude of this risk remains to be established.

The available epidemiological studies, summarized by Hammerness *et al.* [65], do not show a significant association between ADHD drugs and serious cardiovascular events. A recent large study of 1,200,438 children and young adults between 2 and 24 years found no evidence that ADHD drugs increased the risk of serious cardiovascular events [73]. Similarly, several large registry studies of adults [74] and children (3–17 years) [75] suggest that ADHD medication, when medically supervised, was not associated with an increased risk of severe cardiovascular events.

Current guidelines [3] recommend that patients being considered for ADHD medication should have a clinical assessment, including identification of any known heart disease, any history of syncope with exercise, and any family history of sudden unexpected death under the age of 40 years. HR and BP should be taken at baseline and repeated every 3–6 months. It is important to make a referral for further assessment when indicated, and for patients with pre-existing cardiac conditions, dopamine or NA-releasing drugs should be used cautiously and only after consultation with a cardiologist.

Growth and developmental effects

One of the most common side effects of drugs for ADHD is appetite loss, with consequent reduced weight gain and possible growth reduction with prolonged use. The mechanism by which growth is affected has not yet been fully clarified. The decrease in appetite and the consequent reduction in caloric intake represent the obvious probable cause of the growth slowdown [76]. Other possible mechanisms include medication effects on hepatic and/or CNS growth factors and direct effects on cartilage.

Studies providing longitudinal data suggest the height deficit is approximately 1 cm/year during the first 3 years of treatment, while some other data suggest that these effects tend to attenuate over time and ultimate adult growth parameters are generally not affected [72, 77].

In the recently published MTA follow-up into adulthood [55], prolonged use of MPH in the ADHD group resulted in an average height of 1.29 ± 0.55 cm shorter than the control group ($p < 0.01$, $d = 0.21$). Within the treated sample, adherence to drug treatment was classed as consistent, inconsistent, or negligible: participants with the consistent or inconsistent pattern were 2.55 ± 0.73 cm shorter than the subgroup with the negligible pattern ($p < 0.0005$, $d = 0.42$).

Preliminary analysis of the large 2-year naturalistic pharmacovigilance ADDUCE study [67] shows a lower height velocity standard deviation score (SDS) in medicated ADHD subjects than in unmedicated ones, roughly equivalent to a reduction in height velocity of about 0.35 cm/year for a 9.6-year-old boy (mean

age of subjects in the study). In post hoc analyses, the impact on a child's height velocity SDS was apparently associated with the severity of illness, suggesting a possible dose-dependent effect of MPH.

With regard to ATX, a meta-analysis of seven double-blind/placebo-controlled and six open-label studies found that the mean actual weight and height at 24 months were, respectively, 2.5 kg and 2.7 cm lower than the expected values [78]. The difference occurred mostly during the first 18 months of treatment.

In order to prevent growth suppression and ensure an adequate growth pattern to subjects in the age of development, current guidelines [3] recommend:

- Monitoring appetite, weight, height, and BMI every 6 months.
- Differentiating between pretreatment eating problems and medication-induced eating problems.
- Giving medication after meals, rather than before.
- Encouraging the use of high-calorific snacks and late evening meals.
- Reducing the dose or switching to an alternative class or formulation.
- Discontinuing medication on weekends to prevent weight loss or longer drug holidays to allow for catch-up growth.
- Referring to a paediatric endocrinologist/growth specialist if height and weight values are below critical thresholds.

Neurological effects

Tics

Drugs for ADHD might, from a theoretical point of view, exacerbate tic severity as they can increase DA activity in the basal ganglia [79]. A meta-analysis, including nine DBRPC trials, examining the efficacy of medications for ADHD in children with comorbid tic (a total of 477 subjects) concluded that MPH does not worsen tic severity in the short term, although it is possible that MPH may worsen tics in individual cases and that ATX can, on the other hand, significantly improve comorbid tics [80]. The recent Cochrane group systematic review [81] concluded the same. With regard to ATX, although it can have a positive effect on tic frequency, some case reports have described exacerbation of tics during ATX treatment [4]. Thus, tics are no longer a contraindication for the use of ADHD drugs in the EU, but caution is still recommended [82] (EMA, 2010).

The management of tics should include: (1) observation of the intensity of tics over a 3-month period before any decision regarding ADHD treatment; (2) dose reduction; (3) substitution; and (4) if the previous measures are not effective, an antipsychotic can be added to control tics.

Sleep problems

Sleep problems are common in individuals with ADHD, and it is also important to rule out primary sleep disorders that may mimic or exacerbate ADHD. Both AMP and MPH may increase the latency to sleep onset, shorten sleep duration, and decrease sleep efficiency [83]. It is necessary to assess sleep at baseline and to continually monitor throughout treatment, as all ADHD medications can affect sleep. Dose timing adjustments, switching drug formulations, or adding an evening dose of melatonin are often helpful strategies for drug-exacerbated insomnia in children displaying a good medication response [84].

Seizures and epilepsy

Although longer-term effects of MPH and its effects in children with frequent seizures need further study, current evidence supports the use of MPH for the treatment of ADHD in patients with well-controlled epilepsy and even in those with infrequent seizures [85]. When epilepsy is poorly controlled, the frequency of seizures should be carefully monitored; if their frequency increases, or seizures develop *de novo*, then ADHD medication should be stopped.

Psychiatric effects

Psychotic, mood, and other psychiatric symptoms

Drugs for ADHD have been associated rarely with possible severe psychiatric effects, including psychotic symptoms (hallucinations). A review of the literature does not strongly indicate an association between MPH treatment for ADHD and psychosis. However, some open-label trial extension studies reported discontinuations due to psychotic symptoms. In contrast, some positive clinical experience (drugs for ADHD being helpful) have been reported for managing ADHD symptoms in the context of a psychotic disorder. A single study also found that medication with MPH in childhood could show a protective effect by reducing schizotypic features in adults.

Suicide-related events have also been investigated during treatment with drugs for ADHD, with symptoms sometimes anecdotally improving following discontinuation of medication. A recent population-based electronic medical records study showed that, in fact, the incidence of suicide attempts was higher in the period immediately *before* the start of MPH treatment. The risk remained elevated immediately after the start of MPH treatment but returned to baseline levels during continuation of the treatment. The observed higher risk of suicide attempts *before* treatment may reflect emerging psychiatric symptoms that trigger medical consultations, resulting in MPH treatment [86].

Population-based studies indicate that medication for ADHD is associated with a reduced long-term risk (that is, 3 years later) for depression [45] and a potential protective effect on suicidal behaviour [87]. However, individual patients being treated with medications for ADHD should be observed for the emergence of psychotic symptoms, depression, irritability, and suicidal ideation, as part of routine monitoring.

Mood lability, dysphoria, anxiety, hostility, and explosive outbursts may be observed in 5–10% of children taking drugs for ADHD. Among children whose aggressive behaviour develops in the context of ADHD and oppositional defiant disorder or conduct disorder, systematic, well-monitored titration of monotherapy often reduces aggression considerably, thus averting the need for additional medications [88].

Substance misuse

DA-releasing drugs have the potential for misuse and can be diverted by patients or families to this end [89]. The extended-release formulations of drugs for ADHD are less prone to diversion, because they do rapidly increase blood drug levels and are also less easily crushed into powder for injection or snorting. Once-a-day administration also makes parental supervision easier to enforce. Non-dopaminergic medications (that is, ATX) are another option with low abuse potential.

Concern has been raised that therapeutic use of drugs for ADHD may result in ‘sensitization’ and possibly increase the risk for substance use disorder (SUD) later in life. However, ADHD is associated with impulsivity and conduct disturbances, and represents itself a risk factor for SUD. Naturalistic follow-up studies do not support the contention that drugs for ADHD increase the risk for SUD (for example, Swedish registry studies found drug treatment associated with decreased rates in patients with ADHD) [48].

Management and treatment of ADHD in adulthood

ADHD is a chronic condition with symptoms frequently persisting into adulthood. About 60% of affected children have, as adults, significant ADHD-related impairments, including social dysfunction, educational and occupational underachievement, substance abuse, increased risk for accidents, and legal difficulties [90]. Although awareness, recognition, and diagnostic criteria of ADHD in adults have improved in recent years, there is still the need to increase physician support and specialized services for the clinical management of this disorder, as patients make the transition to the adult health care system [91, 92].

The NICE guidelines in the UK provide strong support for the provision of adult ADHD services, recommending that young people with ADHD and receiving treatment from child and adolescent mental health services (CAMHS) or paediatric services should be reassessed at school-leaving age to establish whether treatment should continue into adulthood.

Adult ADHD symptomatology differs from the typical childhood presentations; hyperactivity/impulsivity may diminish over time, while inattention tends more often to persist, with a greater impact in adults. Optimal strategies for ADHD in adulthood are, as in childhood, multimodal, with the main goals of improving symptoms and optimizing functional performance [93]. Adults respond well to the same classes of medication used in children, and MPH and AMP are confirmed as first-line pharmacologic interventions [94]. Adults with ADHD have, in fact, reported improved social relationships, academic/work functionality, and driving, together with reduced criminal behaviour, as a consequence of ADHD medications [95]. Additionally, adults with ADHD treated with drugs prior to 18 years have been shown to have better outcomes across broad quality of life measurements, as compared with subjects not previously so treated [96].

Just as for children and adolescents, drug treatment of adult ADHD consistently yields positive short-term effects, but few trials have evaluated their long-term efficacy and safety. Poor compliance and comorbid psychiatric disorders may further complicate the determination of treatment benefits in adults with ADHD [97]. ADHD medications can cause side effects also during adulthood. The most worrying include increases in both BP and HR. However, as confirmed by a recent large population cohort study [70], there is no increased risk for acute myocardial infarction, sudden cardiac death, or stroke for current ADHD medication users, compared to non-users. While the risks of serious side effects are thought to be low for healthy adults, physicians should, however, be cautious when prescribing for patients with cardiovascular disease, seizure disorders, and psychosis [98].

Even though pharmacologic interventions are considered first-line treatments for ADHD, some adults with ADHD continue to experience significant residual and impairing symptoms. CBT has been shown helpful in the treatment of adult ADHD, alone and in combination with psychopharmacology [99].

Another psychoeducational approach that has gained increasing popularity in the last year is coaching. It is a highly individualized intervention, in which a personally assigned coach guides the patient in accomplishing tasks and goals. Coaching differs from traditional CBT, because it is more focused on solving specific problems or reaching specific goals and is more accessible to the patient on an as-needed basis [100].

Conclusions

ADHD is a chronic, heterogenous condition, with a high prevalence and persistence into adult life and the potential for serious functional impairment extending beyond the affected individual. Established efficient assessment methods and good treatment evidence help clinicians in monitoring and managing this disorder in childhood and adulthood. ADHD drugs, available in different formulations, are, especially in the short term, currently among the more effective drugs in psychiatry and perhaps in general medicine [101], with a good safety profile. Long-term treatment efficacy and tolerability and safety data are still insufficient and need more research. On the basis of the current evidence, however, there does not seem to be any necessity to change current clinical guidelines for the monitoring of the main possible adverse events.

SECTION 6

Motor disorders

37. Neurodevelopmental motor disorders 357

Davide Martino and Antonella Macerollo

Neurodevelopmental motor disorders

Davide Martino and Antonella Macerollo

Introduction

Neurodevelopmental motor disorders are a group of conditions characterized by developmental deficits in learning, control, and execution of motor skills. These deficits may manifest as difficulties in programming and executing fine and gross motor tasks that are crucial for routine activities of daily living and social and academic abilities, as well as an inability to control excessively repetitive or unwanted motor behaviours. The appropriate realization of a motor programme or a sequence of movements requires the convergence of numerous pathways [sensory (somatosensory, proprioceptive, visual, vestibular) pathways, motor pathways, and regulatory pathways, for example cortico-basal ganglia, cerebello-thalamo-cortical and intracortical networks]. This neuroanatomical substrate involves cortical and subcortical structures regulating the correct integration of sensory inputs and motor outputs, which allows the successful execution and learning of advantageous goal-directed movements. The correct functional development of motricity is strongly supported by experience, with appropriate synaptic circuits being reinforced and established as a result of recurrent practice of efficient movement patterns.

The most common neurodevelopmental motor disorders are tic disorders, stereotypic motor disorder, and developmental coordination disorder (DCD), which will be the object of this chapter.

Tic disorders

Phenomenology

Tic disorders are characterized by the recurrent presence of tics, which can be defined as unwanted, discrete, non-goal-directed, non-rhythmic movements (*motor* tics) or vocalizations (*vocal* tics). The basic features of tics which help distinguish them from other abnormal behaviours include: repetitive and patterned character; variability of the type of movement/vocalization and severity; association with premonitory urges; and partial or complete suppressibility on demand. Three tic disorders are included in DSM-5: Tourette's disorder [also called Tourette's syndrome (TS)], persistent (also called chronic) motor or vocal tic disorder; and provisional tic disorder [1]. The core diagnostic criteria of tic disorders are listed in [Box 37.1](#).

The repetitive and patterned character of tics is an important feature to differentiate them from other unwanted movements such as chorea or myoclonus. Regardless of their repetitive quality, tics are highly variable within and across subjects, as regards to muscle groups involved (and thus body location), complexity, and interference with normal voluntary behaviour. The overall severity of tics fluctuates over time, and each tic may wax and wane over the course of time. Their changing pattern is one of the main differences with stereotypies, discussed later in this chapter.

Although virtually any striatal muscle group in the body can be involved in a tic, a cranio-caudal gradient of frequency is typically observed, with the face, head, and proximal upper limbs being the most commonly affected. At the same time, the ability to suppress tics voluntarily is maximal where tics are least frequent (trunk and lower limbs), and minimal in the most cranial body areas [2].

Tics are also classified as simple and complex, depending on whether they involve a single muscle group or consist of coordinated sequences or combinations of movements/vocalizations involving several muscle groups. Motor tics may therefore range from very rapid, simple motor twitches (for example, blinking, facial grimacing, head flicks, shoulder shrugs, etc.) to orchestrated sequences of movements, sometimes resembling purposeful behaviour. Likewise, vocal tics may range from monosyllabic, meaningless vocal utterances to longer fragments of verbal language with a semantic content. Complex tic-like repetitive behaviours include also: echophenomena (echopraxia, echolalia) and paliphenomena, that is, non-voluntary repetition of movements or vocalizations made by another person or his/her own; and socially inappropriate words or gestures, which can also have obscene content, as in coprophenomena (coprolalia, copropraxia). When severe enough, tics may cause impairment in social, academic, and professional functioning. Some tics may have a violent and potentially (although not deliberately) self-harming quality, for example, head banging, hitting, etc.

Premonitory urges (PUs) are uncomfortable sensations that build up in intensity immediately before tics and are markedly alleviated immediately after tic release. Often the linked PUs and tics occur in the same body region. In some patients, PUs are described more as a poorly defined feeling of pressure, tension, or restlessness around the body part associated with a certain tic. Only about 25% of pre-pubertal children are able to describe PUs, whereas this

Box 37.1 DSM-5 criteria for tic disorders**Tourette's syndrome (TS)**

For a person to be diagnosed with TS, he or she must:

- Have two or more motor tics (for example, blinking or shrugging the shoulders) and at least one vocal tic (for example, humming, clearing the throat, or yelling out a word or phrase), although they might not always happen at the same time.
- Have had tics for at least a year; the tics can occur many times a day (usually in bouts) nearly every day, or off and on.
- Have tics that begin before he or she is 18 years of age.
- Have symptoms that are not due to taking medicine or other drugs or due to having another medical condition (for example, seizures, Huntington disease, or post-viral encephalitis).

Persistent (chronic) motor or vocal tic disorder

For a person to be diagnosed with a persistent tic disorder, he or she must fulfil the same criteria of TS, apart from the first criterion, which is as follows:

- The person must have one or more motor tics (for example, blinking or shrugging the shoulders) or vocal tics (for example, humming, clearing the throat, or yelling out a word or phrase), *but not both*.

Provisional tic disorder

For a person to be diagnosed with this disorder, he or she must fulfil the same criteria of persistent (chronic) tic disorder, with the only difference that tics have been present for no longer than 12 months in a row.

Source: data from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, DSM-5, Copyright (2013), American Psychiatric Association.

self-awareness increases dramatically to about 60% during late teen years [3]. Fig. 37.1 summarizes the differences in the main antecedents between tics, compulsions, and impulsive actions.

Patients with tics may also report 'just-right' phenomena, in which they reiterate actions that may or may not involve sensory experiences (for example, repeatedly touching an object or a body part) until these feel 'just right'. 'Just-right' phenomena are more common in patients with comorbid obsessive-compulsive disorder [3].

Another relevant sensory feature associated with tics is the unusual focus of attention on external stimuli which are repetitive, faint, and poorly salient. This phenomenon has been named somatic hypersensitivity or site sensitization and is not related to abnormalities in the ability to discriminate between sensory stimuli of different intensities [4]. Some patients may become easily and disproportionately irritated by excessive irritation by environmental noise (misophonia). The origin of somatic hypersensitivity in tic disorders is still not very well understood but may be related to abnormalities of sensorimotor gating.

The ability to suppress tics is higher in adults than in children and varies across patients. Although suppressing tics leads to a rise in PU intensity, the quality or severity of PUs is not associated with the ability to hold tics in [2]. Although a proportion of patients may experience a rebound worsening of tics, following prolonged tic suppression, this is not a constant feature. More rapid tics, for example eye movements or blinking, are often too quick to be suppressed. Active tic suppression demands attention and may distract from complex cognitive activities, including school-based learning activities. Voluntary suppression of tics is facilitated by reward, for example in social situations where inhibiting tics may lead to greater social acceptance. Relaxation, physical exercise, engagement in attention-demanding tasks, and reduced sympathetic tone may also reduce tic severity. At the same time, psychosocial stress is the most effective contextual factor that modulates tic severity. Raised

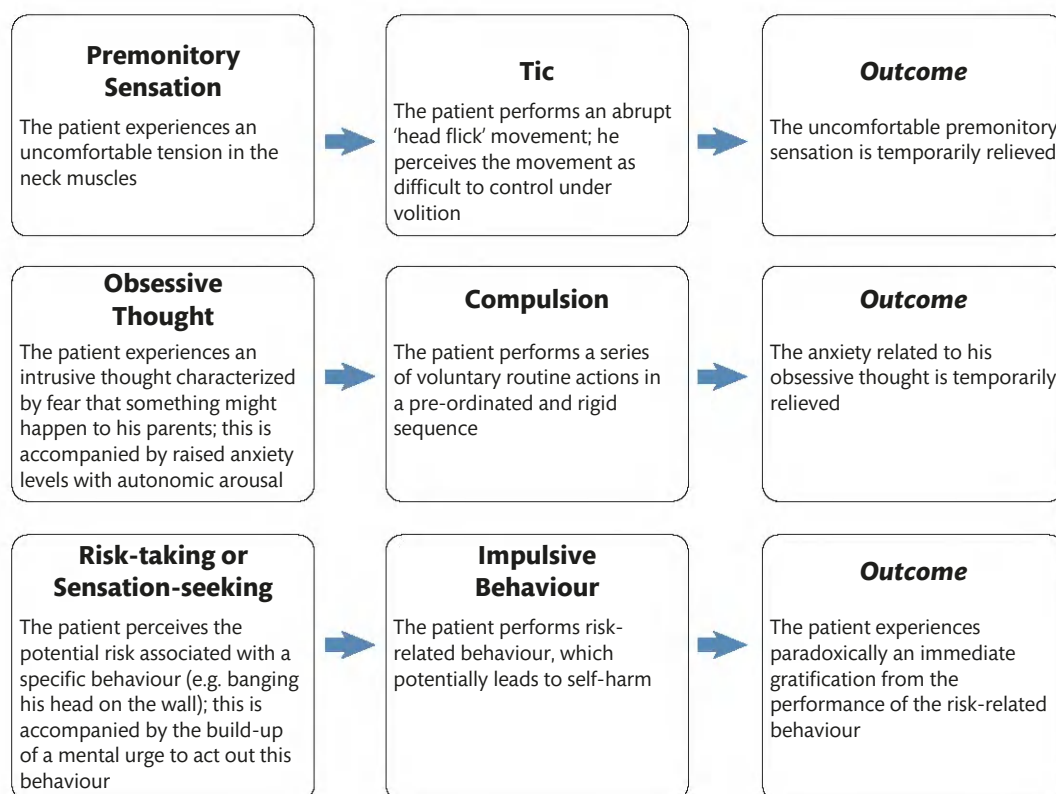

Fig. 37.1 Basic phenomenologic differences between tics, compulsions, and impulsive behaviours.

anxiety levels and fatigue are also important precipitants of tics. Moreover, in some cases, tics and PUs may be precipitated by talking or thinking about them (metacognitive inducibility) [5].

Tic-like rapid movements presenting in adulthood may be labelled as tics, but at least a proportion of them are considered to have a *functional* origin. Apart from age at onset, these abnormal movements differ from typical 'organic' tics for their female predominance, sudden onset often precipitated by minor trauma or panic attacks, uncommon association with PUs or suppressibility, common suggestibility, lack of association with a family history of tic disorders or a personal history of ADHD or OCD, and no response to anti-tic medications such as dopamine antagonists [6].

Tics typically begin between 5 and 8 years of age, and in up to 95% between ages 4 and 13. The first tics are more frequently simple and involve cranial muscles, usually facial (blinking, sniffing, etc.). Severity peaks around puberty (age 10–12) when complex tics usually appear, and tics may spread beyond the cranio-cervical region. Tics usually decrease in the second decade. Persistence of clinically relevant tics in adulthood was found to be associated with higher tic severity in childhood, lower caudate volumes, and poorer performance on tasks involving visuomotor skills during childhood [7].

Most prevalence studies on tic disorders have focused on paediatric populations. A meta-analysis of prevalence data from 1985 to 2011 found that studies applying a school-based assessment yielded a combined prevalence of 0.77% for TS, 1.61% for chronic tic disorders, 2.99% for transient tic disorders, and 2.82% for the 'all tic disorders' category in the population of up to 16 years of age [8]. There is, however, large variability of estimates across studies, due to differences in design and conduct. A male predominance was detectable only in TS, but not in other chronic and transient (provisional) tic disorders. Cohort studies of youth with TS report that half to two-thirds of these patients experience a significant decline of tic symptoms that roughly coincides with late adolescence. In contrast with this, a study in which adults previously diagnosed with TS in childhood were evaluated again after age 20 found that 90% still had tics, suggesting that tic disorders are not rare in adulthood [9].

The lifetime prevalence of any psychiatric comorbidity among TS patients was estimated at 85–90%, with almost 60% suffering from two or more psychiatric disorders, and more than 70% meeting criteria for OCD or ADHD [2, 3]. Overall, other symptoms/behaviours are often a greater cause of distress than tics and have a negative impact on TS patients' quality of life.

ADHD is the most common comorbidity, affecting up to 60% of TS patients, particularly male children. ADHD typically begins before the onset of tics, and its presence is associated with earlier tic onset (5.8 vs 6.2 years in TS patients without ADHD). ADHD is associated with a higher likelihood of reduced social functioning, anxiety disorder, anger control and sleep problems, mood disorders, and conduct or oppositional defiant disorder.

Obsessive-compulsive symptomatology in TS is most often associated with symmetry behaviours, 'just-right' experiences, and repetitive touching, although other types of obsessive-compulsive behaviours may also be observed. In a large sample of more than 5000 children and adolescents with TS, comorbid OCD was associated with ADHD, mood and anxiety disorders, conduct disorder/oppositional defiant disorder, and autism spectrum disorder (ASD) [10].

Self-injurious behaviour is encountered in up to 60% of TS patients. TS patients are 1.4 times more likely to suffer from anxiety than

the general population, independent of comorbid OCD and ADHD. Up to 30% of patients may develop mood disorders in their lifetime, although this seems mostly accounted for by comorbid OCD. About 10% of youth with chronic tic disorders experience suicidal thoughts and/or behaviours [11]. Prevalence estimates of ASD in TS may be as high as 13%. Of note, ASD were found to be associated with a higher risk of rage attacks/explosive outbursts. Finally, 64% of adult TS patients were found to have at least one comorbid personality disorder, with borderline, depressive, obsessive-compulsive, paranoid, passive aggressive, and avoidant being the most common [10].

Pathogenesis

Structural and functional abnormalities were detected in TS patients at numerous levels of the cortico-striato-thalamo-cortical (CSTC) network, which is fundamental for the programming and execution of motor actions and habit formation [12]. On a microscopic level, one transcriptomics and two neuropathological studies of previously medicated TS adults showed reduced numbers and gene expression within inhibitory GABAergic and cholinergic interneurons in sensorimotor parts of the striatum and internal segment of the globus pallidus. A functional imbalance between inhibition/excitation in these structures was hypothesized. Animal model work on rodents and monkeys have shown that injection of the GABA_A antagonist bicuculline in sensorimotor parts of the striatum leads to disinhibition of the CSTC loops and to generation of tic-like rapid movements, whereas injection in the nucleus accumbens (ventral or limbic part of the striatum) leads to vocal utterances resembling vocal tics. Tic-like generation in one of these models followed the somatotopical distribution of respective disinhibited striatal motor areas [13, 14].

Structural neuroimaging studies in TS patients have provided further evidence of abnormalities in CSTC circuits (in particular, in sensorimotor and limbic loops). Voxel-based morphometry studies reported volumetric changes of the caudate, putamen, midbrain, and hippocampus, whereas diffusion tensor imaging tractography showed reduced connectivity between the supplementary motor area and the basal ganglia, as well as in frontal cortico-cortical circuits [15]. Event-related fMRI revealed activation of the sensorimotor area and posterior parietal cortex at tic onset, whereas premotor areas, the anterior cingulate cortex, and the insula were activated in the 2 seconds prior to tic (hence, possibly corresponding to the urge to tic). It has thus been speculated that urge activity in the insula could influence the primary motor cortex to produce tics, bypassing the premotor cortex [16].

There is evidence for defective inhibitory mechanisms in TS brains, at the level of both intracortical inhibitory microcircuits and sensorimotor gating. The latter is classically explored, assessing prepulse inhibition, where an initial small sensory stimulus inhibits a reflex response to a second stronger stimulus. Prepulse inhibition defects have been reported in a proportion of patients with tic disorders and could be associated with the somatic hypersensitivity exhibited by these patients [17].

Another important theory at the basis of tic generation supports the involvement of overactive dopaminergic systems. This is suggested by the observation of excessive phasic dopamine release following stimulation with amphetamine in nuclear imaging studies. It also gives support to the idea that tics represent a form of habit, arising from a dopaminergically mediated reward associated with the relief of the uncomfortable urge induced by the tic movement [12].

A long list of conditions and psychotropic substances may give rise to secondary tics. A later age at onset (late adolescence or adulthood), abrupt onset, and association with other neurological manifestations should prompt to exclude these secondary causes. **Box 37.2** provides a comprehensive list of these causes.

Management

A comprehensive history, collected from patients and reliable informants, and assessment using validated rating instruments for tics and associated behavioural symptoms are crucial in guiding the management of tic disorders (**Fig. 37.2**). Appropriate education of patients and families is a necessary phase of management, which aims at optimizing the understanding and acceptance of symptoms and identifying the best coping strategies with the disorder. Both thorough assessment and education help the clinician in selecting patients who require more active interventions for their tics, when these are needed, and whether and which comorbidities should be treated with priority.

Tics typically require active interventions when they are stigmatizing, socially or academically impairing, influencing mood and self-esteem, and generating situational anxiety. Also, a smaller proportion of cases experience violent tics that are potentially harmful or physically exhausting, leading to pain, headaches, or fatigue. **Fig. 37.3** presents a therapeutic algorithm adapted from recently published guidelines [18, 19].

The first line of interventions for tics encompasses pharmacological and behavioural approaches. The choice of a specific intervention is not only guided by evidence, but relies also on the predicted compliance of each individual to a given treatment, as well as on the need to obtain a rapid effect and the direct availability of certain interventions (for example, behavioural).

Dopamine antagonist drugs have been in the therapeutic arsenal for tics for more than 40 years. Pimozide (0.5–6 mg) and haloperidol (0.5–10 mg) were shown to be superior to placebo by six and three RCTs of fair quality, respectively, although haloperidol showed a worse tolerability profile. The use of fluphenazine (0.5–20 mg) is supported by open-label studies, retrospective case series, and one single-blind, placebo-controlled crossover study. Benzamides like tiapride and sulpiride (50–200 mg) are also used, especially in some European countries. However, there is limited evidence of their efficacy; moreover, sedation is frequently reported by patients on sulpiride (**Table 37.1**) [20].

Among second-generation antipsychotics, the use of risperidone is supported by five RCTs that confirmed its superiority to placebo in treating tics. A meta-analysis showed that risperidone (daily dose range 1–6 mg) does not differ in efficacy from haloperidol, pimozide, and ziprasidone. Initial evidence shows that risperidone could be helpful as an augmentation strategy for associated obsessive-compulsive symptoms and impulse-control disorder. The efficacy of aripiprazole (5–30 mg) is supported by one fair-quality RCT, five prospective open-label studies on relatively large clinical samples, and one meta-analysis. About two-thirds of treated patients across different ages show clinically significant improvement of their tics with this medication, with effects lasting over 1 year in up to 50% of responders. Cardiac safety may also be larger for aripiprazole,

Box 37.2 Secondary causes of tics

• Neurodevelopmental disorders

- Mental retardation
- Autistic spectrum disorders (including Asperger's syndrome)
- Rett's syndrome
- Genetic and chromosomal abnormalities
- X-linked mental retardation (MRX23)
- Albright hereditary osteodystrophy
- Duchenne muscular dystrophy
- Factor VIII haemophilia
- Fragile X syndrome
- Lesch-Nyhan syndrome
- Triple X and 9p mosaicism
- 47,XXY karyotype
- Partial trisomy 16
- 9p monosomy
- Beckwith-Wiedemann syndrome
- Tuberous sclerosis
- Congenital adrenal hyperplasia due to 21-hydroxylase deficiency
- Phenylketonuria
- Corpus callosum dysgenesis
- Craniosynostosis
- Klinefelter's syndrome
- Neurofibromatosis
- Developmental stuttering

• Acute brain lesions

- Post-traumatic
- Vascular
- Infectious
- Varicella-zoster virus
- Herpes simplex encephalitis
- *Mycoplasma pneumoniae*
- Lyme disease

• Post-infectious

- Sydenham's chorea
- Paediatric autoimmune neuropsychiatric disorder associated with streptococcal infections (PANDAS)
- Neurodegenerative diseases
- Huntington's disease
- Neuroacanthocytosis syndromes
- Neurodegeneration with brain iron accumulation

• Other systemic diseases

- Behçet's syndrome
- Antiphospholipid syndrome

• Peripheral trauma

Table 37.1 Medications for the treatment of tics

Medication	Daily dose (mg)	Adverse effects	Level of evidence
Clonidine	0.05–3	Sedation, dry mouth, headache, irritability, mid-sleep awakenings, rebound hypertension, tics and anxiety following abrupt discontinuation	CG: moderate quality, strong recommendation ESSTS: level A evidence
Guanfacine	0.5–4	Orthostatic hypotension, bradycardia, sedation, headache	CG: moderate quality, strong recommendation ESSTS: level A evidence
Haloperidol	0.5–10	Rigidity, parkinsonism, tardive involuntary movements and akathisia; appetite changes; weight gain; salivary changes; constipation; depression, anxiety; fatigue, sedation; hyperprolactinaemia (galactorrhoea, gynaecomastia, irregular menses, sexual dysfunction)	CG: high quality, weak recommendation ESSTS: level A evidence
Pimozide	0.5–6	Similar to haloperidol, but with less movement disorders; QTc interval prolongation	CG: high quality, weak recommendation ESSTS: level A evidence
Risperidone	0.5–16	Sedation, fatigue, depression and acute phobic reactions, weight gain	CG: high quality, weak recommendation ESSTS: level A evidence
Aripiprazole	5–30	Weight gain, increase in BMI and waist circumference, nausea, fatigue, sedation, akathisia, movement disorders, sleep problems; probably lower risk of QT prolongation than with other antipsychotics	CG: moderate quality, weak recommendation ESSTS: level B evidence
Ziprasidone	5–40	Sedation, anxiety, akathisia, movement disorders	CG: low quality, weak recommendation ESSTS: level B evidence
Olanzapine	2.5–20	Sedation, weight gain and increased appetite, dry mouth, transient hypoglycaemia	CG: low quality, weak recommendation ESSTS: level B evidence
Fluphenazine	0.5–20	Similar to haloperidol, but less frequent	CG: low quality, weak recommendation ESSTS: not evaluated
Sulpiride Tiapride	50–200	Sedation; less commonly, paradoxical depression, restlessness, sleep problems, weight gain, hyperprolactinaemia	CG: not evaluated ESSTS: level B evidence
Topiramate	50–150	Weight loss, paraesthesiae	CG: low quality, weak recommendation ESSTS: not evaluated
Botulinum toxin		Focal weakness, hypophonia	CG: low quality, weak recommendation
Delta-9-THC	10	Anxiety, dizziness, fatigue, dry mouth, mood changes, memory loss, psychosis, blurred vision	CG: low quality, weak recommendation
Quetiapine	50–250	Sedation	CG: very low quality, weak recommendation ESSTS: level C evidence
Tetrabenazine	25–150	Sedation, fatigue, nausea, insomnia, akathisia, parkinsonism, depression	CG: very low quality, weak recommendation

compared to other dopamine antagonist drugs, in patients with tics [20].

Alpha-2 agonists have been used to treat tics for more than three decades. Clonidine and guanfacine are considered first-line therapy in the United States and Canada, thanks for their more favourable tolerability profile. Six RCTs of heterogeneous quality demonstrated superiority to placebo for clonidine in both oral and transdermal formulations (0.05–3 mg). Treatment with clonidine requires monitoring for reduced blood pressure, sedation, headache, irritability, dysphoria, and interrupted night sleep. It is also advisable to use a slow titration of clonidine in order to improve tolerability, as well as gradual discontinuation to prevent rebound hypertension. Guanfacine has a longer half-life than clonidine and can be administered only once daily (0.5–4 mg); it has a similar side effect profile to clonidine. Two RCTs and two open-label studies confirmed the efficacy of guanfacine, especially in children with tic disorders. Importantly, one meta-analysis confirmed superiority to placebo for both alpha-2-agonists only for youngsters with comorbid ADHD [21].

Tetrabenazine is a presynaptic dopamine depletor that acts by blocking the vesicular VMAT2 protein and displays minor postsynaptic D2 blockage. Its relatively widespread use in tics is supported by its greater tolerability, compared to antipsychotics; however, there is limited evidence of its efficacy, mainly supported by a single small open-label trial and by retrospective cohort studies reporting improvement of tic severity sustained for up to 2 years. Among GABA agonists, baclofen and topiramate were found to be moderately effective in two medium-sized double-blind RCTs on patients of different ages.

Botulinum toxin type A injections represent a very useful resource in older adolescents and adults for the treatment of persistent, simple motor tics located to the upper face or neck, as well as for a number of vocal tics, including coprolalic utterances. However, as with tetrabenazine, its large use is not supported by a strong evidence of efficacy, which consists only of case reports or small series, three retrospective cohort studies, and one RCT. Hypophonia is a very common side effect of botulinum toxin injections for vocal tics.

Delta-9-tetrahydrocannabinol, the main active compound of cannabis, has been tested in two small RCTs on adults with TS, showing a modest, but promising, benefit on some outcome measures and acceptable tolerability. Nicotine has been investigated as an add-on treatment to haloperidol in a number of studies, but its mild efficacy is outweighed by intolerable gastrointestinal side effects [20].

Complementary and alternative medicine approaches in TS have recently attracted growing interest. Among the most promising interventions, there is interesting evidence of safety and moderate efficacy on tics or tic-related impairment for omega-3 fatty acids and Chinese traditional medicine approaches that include Ningdong and 5-Ling granules. The efficacy on tic severity of 5-Ling granules has recently been reported by a large double-blind RCT [22].

Investigation and application of behavioural therapies specifically targeting tics have remarkably increased in the last decade. The most effective treatment approaches of this kind are habit reversal training (HRT), a related and expanded version of the HRT package called Comprehensive Behavioral Intervention for Tics (CBIT), and exposure and response prevention (ERP) for tics [23, 24]. HRT for tics is built on *awareness training*, during which patients learn to recognize in real time their urges and tics; *competing response training*, whereby non-pervasive motor behaviours physically incompatible with tics are selected and implemented to diminish tic production; and *social support*, based on the engagement of a support person in promoting the deployment of competing motor responses outside of therapy. Six RCTs and other smaller observational studies demonstrated the efficacy of HRT in diminishing tic severity. This was confirmed by meta-analyses, which detected a large treatment effect size, similar to that observed in other widely used behavioural interventions for conditions like OCD or anxiety disorders. A combination of HRT and acceptance and commitment therapy (ACT) has also been proposed but is still not supported by sufficient evidence of efficacy. ACT consists of exercises helping patients to gain distance from distressing cognitions, emotions, and urges.

CBIT is the most popular and, to date, effective extension of HRT. CBIT complements HRT with: (1) *function-based assessment*, which targets contextual factors predictably worsening tics and facilitates support persons and patients to identify strategies to counteract tic-prone situations; (2) *relaxation training*, primarily acting on stress management; and (4) and *psychoeducational interventions*. CBIT consists of 11 1-hour long sessions, six of which weekly, two scheduled every 2 weeks, followed by three booster monthly sessions, with a fixed protocol of homework assignments. This treatment protocol was three times superior to supportive therapy plus psychoeducation in two large multi-site RCTs, one with children and one with adults with TS, demonstrating very good tolerability and low attrition, sustained improvements for more than 6 months, and amelioration of familial distress, obsessive-compulsive symptoms, and anxiety [23]. Preliminary evidence demonstrated the non-inferiority of HRT administration via a tele-health approach, compared to face-to-face administration.

ERP is largely used in OCD. Its adaptation for tic treatment relies on prolonged exposure to urges associated with sustained suppression of tics, thus generating habituation to the urge and a progressive decrease in the motivation of the patient to tic. Only one RCT has shown non-inferiority of ERP to HRT [24].

A cognitive psychophysiological model, aiming to change the background activity against which tics occurs and treat associated metacognitive and perfectionist beliefs, has recently been tested in an open trial [25]. Other therapeutic approaches focusing on stress modulation that have recently been tested in open-label studies include mindfulness-based stress reduction programmes in small group classes, which yielded a promising percentage of responders, or aerobic exercise sessions such as kickboxing routines. Neurofeedback modulation of EEG oscillatory activity of cortical areas involved in cognitive control has also been tested in preliminary open-label studies and found to attenuate ADHD and tic symptoms. Controlled trials for these approaches are lacking. More research is also needed to increase knowledge of predictors of good response to CBT and patient selection criteria.

Within the realm of neuromodulation strategies for more severe cases of TS, deep brain stimulation (DBS) remains the only active intervention that is extensively being investigated for adult TS patients who are deemed refractory to pharmacological and behavioural interventions. The main patient selection criteria for DBS in TS proposed by recommendation documents [26] are listed in **Box 37.3**.

Consensus on the ideal anatomical target has not yet been reached to date, mostly due to the lack of adequately powered active comparator trials. The most frequently used targets, supported by crossover RCTs, are the centromedian/parafascicular-substantia periventricularis-nucleus ventralis oralis internus crosspoint of the thalamus and the globus pallidus pars interna (more frequently the anteromedial, or limbic, portion) [27, 28]. Although DBS of TS has not raised major safety concerns to date, its efficacy appears to be still quite variable across patients, and long-term observation is warranted. The application of adaptive approaches using looped paradigms that adapt stimulation parameters to real-time brain oscillatory activities associated with tic generation is currently being investigated.

Box 37.3 Recommendation on patient selection for deep brain stimulation in Tourette's syndrome

- Diagnosis of TS or other chronic tic disorder.
- Age 18 or above (according to some authors, 25 or above).
- Tics as prominent feature of the clinical presentation.
- High tic severity (proposed as ≥ 35 on the Yale Global Tic Severity Subscore for a stable period of time, suggested by some authors of at least 12 months) and/or presence of potentially highly disabling or harmful tics (for example, tics associated with a clear self-injurious component).
- Tics are considered refractory to pharmacological and behavioural interventions. Failure of pharmacological treatment implies having tried a course with medications from at least three different pharmacological classes (for example, antipsychotics, α_2 -agonists, benzodiazepines), lasting at least 12 weeks (according to other authors, 6 months) for each drug, at adequate dosage and with proven compliance. Failure of behavioural therapy implies having tried at least ten sessions of behavioural treatment (either HRT-based or ERP-based).
- Stable and optimized treatment of medical, cognitive, and behavioural comorbidities.
- Expected compliance during monitoring (stable psychosocial environment).

Stereotypic motor disorder

Phenomenology

Stereotypies are repetitive, non-goal-directed actions predominantly seen in childhood. Unlike tics, they can be highly consistent over time (≥ 4 weeks), are generally not preceded by sensory or mental experiences, and may be distracted by surrounding stimuli (for example, by calling the child's name) [29]. *Common stereotypies* are the most frequent, occurring in 20–50% of children. These comprise non-disabling habits which change pattern during development, including (in order of the most frequent time of appearance) thumb sucking, body rocking, nail biting, foot tapping, head banging, chewing, or hair twisting. Common stereotypies only seldom require medical intervention, and this is usually related to medical sequelae caused by their persistence and intensity such as dental malocclusion, digital deformities, paronychia, skin abrasions, or temporomandibular disorders. *Complex motor stereotypies* consist of different limb movements (flapping, waving, fisting, finger or wrist movements). These are subdivided into *primary* (stable or remitting, occurring in developmentally normal children) and *secondary* (occurring in conjunction with a neurologic or behavioural disorder), which, in some cases, may develop into self-injurious behaviours (for example, eye poking, biting, head banging, complex hand movements) [30, 31]. Other secondary stereotypies include atypical gazing, pacing, running, and jumping, all typically associated with autism. *Head nodding* begins earlier, is a quasi-rhythmic stereotypy which may also involve the shoulders, and often regresses in later childhood. In general, intense emotional states (particularly excitement), being engrossed in demanding activities, fatigue, or boredom may trigger stereotypies. Movements related to intense imagery have also recently been identified as a subtype of primary complex motor stereotypies.

The DSM-5 defines repetitive habit behaviours that cause impairment to the child as a stereotypic movement disorder (Box 37.4) [1]. Complex motor stereotypies and head nodding fulfil the DSM-5 criteria for stereotypic movement disorder.

Birth and developmental history, including defective communication and social skills, may be very helpful to identify disorders underlying secondary complex stereotypies. Family history of complex motor stereotypies may be present in as many as 40% of cases. Drug history is also relevant; for example, toxic effects of amphetamines include severe head banging and hand biting stereotypies [29].

Complex motor stereotypies have been estimated to occur in up to 3–4% of the general population of pre-school children, but in more than 60% of autistic pre-schoolers and 25% of non-autistic pre-schoolers with similar intellectual abilities [32]. The prevalence of complex motor stereotypies may be as high as 40–60% in institutionalized children with severe learning disabilities, with self-harming forms estimated to be 5–6 times less common. More than 80% of complex motor stereotypies begin before age 2; one-third of cases improve or resolve, in most cases during the first year, and 60% stabilize, although often persisting at least through the teenage years. If the behaviour persists through childhood, it is more likely that it will become a substantial problem with age. Overall, there is a male predominance in complex motor stereotypies, in part confounded by the different prevalence of underlying diagnoses between the two genders.

Box 37.4 DSM-5 criteria for stereotypic motor disorder

- Repetitive, seemingly driven, and apparently purposeless motor behaviour (for example, handshaking or waving, body rocking, head banging, self-biting, or hitting one's own body).
- The repetitive motor behaviour interferes with social, academic, or other activities and may result in self-injury.
- Onset in the early developmental period.
- The repetitive motor behaviour is not attributable to the physiologic effects of a substance or neurologic condition and cannot be better explained by another neurodevelopmental or mental disorder (for example, trichotillomania or OCD).

The following *specifiers* are used:

- With self-injurious behaviour (or behaviour that would be self-injurious if not prevented).
- Without self-injurious behaviour.

Whether the stereotypy is associated with a known medical or genetic condition, developmental disorder, or environmental factor is also specified, and an additional code is used to identify the associated element. *Severity* is specified as follows:

- Mild—symptoms are easily suppressed by sensory stimulus or distraction.
- Moderate—symptoms necessitate explicit protective measures and behavioural modification.
- Severe—continuous monitoring and protective measures are required to prevent serious injury.

Source: data from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, DSM-5, Copyright (2013), American Psychiatric Association.

The main causes of secondary stereotypies are neurodevelopmental disorders including severe learning disabilities and autistic spectrum disorders (Fig. 37.4). Therefore, identification of intellectual disability or developmental delay is crucial in the differential diagnosis of stereotypies. Some forms are associated with chromosomal aberrations (for example, Down's syndrome, Williams syndrome, fragile X syndrome, cri-du-chat syndrome) or with Smith-Magenis syndrome. Deprivation stereotypies are permanent and observed in patients with congenital sensory deprivation.

Another important genetic cause of stereotypies is Rett's syndrome, an X-linked, neurodegenerative illness that typically presents with stereotypies in the developmental period [33]. Rett's syndrome is caused by mutations in the *MECP2* gene, which codes for a protein that acts as a transcriptional repressor binding to methylated DNA. Whereas stereotypies in ASD are more intermittent, randomly distributed with preference for distal extremities, and associated frequently with visual inspection and flickering of the fingers, the stereotypies in Rett's syndrome are more continuous, predominantly located in the hands, mouth, and axial districts, and commonly involve objects.

Genetically inherited neurometabolic causes of stereotypies include, among others, phenylketonuria and adenylosuccinate lyase deficiency. Among acquired causes of stereotypies, autoimmune encephalopathies such as anti-NMDA receptor antibody-mediated encephalitis have been reported and may be triggered by emotional stimuli. These stereotypies are typically located to the upper limbs and bucco-linguo-facial regions, and sometimes may be difficult to differentiate from chorea. When rarer forms of repetitive actions are present, epileptic automatisms should be considered.

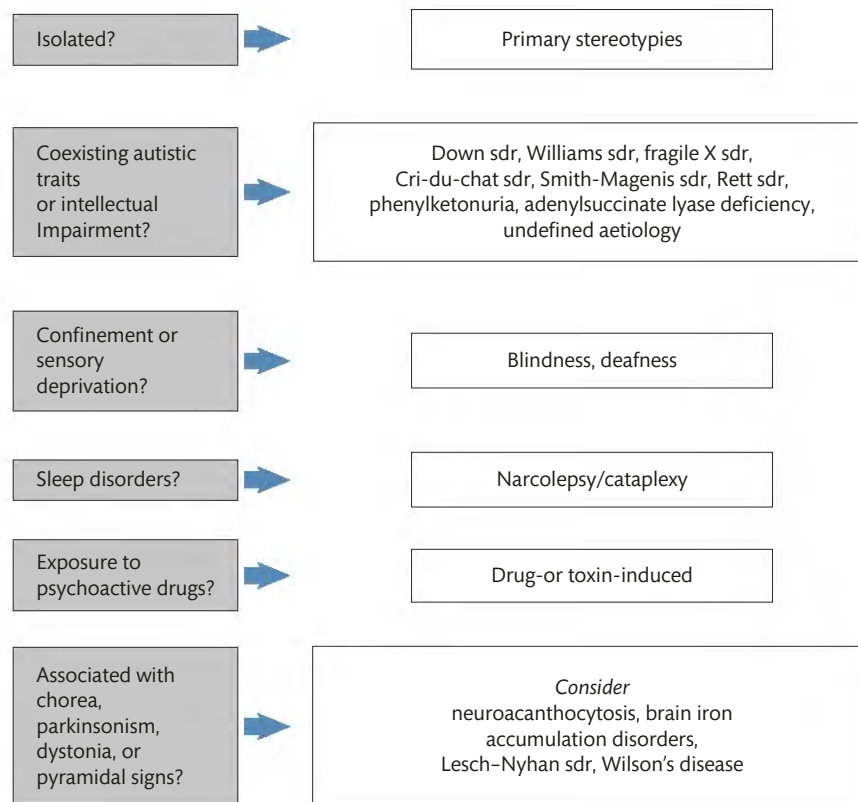

Fig. 37.4 Aetiology of motor stereotypes.

Adapted from Martino D, Espay AJ, Fasano A, *et al.*, Unvoluntary Motor Behaviours. In: Chapter 3: Disorders of Movement, pp. 97–153, Copyright (2016), with permission from Springer-Verlag.

Pathogenesis

Abnormalities of dopaminergic transmission in the basal ganglia are involved in the generation of stereotypes. Systemic or intrastriatal infusion of amphetamines and dopamine agonists in rats may cause highly repetitive behaviours (sniffing, gnawing, licking, biting), which resemble stereotypes in humans, and can be antagonized by dopamine D1 receptor blockers. Amphetamines and other psychostimulants, particularly cocaine, potentiate dopaminergic release and transmission and are known to be able to cause stereotypes in the developmental period. Tardive stereotypes are very rare in the developmental period. In general, specific movements involving the arms (rhythmical extensions of the elbow), trunk, and pelvis, such as ‘copulatory dyskinesias’, may be considered stereotypes [34].

Management

Overall, a functional behavioural assessment by a psychologist may be helpful to determine the impact of stereotypes on the youngster’s routine daily life and can aid in identifying the types of activities that may occur jointly with, or exacerbate, stereotypes. Family members and significant others will urge to seek specialist attention when they recognize typical stereotyped behaviours. The aetiologic diagnosis relies primarily on a complete medical history and physical examination, complemented by a series of instrumental tests, primarily biochemical or genetic.

Isolated primary stereotypes can be regarded as developmental variants of physiological habits that often do not require specific treatment, apart from appropriate psychoeducation. The main aim

of psychoeducational interventions in motor stereotypes is to diminish parental anxiety and correct inaccurate beliefs and perceptions in order to avoid unnecessary distress or stigmatization related to these motor behaviours. The management of stereotypes, as for other developmental motor disorders, should be tailored to the characteristics of the patient, in particular his/her age, behavioural comorbidities, and the aetiology of the stereotypes. Similar to standard practice in tic disorders, motor stereotypes require an active intervention when, after accurate psychopathological screening, these cause social isolation or stigma, predispose to physical injury directly associated with the self-injurious character of the movements, and when these generate substantial familial distress. In these cases, referral to a child psychologist or psychiatrist or to a developmental-behavioural paediatrician is advisable.

The mainstay of active treatment of common or primary complex motor stereotypes (Fig. 37.5) is behavioural therapy [35]. This includes two components: intervention on the context of environmental surroundings, and direct intervention on the patient. The principle of intervening on the environmental context is to adjust the surroundings in order to minimize the risks of injury and the vulnerability associated with more violent or erratic movements. Environmental interventions may target antecedents and consequences. Antecedent-based strategies have originally included providing visual or verbal cues to forewarn the patient of a change in the activity, engaging in calming (for example, taking a nap) or highly preferred activities prior to a difficult or less preferred activity. Physical exercise has also been used. Other examples of

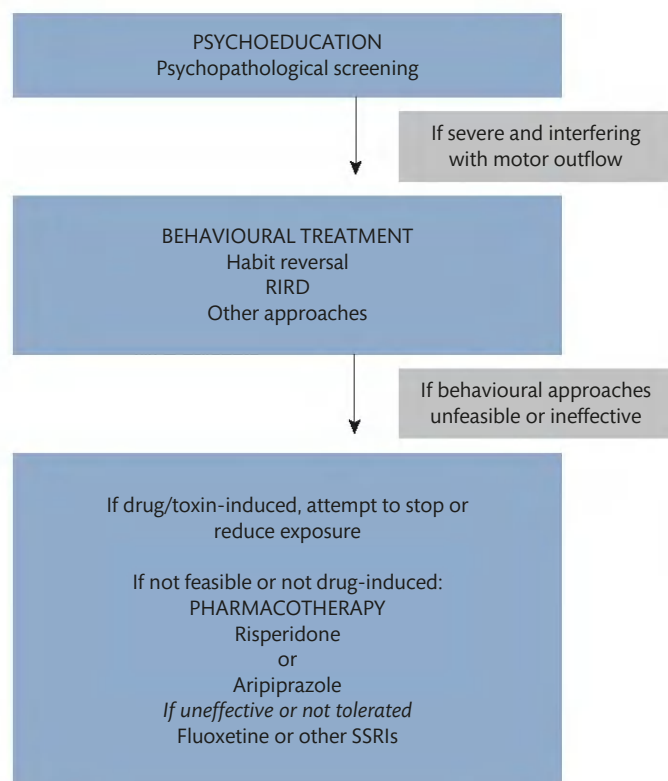

Fig. 37.5 Decision tree for the treatment of stereotypies.

antecedent-based strategies include: the removal of stimuli triggering stereotypies, as, for example, using gloves or adhesive plasters to prevent thumb sucking; contingency manipulation, for example using bitter- or aversive-tasting substances to prevent nail biting or thumb sucking; and non-contingent stimulation or environmental enrichment, consisting of providing the patient access to appropriate, competing sources of reinforcement such as preferred objects. The safety of the environment can be increased also by protecting from physical consequences such as using a helmet in cases of severe head banging or dental occlusion splints for tooth clenching.

Several behavioural approaches have been applied to primary complex motor stereotypies, whereas these usually show lower efficacy and feasibility in secondary stereotypies. More recently, it was shown that behavioural treatments may retain their efficacy also when provided in a home-based, parent-administered fashion through an instructional DVD [36]. Habit reversal therapy using differential reinforcement has demonstrated efficacy lasting more than 12 months. Evidence is less strong for other approaches, including response interruption and redirection in secondary stereotypies associated with ASD, relaxation training, or response blocking [35].

Pharmacological interventions are taken into account only when behavioural strategies are either unfeasible or ineffective (Fig. 37.5) [34, 37]. Most of the data concerning drug therapies refer to secondary stereotypies associated with learning disabilities and/or autism. Evidence of efficacy is overall limited. Drugs for depression, in particular fluoxetine and clomipramine, are the family of psychotropic agents probably the most investigated. A meta-analysis has

documented a small, but significant, effect of SSRIs in decreasing stereotyped behaviours in autism. The effect of naltrexone, an opioid receptor competitive antagonist, in ASD was systematically reviewed, showing that this drug may improve hyperactivity and irritability, whereas its actual effect on stereotyped behaviours remains uncertain. Drugs for psychosis have also been explored. A meta-analysis of three RCTs demonstrated that risperidone may decrease stereotypies subscale scores in autism [38]. Aripiprazole showed effect in the treatment of stereotypies in autistic children, with better tolerability, compared to risperidone or haloperidol. Finally, a Cochrane review of five double-blind RCTs on self-injurious behaviours in adults with learning disabilities concluded for a weak evidence for any of the active drugs investigated, clomipramine and naltrexone among others [34].

Developmental co-ordination disorders

Phenomenology

DCDs are characterized by motor skills deficits, with onset in the early developmental period, that are not explained by intellectual disability, visual impairment, or other neurologic motor problems such as cerebral palsy, muscular dystrophies, or degenerative disorders. The specific DSM-5 criteria for DCDs are listed in Box 37.5 [1]. DCDs constitute a broad clinical spectrum, in which the severity of motor impairment and the burden of comorbidities vary considerably. Their prevalence also varies widely across different studies, falling within a conservative estimate range of 1.5–5% of children below age 10, with an additional 10% of children possibly affected by minor forms of DCDs. A 1.7:1 male-to-female ratio has been reported in a study on more than 7000 British children, but no well-documented interracial or inter-ethnic differences [39].

In line with the introductory considerations at the beginning of this chapter, the pathogenesis of DCDs can be related to abnormal maturation and/or integration of the different building blocks of motor functioning, for example muscular tone and strength, gross

Box 37.5 DSM-5 criteria for developmental co-ordination disorder

- Acquisition and execution of co-ordinated motor skills are below what would be expected at a given chronologic age and opportunity for skill learning and use; difficulties are manifested as clumsiness (for example, dropping or bumping into objects) and as slowness and inaccuracy of performance of motor skills (for example, catching an object, using scissors, handwriting, riding a bike, or participating in sports).
- The motor skills deficit significantly or persistently interferes with activities of daily living appropriate to the chronologic age (for example, self-care and self-maintenance) and impacts academic/school productivity, prevocational and vocational activities, leisure, and play.
- Onset in the early developmental period.
- The motor skills deficits cannot be better explained by intellectual disability or visual impairment and are not attributable to a neurologic condition affecting movement (for example, cerebral palsy, muscular dystrophy, or a degenerative disorder).

Source: data from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, DSM-5, Copyright (2013), American Psychiatric Association.

and fine motor skills, planning and kinematic monitoring of movement, and sensory–motor integration. These functional blocks depend on the normal maturation and connectivity of integrated pathways, involving the motor cortex, cerebellum, and sensory systems (proprioceptive, visual, vestibular). Different forms of DCDs may differ, according to which of the core processes of motor development is primarily dysfunctional, although subtyping of DCDs is still under investigation. Some disorders referring to specific core neuromotor developmental processes, such as ‘sensory integration disorder’, might, in fact, represent subtypes of DCDs, rather than different conditions.

Pathogenesis

Like other developmental motor disorders, DCDs are also believed to result from alterations in the global organization of brain networks, which is demonstrated by structural and functional differences in sensory–motor tract connectivity between DCDs and typically developing children [40]. DCDs have a multifactorial aetiology, involving genetic, pre-/perinatal, and environmental factors. The heritability of DCDs has been estimated to be between 0.47 and 0.69, with a likely polygenic architecture of the genetic contribution to their pathogenesis. Intrauterine exposure to alcohol, and possibly to stimulants like cocaine or methamphetamine, is an important risk factor for the development of DCDs, as the overlap between DCDs and fetal alcohol spectrum disorder suggests [41]. Likewise, extremely pre-term infants (particularly those born at <37 weeks of gestational age) have a substantially higher risk for developing DCDs, compared to infants born at term [39]. Postnatal exposure, including exposure to lead, manganese, and iron deficiency, may also be contributing factors.

Several comorbidities may be associated with DCDs. Common problems that aggravate motor co-ordination difficulties in children include problems with attention and concentration such as those in ADHD [39]. Children with ASD have also been reported to exhibit frequently ‘motor clumsiness’, although there is little overlap in connectivity abnormalities between these two groups of disorders [42, 43]. Many children with motor difficulties have language difficulties, including stuttering and orofacial dyspraxia, and may have problems in written expression and other learning disabilities.

Assessment

The diagnosis of DCDs is based on an accurate history and physical examination of the fine and gross motricity of the child. Presentation varies with age, and therefore, information on specific motor co-ordination problems should be sought across the different stages of the neurodevelopmental period. [Table 37.2](#) summarizes the main manifestations of motor co-ordination abnormalities.

The physical examination of the child in the context of DCDs can be divided into two main parts: (1) the observation of motor co-ordination within daily activities, including playing; and (2) dedicated manoeuvres aiming at the assessment of specific motor tasks and abilities. The first part includes assessment of routines associated with academic activities or activities of daily living, for example cutting with scissors, tying shoes, drawing or colouring, throwing or kicking a ball, putting on or taking off a coat or a pair of trousers. The second part of the assessment may involve different manoeuvres that have not, to date, been operationalized in a universally accepted assessment protocol. Examples of these manoeuvres are performing sequential finger tapping in search of sequential errors and adventitious or mirror movements; finger-to-nose or finger-chase tasks; testing energy investment in a given sequential motor task (for example, drawing, writing, etc.) when sustained for 2–3 minutes; searching for ‘motor clumsiness’, indicating visuospatial deficits; testing the accuracy of fine motor tasks, for example activities involving small or miniature toys (miniature domestic utensils, small blocks for building activities, etc.); and testing co-ordination in gross motricity typically associated with sports or physical play activities.

Overall, children with DCDs typically underperform in many activities of daily living, when compared to typically developing children of the same age. Interestingly, limited physical activity levels resulting from DCDs may increase the risk for cardiovascular disease and predispose to obesity [44], as well as predispose to reduced self-esteem and problems with peer relation and depression, in addition to the learning difficulties that may occur in comorbidity with DCDs [45–47]. In addition, children with DCDs may exhibit a range of gait abnormalities and an increased risk of falls, associated with altered control of the centre of mass and a diminished limit of stability in the backward direction [48, 49].

Table 37.2 Main motor manifestations associated with developmental co-ordination disorders throughout the developmental period

Stage of development	Manifestations potentially associated with DCDs
First year of life	<ul style="list-style-type: none"> • Hypertonic reactions to auditory or visual stimuli • Persistence of primitive (Moro, plantar, rooting) reflexes • Delayed ability to roll over or sit without head-lag; tendency to slip through the examiner's grasp • Ability to self-correct posture and sit unassisted by 9 months of age • Persisting Babinski sign at the end of the first year of life • Persisting crossed-adductor reflexes and ankle clonus
Second and third years of life	<ul style="list-style-type: none"> • Difficulty in making a pincer grasp (that is, picking up a small object with the index and thumb) • Inability to furniture-walk by 18 months of age • Refusal of foods requiring greater chewing ability by the end of the third year of life
Pre-school and school years	<ul style="list-style-type: none"> • Obvious delay in ability to jump and hop • Complete lack of, or premature, hand dominance (although true ambidexterity is possible) • Difficulty in pencil grasp • Inco-ordination in playing with a ball • Inco-ordination in other fine motor tasks such as tying shoes, drawing, colouring, etc.

A normative functional skills assessment may be used to evaluate the breadth and severity of the DCD. This relies on commonly used tests of motor impairment, which include: the Bruininks–Oseretsky Test of Motor Proficiency (BOTMP), suitable for youth aged 4–21 years and frequently administered by therapists to monitor the efficacy of a treatment course; the Movement Assessment Battery for Children (MABC), which evaluates comprehensively manual dexterity, static and dynamic balance, and the functional interactions between the child and the surrounding environment; and the Test for Gross Motor Development, second edition (TGMD-2), used in children aged 3–10 years and focused on locomotor and object control abilities. Additional commonly used instruments for a broader neurodevelopmental evaluation are, among others, the Touwen Test for children with minor neurologic dysfunction and the Physical and Neurological Examination for Soft Signs (PANESS).

The diagnostic workup of DCDs should also include investigations aiming to rule out alternative causes for motor skills deficits. Among these, laboratory and neurophysiological tests to rule out muscle and peripheral nerve disorders and screening for metal toxicity and iron deficiency and metabolic abnormalities, such as thyroid dysfunction, may be warranted. Brain imaging and genetic screening for ataxias, myopathies, peripheral neuropathies, and metabolic syndromes could be necessary in specific cases, and neurological consultation is advised.

Management

The large inter-individual variability of adaptive functioning problems generated by DCDs requires a treatment approach that is highly personalized. A recent meta-analysis has identified strong effects in improving motor performance for task-oriented interventions and physical or occupational therapy, compared to process-oriented therapies, with insufficient evidence in support of chemical supplementation [50].

Physiotherapists and occupational therapists administer task-oriented interventions, often in collaboration with supporting figures like teachers and the direct engagement of parents. Task-oriented interventions exploit a top-down approach, employing specific techniques that target difficulties with specific motor challenges, for example catching a ball, performing fine digital tasks, handwriting, etc. Cognitive motor intervention is an example of these task-oriented treatments. It is based on designing a set of exercises that children should practise, with the assistance and supervision of parents, until the motor skills are mastered. The possibility of measuring objectively the treatment goal represents an important advantage of this approach. Cognitive motor intervention builds substantially also on motivational and cognitive reinforcers as crucial drivers of motor learning and aims at generating a schema that could be reused later also in other situations [51].

An alternative (bottom-up) approach that has been used by physiotherapists and occupational therapists is based on the assumption that general mechanisms like dysfunctional sensory integration or abnormal kinaesthetic perception subdue the motor co-ordination difficulties. This approach modulates the exposure to external stimuli (visual, auditory, tactile, proprioceptive) that influence motor performance in children with DCDs, who may be either

hypersensitive or hyposensitive to endogenous and exogenous stimulation. It also exploits techniques that foster self-regulatory mechanisms of sensory-motor integration. The efficacy of sensory integration therapies could be higher in combination with occupational therapy, although a recent meta-analysis has demonstrated a weak effect in improving motor performance, and doubts have been casted on their overall value [50, 52].

More recently, specific programmes aiming at improving balance strategies in DCDs have been tested in RCTs. Task-specific balance training approaches, such as functional movement training and a specific adaptation of the latter—functional movement-power training, showed efficacy in enhancing balance strategies and neuromuscular performance in children with DCDs [53]. The efficacy of other treatment approaches, including kinaesthetic or visual training and neurodevelopmental treatment, has a weak or insufficient evidence base.

Finally, there are no pharmacologic approaches that showed consistent efficacy in improving motor performance in DCDs. Methylphenidate showed a moderate effect size in three studies and represents the most explored medication in this context [50]. Other pharmacologic strategies may help specific comorbidities that affect motor co-ordination; for example, propranolol or other beta-blockers may ameliorate severe hand tremor when this is aggravating co-ordination problems.

Pathways of neurodegeneration underlying dementia

Noel J. Buckley and George K. Tofaris

Shared mechanisms of neurodegeneration

Dementia has become the most prevalent disease burden of our time. In the UK alone, there are currently over 850,000 sufferers, a figure that is predicted to rise to 1 million by 2025 and 2 million by 2050. This presents an enormous societal and economic burden (currently £26 billion per annum). Globally, the figures are even more staggering with around 47 million sufferers and an associated economic cost of close to \$1 trillion (https://www.alzheimers.org.uk/download/downloads/id/2323/dementia_uk_update.pdf; <https://www.alz.co.uk/research/WorldAlzheimerReport2015.pdf>). Neurodegenerative diseases are progressive, age-related multifactorial diseases with increasing prevalence and no cure or lasting symptomatic therapy. The need to understand the cellular and molecular mechanisms that underpin dementia has never been more urgent.

There are many causes of dementia, but most are due to neurodegenerative diseases (NDDs), principally Alzheimer's disease (AD), Parkinson's disease (PD), Huntington's disease (HD), and fronto-temporal dementia (FTD). Historically, these diseases have been studied in isolation as separate entities, but recently a consensus has arisen that, despite arising from distinct aetiologies, NDDs share many common underlying mechanisms that can be exploited to identify novel therapeutic targets. In broad strokes, these common cellular mechanisms include misfolded protein aggregation, endoplasmic reticulum (ER) stress, mitochondrial dysfunction, synaptic dysfunction, cellular transport, and inflammation. These cellular functions share overlapping molecular aetiologies, so, for example, cellular stressors, such as α -synuclein or β -amyloid ($A\beta$), may give rise to misfolded proteins that, in turn, generate ER stress and disrupt cellular transport, resulting in disruption to cellular trafficking and mitochondrial and synaptic function. Accordingly, discovering the underlying molecular players, their mechanisms, and how their interactions disrupt cellular function, leading to neuronal dysfunction and subsequent loss, has become a major goal in understanding the molecular and cellular aetiology of NDDs. One caveat to bear in mind is that even if the ultimate symptoms of NDDs primarily reflect loss of synaptic function, neuronal

connectivity, and neuronal death, nevertheless disease pathogenesis takes place in a complex cellular milieu and requires interactions among astrocytes, microglia, and the cerebral vasculature. Indeed the 'neurovascular unit' has been proposed as a term to encompass this complexity. Although this parsimony of common mechanism is an attractive concept, it is equally important to recognize that each NDD does have its own distinct signature, so we need to be cognizant of both disease-specific and disease-common mechanisms. Here, we focus on mechanisms common among NDDs, but the following chapters in this book complement this approach and adopt a disease-specific focus.

Pathology and genetics

At first sight, the pathologies of NDDs such as AD and PD appear distinct. On the one hand, AD is associated with progressive deficits in memory, cognition, and behaviour, while, on the other hand, PD is primarily considered a dysfunction of motor control. However, 30% of AD sufferers develop PD, and a similar proportion of PD patients develop dementia. This overlap extends to the primary molecular pathology of both diseases; AD is characterized by extracellular deposits of $A\beta$ plaques and intracellular accumulations of tau neurofibrillary tangles distributed throughout the forebrain, whereas PD is characterized by accumulation of α -synuclein in Lewy bodies (LBs) within the dopaminergic neurons of the midbrain. However, LBs are not restricted to PD and are also found in the amygdala of over half of patients diagnosed with familial or sporadic AD, as well as those suffering from dementia with Lewy bodies (DLB) [1]. Similarly, neuronal inclusions of TDP43 (TAR-DNA binding protein 43) are common to AD, FTD, and amyotrophic lateral sclerosis (ALS) [2–4], while tau (encoded by the *MAPT* gene) neurofibrillary tangles are present in the brains of AD, DLB, and FTD [5]. Further evidence of common aetiology among NDDs is provided by the overlap of the underlying genetics of NDDs. An example is provided by the microtubule-associated protein (MAPT) H1 haplotype that is associated with both AD and PD, with the suggestion that these *MAPT* variants increase the risk of PD by a crossover of the mechanisms governing aggregations in LBs and neurofibrillary tangles [6]. More recently, several loss-of-function variants in the

ATP-binding cassette transporter A7 (*ABCA7*) (required for protein aggregate clearance) have been associated with both AD and PD [7]. Common genetic association goes beyond AD and PD; a notable example is *C9orf72* (chromosome 9 open reading frame 72) bearing hexanucleotide GGGGCC repeat expansions as a causative gene in both FTD and ALS [8, 9] and even more prevalently in FTD-ALS

[10]. Further common genetic causality of multiple NDDs is evidenced by mutations in Fused in Sarcoma (*FUS*), an RNA-binding protein, valosin-containing protein (*VCP*), and Ubiquitin 2 (*UBQLN2*), all of which are associated with a minority of ALS and FTD cases [11–14]. The commonality of function of many risk genes associated with AD and other NDDs can be seen in Fig. 38.1.

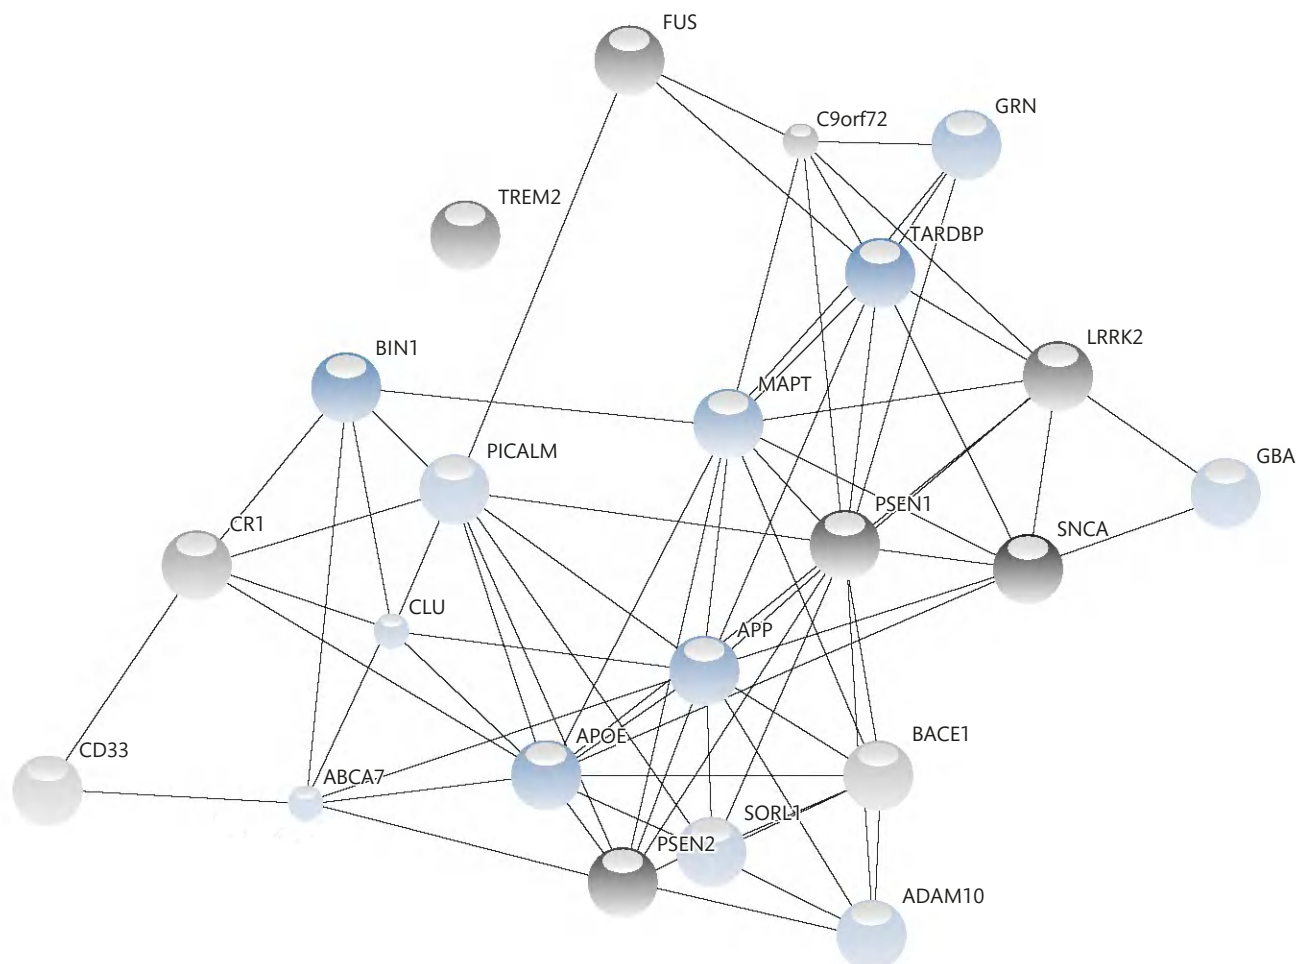

Fig. 38.1 Associations among genes linked to AD, PD, FTD, PDD, DLB, using the functional protein association network tool STRING (<https://string-db.org>). APP represents a clear hub in this network. The primary known function of genes are shown below (information extracted from STRING and AlzPedia (<http://www.alzforum.org/alzpedia>)), but in many cases, links between pathogenic mechanisms and associated genes are unknown or poorly characterized.

ABCA7—ATP-binding cassette, sub-family A (ABC1), member 7; expressed in macrophages and microglia. Plays a role in phagocytosis by macrophages of apoptotic cells. Binds APOA1 and may function in apolipoprotein-mediated phospholipid efflux from cells.

ADAM10—ADAM metalloproteinase domain 10. A sheddase thought to be the physiological α -secretase for APP.

APOE—apolipoprotein E; a secreted lipoprotein that mediates binding, internalization, and catabolism of lipoprotein particles. Involved in clearance of A β from the brain and cerebral vasculature.

APP—amyloid beta (A4) precursor protein; a type I transmembrane protein whose proteolysis gives rise to β -amyloid peptides.

BACE1—beta-site APP-cleaving enzyme 1; a transmembrane aspartyl protease responsible for β -secretase processing of APP.

BIN1—bridging integrator 1; functions in clathrin-mediated synaptic vesicle endocytosis and endocytic recycling.

CD33—mediates sialic acid-dependent binding to cells. Slows phagocytosis and A β clearance.

PSEN1—presenilin 1; probable catalytic subunit of the gamma-secretase complex, an endoprotease complex that catalyses the intramembrane cleavage of integral membrane proteins, including APP, in a processive fashion that releases A β peptides of different lengths.

PSEN2—presenilin 2; probable catalytic subunit of the gamma-secretase complex, an endoprotease complex that catalyses the intramembrane cleavage of integral membrane proteins, including APP.

CLU—clusterin; isoform 1 functions as an extracellular chaperone that prevents aggregation of non-native proteins. Inhibits the formation of amyloid fibrils by APP, APOC2, B2M, CALCA, CSN3, SNCA, and aggregation-prone LY2 variants. Functions primarily as an extracellular chaperone but also mediates neurotoxicity of β -amyloid.

CR1—complement component (3b/4b) receptor 1. Mediates cellular binding of particles and immune complexes that have activated complement. Effects inflammation and amyloid accumulation.

Proteostasis

The realization that a neurodegenerative phenotype, very similar to the corresponding sporadic disease, can result from single genotypes has led to the identification of the key effector proteins in these diseases and a common theme that may explain their role in the progression of diverse pathologies, that is, the idea that specific proteins accumulate within or outside neurons and misfold into toxic conformers, which may also spread to distant brain regions within interconnected neuronal networks. Several genes that cause monogenic AD, such as amyloid beta precursor protein (*APP*), presenilin1 (*PSEN1*), and presenilin2 (*PSEN2*), as well as variants in the genome, such as phosphatidylinositol binding clathrin assembly protein (*PICALM*), have mapped out the pathway of A β clearance and suggested that increased production and deposition of A β _{1–42} in the brain of patients with sporadic AD may be the initiating pathogenic event [15]. Similarly, tau mutations were identified in familial cases of FTD, and tau fibrils in neurofibrillary tangles is a cardinal feature of sporadic AD. α -synuclein mutations or multiplications are rare causes of PD that share the same pathology with sporadic PD, namely the misfolding of α -synuclein into LBs.

These pathological changes are thought to predate the clinical presentation by several years. For example, studies of a familial AD cohort (the Dominantly Inherited Alzheimer Network [DIAN]) suggest that A β _{1–42} levels in the CSF begin to decline as early as 25 years before the onset of symptoms [16]. This is followed by the appearance of fibrillar amyloid deposits in the brain detected by Pittsburgh compound B (PiB)-PET, increased levels of tau in the CSF, and progressive brain atrophy roughly 15 years before clinical presentation [16]. Cerebral hypometabolism and subtle episodic verbal memory impairment seem to begin about 10 years before overt dementia [16]. This time course may be generally similar to that of sporadic AD, based on cross-sectional studies [17], suggesting that detectable biochemical and histopathological abnormalities occur at least two decades before clinical symptoms.

Fibrillar assemblies of A β _{1–42}, tau, and α -synuclein also exert non-cell autonomous effects, which are reminiscent of ‘prion-like’

phenomena. The strongest evidence that this may occur in the human brain comes from the identification of LB pathology in embryonic neural grafts 12–16 years after transplantation into the brain of people with PD [18, 19]. Direct inoculation of human brain extracts or human brain-extracted fibrils from patients with LB pathology or multi-system atrophy led to progressive α -synuclein aggregation and neurodegeneration in connected areas of the brain in animal models, including non-human primates [20–22]. The propagation of α -synuclein in mouse brain has also been demonstrated with recombinant fibrils, but cell loss in this model was not always seen [20, 23, 24]. Similarly, tau pathology without neurodegeneration was observed in wild-type or transgenic mice expressing human tau, after seeding with fibrils extracted from human brain or mouse brain expressing the pathogenic P301S tau mutation [25, 26]. Intracerebral infusion of dilute A β -rich brain extracts from AD patients or from aged APP-transgenic mice also stimulated the premature formation of plaques and amyloid angiopathy in these models [27]. Spreading of α -synuclein and tau aggregates from the periphery to the brain has also been demonstrated [25, 26, 28].

Progress in identifying pathogenic proteins and their mode of propagation opened up the possibility for targeted therapies aimed at preventing their spread or promoting the clearance of their misfolded conformers. However, the most widely tested therapeutic approach to date—the use of active or passive immunotherapy—has not shown adequate clinical efficacy, even though there was evidence in some trials that such approaches promote the clearance of A β _{1–42} [15]. A similarly poor response was detected in a larger trial that examined the effect of A β _{1–42} immunotherapy in a group of patients with mild cognitive impairment. Whether such therapies need to be given at the pre-symptomatic phase of the disease to be effective is currently being investigated in around 300 pre-symptomatic members of a large Colombian pedigree with the *PSEN1* E280 → A280 missense mutation and a smaller number of pre-symptomatic American participants from the DIAN cohort who carry other presenilin mutations. In contrast to the disappointing results in humans, immunotherapies in preclinical models effectively reduced

C9orf72—chromosome 9 open reading frame 72; may play a role in endosomal trafficking and autophagy. Sequesters critical RNA-binding proteins in RNA foci.

FUS—fused in sarcoma; binds both single-stranded and double-stranded DNA and participates in transcription, processing, and nucleus-to-cytoplasm transport of mRNA.

GBA—glucosidase-beta acid; a lysosomal hydrolase that digests glycolipids. Impairment leads to lipid build-up in lysosomes, leading to cellular damage and inflammation.

LRRK2—leucine-rich repeat kinase 2; regulates autophagy and protein trafficking via phosphorylation of Rab proteins. Common PD-linked mutations in *LRRK2* activate its kinase activity.

PICALM—phosphatidylinositol-binding clathrin assembly protein; accessory protein in the endocytic pathway—assembles clathrin and adapter protein complex 2 (AP2) to cell membranes at sites of coated pit formation and clathrin vesicle assembly. Also affects internalization of APP, and thus production of A β .

GRN—granulin; a secreted growth factor with cytokine-like activity involved in inflammation, wound healing, and cancer. Has neurotrophic properties.

SNCA—synuclein alpha. Fibrillar assemblies of alpha-synuclein are the main component of Lewy bodies and Lewy neurites. Its normal function is unclear, but it is implicated in synaptic vesicle recycling, SNARE assembly, and neurotransmitter release.

SORL1—sortilin-related receptor, L. A multi-functional endocytic receptor that may be implicated in the uptake of lipoproteins and proteases. Binds to APP and traffics APP between the secretory pathway, cell surface, and endosome.

MAPT—microtubule-associated protein tau; promotes microtubule assembly and stability, and might be involved in the establishment and maintenance of neuronal polarity.

TARDBP—TAR DNA-binding protein; DNA- and RNA-binding protein which regulates transcription and many aspects of RNA processing such as splicing, trafficking, stabilization, and miRNA production.

TREM2—triggering receptor expressed on myeloid cells 2; may have a role in chronic inflammation and may play a role in amyloid-related neuroinflammation via phagocytosis of amyloid and neuronal debris.

the burden of pathological aggregates. The reason for this discrepancy is currently unclear but suggests that the complex cellular states of the human diseased brain beyond the culprit protein need to be considered.

One limitation of targeted therapies against misfolded proteins, as exemplified by immunotherapies, is the assumption that during 'degenerative' cellular states in the sporadic forms of these diseases, the neuronal mechanisms that normally handle misfolded proteins will rapidly recover and respond adequately to further protein aggregation, which *in vivo* may actually occur over a period of hours [29]. Age-related deficiencies in protein homeostasis (proteostasis) could contribute to the accumulation of aggregating proteins [30]. For example in AD or PD brains, there is upregulation of chaperones and accumulation of proteasomal and autophagic components [31].

Accumulation of misfolded proteins typically triggers the activation of chaperones, which either attempt to refold proteins or help redirect non-native conformers towards degradation by proteasomes or lysosomes. Proteasomes are large multi-subunit complexes that consist of a 19S regulatory cap and a 20S proteolytic core. The 19S regulatory particle recognizes ubiquitinated substrates, removes ubiquitin chains, and unfolds the substrate to allow entry into the 20S core where it is rapidly degraded into peptides [32]. Although the proteasome is the primary source of protein degradation in the cell, restricted entry into the proteolytic chamber of the 20S component does not permit the degradation of misfolded or large protein complexes. One way to bypass this limitation is to employ chaperone complexes, such as the BAG1-HSP70 or cytosolic VCP/p97, that retrieve misfolded proteins from aggregates and then direct them to the proteasome. Alternatively, larger aggregates can be directed en masse to the lysosome via autophagy. Autophagy complements the proteasome in three forms: macroautophagy, chaperone-mediated autophagy (CMA), and microautophagy. Macroautophagy is the best-understood form and entails the sequestration of organelles or aggregates into a double-membrane structure known as the autophagosome. The resulting autophagosome is then transported to, and fuses with, the lysosome, thereby delivering its cargo for degradation. In contrast, microautophagy occurs by direct engulfment of the cytosol at the lysosome membrane, and CMA occurs through HSC70-mediated delivery of proteins across the lysosomal membrane via the LAMP2A receptor [33].

Selective targeting of misfolded proteins to the proteasome or lysosome is initiated by the addition of polyubiquitin chains in a three-step enzymatic process involving E1 ubiquitin-activating enzymes, E2 ubiquitin-conjugating enzymes (E2s), and E3 ubiquitin ligases (E3s). There are more than 650 E3s and 30 E2s that regulate the degradation of protein substrates, making this system highly specialized. Ubiquitin chains are formed through conjugation of ubiquitin monomers to protein substrates via distinct lysine residues; K48- and K11-linked ubiquitin chains are the main linkages that direct substrates to the proteasome, whereas K63-linked chains mediate trafficking to the lysosome. This is achieved by the action of adaptor complexes, which recognize the ubiquitin chain and direct the ubiquitinated proteins to the relevant pathway. Deubiquitinating enzymes (DUBs) remove ubiquitin chains and may determine commitment to degradation or trim ubiquitin chains to fine-tune the degradation process. The relevance of ubiquitin-dependent quality control is well established in PD, especially in a subgroup of *familial* cases that are caused by mutations in the E3 ligases Parkin or FBXO7.

Ubiquitin signalling also regulates α -synuclein degradation and counteracts its proteotoxicity. For example, the E3 ligase CHIP that normally eliminates cytosolic misfolded proteins was implicated in the clearance of oligomeric α -synuclein [34]. The E3 ligase NEDD4 exerts a protective effect in diverse models of α -synuclein toxicity, at least in part, by directly promoting the ubiquitination and lysosomal degradation of α -synuclein [35, 36]. Interestingly, a small molecule activator of NEDD4 protects induced pluripotent stem cell (iPSC)-derived dopaminergic neurons expressing the pathogenic A53T mutation [37]. Ubiquitination in LBs is significantly reduced in the pigmented neurons of the substantia nigra, compared to other brain regions, and this pattern inversely correlates with the upregulation of the deubiquitinase USP8 [38]. USP8 deubiquitinates α -synuclein and opposes its lysosomal degradation *in vitro*, whereas USP8 knockdown in fly models prevents α -synuclein accumulation and toxicity [38]. The role of Parkin in mitophagy is discussed in Mitochondrial dysfunction, p. 377.

Endoplasmic reticulum stress

Defects in protein trafficking between organelles, especially the ER to Golgi and endosomes to lysosomes, are also critical in neurodegeneration. For example, mutations in VPS35, a component of the retromer complex which functions in endosomal protein sorting cause late-onset forms of familial PD and AD [39]. Heterozygous mutations in the lysosomal enzyme glucocerebrosidase (GBA), which, when biallelic, cause Gaucher's disease, are the most common risk factors for PD; and mutations in the kinase LRRK2, which is the most common form of autosomal dominant PD with LB pathology impair endosomal trafficking and autophagy [39]. The significance of these pathways for the viability of vulnerable neuronal subpopulations in PD and AD is reinforced by genome-wide analysis of variants in common sporadic forms of these diseases (for example, GAK and RAB7L in PD and PICALM in AD) that function in these pathways. Misfolded proteins accumulating in the ER lumen are normally recognized by ER membrane-associated complexes and retrotranslocated to the cytoplasm by the AAA ATPase VCP/p97-NPL4-UFD-1 complex. The retrotranslocated protein is then ubiquitinated and delivered to the proteasome for degradation, thereby eliminating terminally misfolded proteins from the ER. In neurodegenerative diseases, ER stress due to accumulation of misfolded proteins in the ER lumen activates the unfolded protein response (UPR), a protective cellular response that aims to reduce unfolded protein load and restore protein-folding homeostasis. The UPR has three arms, which initiate signalling cascades through protein kinase RNA (PKR)-like ER kinase (PERK), inositol-requiring enzyme 1 (IRE1), and activating transcription factor 6 (ATF6). Paradoxically, persistent activation of the PERK-eIF2 α branch of the UPR is detrimental, as it causes uncompensated decline in global translation rates, leading to synaptic failure and neuronal death [40]. Restoring translation by targeting PERK or more selectively eIF2 α , using repurposed drugs such as trazodone, was neuroprotective and enhanced memory in animal models of prion disease and tauopathy despite the accumulation of misfolded proteins [41]. In this respect, specialized enzyme complexes that function in protein folding, trafficking, or degradation are emerging at the frontier of experimental therapeutics in neurodegenerative diseases.

Mitochondrial dysfunction

Mitochondria are responsible for ATP generation, intracellular calcium (Ca^{2+}) homeostasis, reactive oxygen species (ROS) formation, and apoptosis. Neurons are exquisitely sensitive to mitochondrial dysfunction because of their high energy demands, and it is not surprising that many NDDs are linked to mitochondrial dysfunction. Numerous studies have shown mitochondrial structural changes that precede pathology in AD brain [42] and expression of β -amyloid leads to loss of activity of several key mitochondrial enzymes involved in the tricarboxylic acid (TCA) cycle or the electron transport chain, including the α -ketoglutarate dehydrogenase complex, the pyruvate dehydrogenase complex, and cytochrome oxidase [43].

Early evidence for the role of mitochondrial dysfunction in dopaminergic neurons came from observations in methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) users who developed parkinsonism. Subsequent studies showed that MPTP is rapidly taken up by astrocytes, metabolized to 1-methyl-4-phenylpyridinium (MPP⁺), which is taken by dopaminergic neurons and inhibits complex I in the electron transport chain, thereby inhibiting ATP production, decreasing intracellular Ca^{2+} -buffering capacity, and increasing ROS production, all of which lead to neurotoxicity. Complex I activity is also lowered in PD brain, and several genes linked to PD are all linked to mitochondrial function, including *SNCA* (*PARK1/4*), *Parkin* (*PARK2*), *PINK1* (*PARK6*), *PARK7*, *LRRK2* (*PARK8*), and *HTRA2* (*PARK13*) [44]. Dissipation of the mitochondrial membrane potential induces translocation of the kinase pink1 to mitochondria and activation of Parkin through phosphorylation of ubiquitin and the ubiquitin-like domain of Parkin. This cascade initiates the degradation of mitochondrial proteins by the proteasome in a p97-dependent fashion or mitophagy, a process opposed by the mitochondrial deubiquitinase USP30 [45].

In HD brain, the activities of Complex I, II, and III are all inhibited. HD is a monogenic disorder, so the primacy of mutant huntingtin (HTT) in disease aetiology is beyond dispute, but still the mechanism of action remains unclear. There is evidence of direct interaction of mutant HTT with mitochondria, resulting in depolarization [46]; again these mitochondrial changes preceded overt disease symptomatology. In addition, it is likely that some of the mutant HTT interaction with mitochondria is mediated indirectly via dysregulation of key transcription factors such as p53 and CREB-binding protein [47]. These examples serve to illustrate the mitochondria as the recipient of cellular stressors, but mitochondrial dysfunction and mitophagy can ultimately amplify inflammatory responses by releasing ROS into the cytoplasm and extracellular space—once again muddying the relationship of cause and effect of NDD pathology.

Common molecular pathways in NDD: REST

In the preceding sections, we have illuminated common pathologies, genetics, and cellular processes that accompany all NDDs. Here, we explore the idea that common molecular mechanisms may also be at play in driving or protecting against neurodegeneration. Our exemplar is the transcriptional repressor RE1-silencing transcription factor (REST), a key regulatory factor that has been implicated in the pathogenesis of several NDDs, including HD, PD, and AD [48–51]. REST was discovered over 20 years ago [52], and its role was initially seen as that of a transcriptional silencer of differentiated neuronal

genes in neural progenitors and non-neural tissue. Initially, it was thought that REST was silenced during neuronal differentiation, thereby allowing the expression of differentiated neuronal genes. However, REST's role is now seen as much more multi-faceted, and we now know that REST is not silenced during neuronal differentiation but continues to be expressed at low levels in several areas of the adult brain, notably the cerebral cortex where it represses the expression of many neuronal genes [53–57]. However, the role of REST during neurodegeneration is controversial, since it has been shown to be both pro-apoptotic and neuroprotective, depending on circumstances. In HD, in the presence of mutant HTT, levels of nuclear REST are increased, leading to repression of numerous REST target genes, including *BDNF*, an essential neurotrophic factor required for survival of medium spiny GABAergic neurons in the striatum [50, 51]. REST has also been shown to be pro-apoptotic in hippocampal CA1 neurons subjected to ischaemic insults, resulting in increased levels of nuclear REST and enrichment at the miR-132 promoter, leading to silencing of miR-132 expression and subsequent neuronal death [58]. The role of REST in PD is less clear. Administration of the dopaminergic neurotoxin MPTP to REST-null mice led to enhanced loss of dopaminergic neurons, indicating that REST was normally neuroprotective [48], whereas earlier studies showed that MPTP increased migration of REST from the nucleus to the cytosol, accompanied by subsequent increase in REST target gene expression and increased cell death [59]. This apparent contradiction can be resolved by considering that, in both cases, REST levels at their target genes are decreased either due to ablation of the REST gene or migration of the REST protein from the nucleus, and both result in increased susceptibility to MPTP toxicity. Stated otherwise normal (nuclear) levels of REST are neuroprotective. This neuroprotective action of REST has been more directly interrogated in a recent study that indicates a neuroprotective role for REST in the ageing brain that is lost in the brain of patients with mild cognitive impairment and AD, FTD, and DLB [49]. Further, using SHSY5Y neuroblastoma cells, they showed that REST bound the promoters of many cell death genes, including p38 MAP kinase, FAS, FADD, and TRADD, as well as the presenilin 2 promoter. Moreover, REST was induced in both cultured mouse and human cortical neurons in response to challenges with $\text{A}\beta_{1-42}$ or H_2O_2 , and ablation of REST in mouse cortical neurons led to an increase in the expression of pro-apoptotic genes and increased neurodegeneration in response to $\text{A}\beta$ challenge. So how can these studies be reconciled?

WNT signalling has long been associated with AD pathogenesis, and numerous studies have shown that canonical wnt signalling protects against β -amyloid toxicity [60–62]. Acute exposure of rat cortical neurons to $\text{A}\beta$ activates non-canonical wnt signalling via the JNK/PCP pathway and subsequent activation of several transcription factors, including EGR1 and KLF10, as part of a pro-apoptotic pathway [63]. Furthermore, this pathway is also detectable in the brain of people and in animal models with amyloidopathy, but not tauopathy, adding weight to the evidence that this non-canonical pathway is activated by $\text{A}\beta$ in AD. Since REST is known to be directly regulated by canonical wnt signalling [64, 65], then when taken together, these observations suggest a model whereby exposure to $\text{A}\beta$ controls a bipartite signalling cascade, with canonical wnt signalling controlling an anti-apoptotic arm, in which REST represses pro-apoptotic genes, and non-canonical wnt signalling controlling an antagonistic pro-apoptotic arm in which JNK/PCP activates pro-apoptotic genes.

This model supports the suggestion that high levels of REST in the ageing brain play a neuroprotective role and may be sufficient to protect against dementia, even when the brain shows significant structural pathology, including A β deposits [49]. This conditionality of A β -induced neurodegeneration is also reflected in the levels of A β *in vivo*, which fluctuate as a function of neuronal activity [66], diurnal cycle [67, 68], and ageing [67]. Importantly, diurnal variation of A β occurs in the brain of APP^{Swe}/PS1 Δ E9 mice before the appearance of A β plaques. Furthermore, in the human brain, increases in A β also precede the appearance of A β plaques or any symptoms of AD. In other words, neurons are constantly exposed to fluctuating levels of A β , yet this does not immediately result in an increase in A β plaque formation or neuronal death. REST could thus act as a gatekeeper in this bipartite response to A β and could act as an essential component of a homeostatic response to neurodegenerative stressors such as A β , perhaps as an inhibitory node of a feed-forward inhibition loop, a widespread regulatory motif that homeostatically regulates many molecular pathways [69] by modulating the dynamic response of network output to a varying input, that is, they buffer a gene network against fluctuations in input, whether as signal or noise. This would allow a neuron to tolerate low A β exposure without committing to an irreversible apoptotic response, yet still permit apoptosis in the presence of persistent A β exposure. Taken together, these observations indicate that REST occupies a unique position as a key regulator of neuroprotective pathways induced in the ageing brain, offering protection against β -amyloid-induced neurodegeneration. Since REST is induced in response to several stressors, including Fe²⁺, H₂O₂, and the glutathione synthesis inhibitor buthione sulfoxide [49], then this may provide a model whereby REST provides neuroprotection against a wide range of neurodegenerative stressors. More generally, this multifaceted role of REST may reflect the perspective that although the molecular function of a gene may be largely fixed, the biological process that this function subserves is highly context-dependent. This system's perspective is reflected in the different gene modules and networks in which a gene may be embedded, which will, in turn, depend on the cell type and cell state, that is, it is the network interactions and output that determine the 'function' of the gene.

Novel cellular models of neurodegeneration

The underlying cause of most NDDs is a complex cocktail of genetic and environmental risk factors, and this is nowhere clearer than in AD [70]. The predominant hypothesis to date has been that of the 'amyloid cascade', the initial evidence for which came from the observations that autosomal dominant AD arises from mutations in either the amyloid β precursor protein (*APP*) gene or in genes encoding APP secretases. In brief, the amyloid cascade hypothesis posits that faulty processing of APP generates neurotoxic A β fragments and consequent neurodegeneration and other hallmarks of AD pathology, including aggregation of phosphorylated tau and synaptic loss [71]. However, as stated earlier, clinical trials of immunotherapies targeting A β ₁₋₄₂ have failed. Although these failures may be most related to clinical trials being conducted too late or on participants without amyloid pathology, they nonetheless serve to emphasize that late-onset AD is likely to be complex and that a fuller understanding of the molecular mechanisms of the canonical amyloid cascade, as well as associated processes, including inflammation, for example,

is an essential prerequisite to developing therapeutic interventions. This amyloid cascade hypothesis has led to the development of numerous animal models as investigative tools to interrogate disease mechanism and as screens to identify therapeutic targets. The majority of these are murine and based on the introduction of cock-tails of mutations targeting *APP*, *PSEN1*, *PSEN2*, and *MAPT* [72]. However, rodent models have several severe limitations, especially in relation to AD. Firstly, there are numerous important intrinsic differences between human and rodent neurons, including marked differences in the transcriptome of the ageing brain [73, 74], human-specific transcriptional modules in AD brain [75], neuronal size and complexity of the dendritic tree [76], protein composition of the post-synaptic density [77], and speed of synaptic information transfer [78]. Secondly, overexpression of mouse APP does not aggregate in amyloid plaques, a striking difference between mice and humans. Subsequent generation of mouse transgenic lines, such as PDAPP and Tg2576, which bear mutant human *APP* genes, still fail to exhibit cardinal hallmarks of AD, including neurofibrillary tangle formation and neuronal death [79, 80]. Thirdly, more recent mouse models based on the 3 \times Tg triple mutation (APP Swedish; *MAPT* P301L; *PSEN1* M146V) offer some improvement, including synaptic dysfunction preceding the deposition of plaques and tangles [79], but only by forcing the overexpression of a set of mutations that do not have any pathophysiological counterpart in humans. Fourthly, animal amyloid models show cognitive deficits in the absence of discernible neuronal pathology; yet in humans, cognitive impairment is accompanied by neuronal pathology and death. This profound incongruity undermines the usefulness of animal models in a myriad of AD drug development programmes. Fifthly, there is a tacit assumption that the underlying regulatory molecular machinery is conserved between mouse and human. Whereas this is true on a coarse-grained analysis, it is demonstrably untrue at a detailed level; comparison of the cistromes of numerous transcription factors shows only a small conservation of transcription factor binding sites (TFBS) between mouse and human [80], and furthermore, genes associated with hominid-specific TFBS are specifically enriched in neurological pathways [81]. This latter issue is brought into sharp focus by a recent study on the transcriptional repressor REST, elevated levels of which are found in the normal ageing brain, but not in AD brain (see earlier), and which confer neuroprotection by repressing pro-apoptotic genes in the normal ageing brain [49]. However, close inspection of human and mouse REST cistromes [82] shows that many of the genes conferring protection in the human brain are REST targets only in humans, but not in mice. These differences in the underlying topology of mouse and human gene networks may result in potentially critical species-specific gene-gene interactions that undermine the relevance of mouse systems as tools to investigate molecular mechanisms and the discovery of therapeutic targets in human cells. This has led to searches for human cellular neuronal models that obviate these limitations and reduce our reliance on rodent models. Until recently, human cellular models were dominated by non-neuronal cell lines, such as HEK293, or neuroblastoma lines, such as SH-SY5Y, all of which suffer from many limitations, including their non-neuronal origin, aberrant cell signalling, and chromosomal abnormalities, serious concerns that curb any enthusiasm for their usage. However, the twin developments of cellular reprogramming and gene editing have completely changed the experimental landscape of modelling disease using human cells.

Induced pluripotent stem cells

Yamanaka's groundbreaking discovery of reprogramming somatic cells [83] to become iPSCs has revolutionized much of biology. iPSCs have the cardinal properties of an embryonic stem cell: (1) they can self-renew and maintain their pluripotent state; and (2) they can differentiate to (almost) any lineage. Equally importantly, iPSCs obviate many ethical concerns over the use of primary human embryonic stem cells, since they do not require the destruction of human embryos. Unlike immortalized human cell lines, iPSCs are 'normal', can be derived from any personal genetic background, and can be produced by reprogramming a wide range of somatic cells, including readily available skin fibroblasts and hair follicle cells, making it possible to readily make patient-specific iPSCs. These, in turn, can be differentiated towards multiple neuronal (and glial) types relevant to individual NDDs, associated with loss of specific neuronal populations such as cortical neurons in AD, medium spiny GABAergic neurons of the basal ganglia in HD, and dopaminergic neurons of the substantia nigra in PD. iPSC neurons have many features that lend themselves to modelling neurodegeneration *in vitro* [84–86], including: (1) acquisition of electrical excitability, as evidenced by the expression of voltage-sensitive sodium (Na^+) and potassium (K^+) channels; (2) firing of action potentials; and (3) physical evidence of synapses on the basis of juxtaposition of pre- and post-synaptic markers [3]. Not only do these iPSC-derived neurons offer potential to generate cells for replacement of damaged tissue, but they also offer unparalleled human cellular models of disease and discovery tools for therapeutic target identification and drug screening [84, 87].

Gene editing

The advent of gene editing, particularly by use of CRISPR/CAS9 [88, 89] offers the possibility of introducing, or reversing, disease-associated mutations. As with iPSCs, this development opens up possibilities for repair and replacement and for generating new cellular models. The most widely used CRISPR/CAS9 system can be thought of as comprising a dual module made up of a unique genomic address delivery system [provided by single-guide RNAs (sgRNAs) and a cargo (CRISPR-associated protein 9 (CAS9))]. The sgRNA binds to its unique genomic address and then takes delivery of the CAS9 cargo. CAS9, in its native form, then introduces double-stranded DNA breaks, which are subsequently repaired by endogenous DNA repair mechanisms and, as a consequence, introduces discrete mutations into the targeted locus. More recently, numerous engineered forms of CAS9 have been introduced that use CAS9 simply as a delivery vehicle to introduce novel genome-modifying activities to greatly expand the repertoire of genomic and epigenomic changes, including: (1) reversion of specific disease-associated SNPs; (2) exerting local control of transcriptional activation or silencing; and (3) manipulation of specific epigenetic marks [90, 91]. The combined power of iPSCs and gene editing now lets us derive neurons from any patient-specific background, study their behaviour before and after making highly discrete changes to the genome or epigenome, and attribute any changes in behaviour to a specific genetic locus. An example of this power can be seen in studies of iPSCs derived from a familial AD background. iPSC neurons derived from patients carrying a duplication of the *APP* gene have higher levels of $\text{A}\beta_{1-40}$, increased tau phosphorylation, and raised levels of GSK β , relative to normal iPSCs, all of which are seen in AD brain [92]. Use of CRISPR/CAS9 to introduce AD disease causing mutations in the *APP* gene (*APP^{swE}*)

and the *PSEN1* gene (*PSEN1^{M146V}*) of iPSC neurons also gave rise to elevations in $\text{A}\beta$, and in this latter case, use of gene editing allowed unambiguous attribution of the change in cellular phenotype to specific disease mutations [93].

Outlook

The primacy of any of the biological processes discussed here in the aetiology and pathogenesis of NDDs is an ongoing source of contention, and undoubtedly it varies within and among diseases. More likely is that pathogenesis is not a linear cascade, but any of these processes can act as a driver and recruit other processes into tipping neurons into a neurodegenerative state. Although the brain has only a limited capacity to replenish lost neurons, it does exhibit remarkable plasticity, which ensures that the myriad of its neuronal connections continues to function until a critical threshold is eventually reached. It is now considered likely that a prolonged period of neuronal compensated dysfunction may precede cell loss. Identifying stages on this neurodegenerative trajectory that are reversible and irreversible will be key to developing future therapeutic targeting strategies. Similar to the approaches that have been so successful in cancer, a deeper understanding of the fundamental biology that drives neuronal degeneration, rather than a focus on a singular cellular process, is likely to lead to successful targeted therapies.

Delirium

Ravi S. Bhat and Kenneth Rockwood

Introduction

Delirium is a common term; it has been used to name creations as varied as a waltz, a book series, and an alcoholic beverage. Delirium is also a common condition; while no age is unaffected, elderly people are most often affected, especially those in long-term care (LTC) or admitted to hospitals. In such people, it is associated with very poor outcomes. While about half do not remember, those who do live with the anxiety evoked by their experience [1]. Delirium is associated with more in-hospital complications, longer stays in hospital, a greater likelihood of transfer to nursing homes, and higher mortality. Hospitals incur greater costs in managing delirium. Despite its common usage, frequency of occurrence, and impact on people and health care systems, delirium remains poorly diagnosed.

Delirium has been recognized and described for two millennia [2]. The stability of description is remarkable. Delirium was thought to be an acute and transient mental disorder, associated mostly with febrile illnesses and alcohol. It is still considered to be a disorder of acute onset, but now it is recognized that its course is not always transient [3].

Research on delirium has progressed in the past couple of decades [4]. There is greater confidence in our ability to prevent delirium than in our ability to treat it [5]. The problem in translation of current research is held back by the consistent and widespread reports of persistently high rates of diagnostic error [6]. To this end, delirium needs to be better understood, so that we can provide better care to the most vulnerable older people [7], especially in the context of a rapidly ageing society and our increasingly refined understanding of frailty and dementia subtypes.

The delirium concept—evolution and classificatory systems

The key conceptual change of delirium reflects how populations are ageing. Something that was likely observed in adults with acute illnesses, intoxications, or withdrawals is now seen mainly in older people in hospitals and nursing homes or in adults with very severe or terminal illnesses; this age and specialty distribution is reflected in a recent delirium prevalence study in a university hospital in Ireland [8].

In the first available descriptions, delirium was distinguished from insanity [2]. Transiency was an important contrasting feature between delirium and insanity, with the latter seen to be a permanent condition [9]. Since the beginning of the nineteenth century, delirium began to be conceptualized as a disorder of consciousness, with ‘clouding’ coming to represent both an alteration in the level and fragmentation of consciousness [2]. The literature from this era is rich in clinically descriptive detail, but problematic in its application. Delirium has been seen either as not being a problem of consciousness or as a problem of content of consciousness [10]. The clinical features of delirium are such that it does not allow for it to be operationalized either on a binary measure, as in present or not present, or to be thought of as being along a continuum. The modern approach to the problem has been to work by trial and error ([Table 39.1](#)), with the word ‘consciousness’ being finally removed in DSM 5. The European Delirium Association and the American Delirium Association have jointly critiqued this change, asserting that ‘*conceptualisation of delirium must extend beyond what can be assessed through cognitive testing (attention) and accept that altered arousal is fundamental*’ [11] (2014). It might be that the essence of consciousness is not readily captured and is in need still of both a better description and, with it, quantification.

Attention is easier to define than consciousness, though seemingly hard to standardize for routine clinical examination. Impairments in attention have been as a reduced ability to direct, focus, shift, and sustain attention, which incorporates most aspects of what is currently known about it [12]. However, there are problems in both addressing it in research and translating this into clinical practice, not the least because of overlap between the constructs of attention, working memory, and executive control [13]. DSM-5 certainly achieves high inter-rater reliability [14], but when interpreted strictly, it may miss many cases [15], as might be expected when a key component is missed. In contrast, the ICD-10 rigid criteria achieve high specificity at the cost of low sensitivity, because of the requirement of a number of mandatory features [14].

Regardless, it is important not to limit our understanding of a phenomenon because of artificially imposed constraints by definitions and rating scales derived thereof. Recognizing this limitation, Paula Trzepacz, David Meagher, and José Franco have proposed their Trzepacz, Meagher, and Franco (TMF) research criteria for delirium, based on an analysis of data from the Delirium Rating

Table 39.1 Comparison of diagnostic systems

	ICD-10	DSM-III	DSM-III-R	DSM-IV	DSM-5
Clouding of consciousness	Reduced clarity of awareness of the environment	Reduced clarity of awareness of the environment	Not stated	Not stated	Not stated
Consciousness	As above	As above	Reduced level of consciousness	Reduced clarity of awareness of environment	Not required
Attention	Reduced ability to focus, sustain, or shift attention	Reduced ability to focus, sustain, or shift attention to environmental stimuli	Reduced ability to maintain attention <i>and</i> to shift attention to <i>new</i> external stimuli	Reduced ability to focus, sustain, or shift attention	Reduced ability to focus, sustain, or shift attention
Awareness	As above	As above	Not stated	As above	Reduced orientation to the environment
Disturbances in cognition	Both immediate recall and recent memory and disorientation in time, place, or person required	Disorientation and memory impairment. Required feature if testable	Disorientation to time, place, or person and memory impairment	<i>Change</i> in cognition (memory deficit, disorientation, language disturbance) or ...	Change in cognition (memory deficit, disorientation, language, <i>and</i> visuospatial ability) or ...
Disturbances in perception	Not required	Defined as misinterpretations, illusions, or hallucinations	Defined as misinterpretations, illusions, or hallucinations	... development of perceptual disturbance not accounted for by dementia	... perception (included in 'change in cognition' above)
Disturbances in speech/thinking	Not required	Defined as 'at times incoherent'	Disorganized thinking: rambling, irrelevant or incoherent speech	Not required	Not required
Sleep-wake cycle disturbances	One of three features: insomnia, nocturnal worsening of symptoms, and disturbing dreams	Defined as insomnia or daytime drowsiness	Defined as insomnia or daytime sleepiness	Not required	Not required
Psychomotor disturbances	One of following: shifts from hypo- to hyperactivity; ↑ reaction time; ↑ or ↓ flow of speech; enhanced startle reaction	Defined as ↑ or ↓ psychomotor activity	Defined as ↑ or ↓ psychomotor activity	Not required	Not required
Onset	Developing rapidly; time course not defined	Developing over a short period of time—hours to days	Developing over a short period of time—hours to days	Developing over a short period of time—hours to days	Disturbance in attention and awareness defined developing over a short period of time—hours to days
Presence of fluctuation	Diurnal pattern	Diurnal pattern	Diurnal pattern	Diurnal pattern	Diurnal pattern of fluctuating severity of inattention and ↓ awareness
Requirement of cause	Cerebral or systemic disease	Evidence or presumption of organic factor judged to be aetiologically related allowed	And presumption of aetiology if symptoms not accounted for by a 'non-organic mental disorder'	Direct physiological consequences of a general medical condition	Broader categories
Exclusion	Not stated	Not stated	Not stated	Dementias	Other major neurocognitive disorders and coma

Essential
 Either/or (use ambiguous)
 Additional
 Not stated/not required

Scale-Revised-98 (DRS-R-98) [7]. These criteria have three domains of impairment: attentional/cognitive, circadian, and higher-level thinking [7]. The TMF criteria had high sensitivity and specificity (87.4% and 89.2%, respectively) and were better balanced than DSM-III-R (100% and 31.6%, respectively), DSM-IV (97.7% and 74.1%, respectively), DSM-5 (97.7% and 72.6%, respectively), and ICD-10 (66.2% and 100%, respectively).

Epidemiology of delirium

Elderly people will make up approximately 16% of the world population by 2050 [16]. While, at any given time, about 4–6% of older adults are in nursing homes, around 30–50% of them will use a nursing home before their deaths [17]. Older people are high users of hospitals; around 40% of acute hospital stays were for people aged 65 years and older. A recent study suggested that hospitalization appears to be related to the proximity to death and nursing home use to ageing, which, if true, implies that nursing home use is likely to grow more rapidly than hospital use as populations age [18]. Another study found that multi-morbidity and neuropsychiatric diagnoses were the highest risks for LTC dependency [19]. If correct, these findings imply two things. Firstly, that people in hospitals and nursing homes are more likely to be the oldest old, to have higher rates of cognitive impairment, and to be frail and closer to death—all factors associated with high rates of delirium. Secondly, an understanding of delirium, the problems of its diagnosis, and management must broaden to include delirium in nursing homes and other settings.

In the general population, delirium is more common with advancing age and in the presence of dementia. In people ≥ 65 years, the point prevalence of delirium is estimated to be around 2% [20]. A population-based study examining the 30-day prevalence in the oldest old diagnosed delirium in 17% among the 85-year olds, 21% among the 90-year olds, and 39% among participants aged 95 years and older [21]. Overall, delirium was present in 52% of those with dementia, compared to only 5% of those without dementia. LTC is variably defined in studies [20]; when defined narrowly to include nursing homes, the prevalence estimates are still quite varied, ranging from just over 1% to 70% [20].

Eleven to 25% of hospitalized elder patients have delirium on admission, and a further 30% will develop it during the course of hospitalization [22]. The former is inaccurately termed ‘prevalent’ delirium, missing points in patient flow in and out of the hospital through emergency departments (EDs). Delirium occurs in 8–10% of older patients presenting to EDs, and 15% still have delirium at ED discharge [22]. Two-thirds of people with ‘excited delirium’, a poorly recognized state, die at the scene or during transport by paramedics or police [23]. Excited delirium is a term used most often in the forensic literature to refer to patients who, in other contexts, might have been referred to having hyperactive delirium. A key difference seems to be the context, with ingestion of drugs or toxins by community-dwelling people, many of whom are not elderly and whose initial encounter is frequently with the police, being the characteristic case. The mortality rate is non-trivial, and the term is meant also to suggest extreme adrenergic activation, for a variety of reasons. Given our limited experience with, and understanding of, this special case, we will not be referring to it further (see [23]).

Of the 11% of patients who had delirium in the ED on day 1, in nearly three-quarters, it persisted into day 2 and for about half of them for all 3 days [24]. Thus, the timing of delirium assessments can miss cases.

Once admitted, one study found a point prevalence of delirium of approximately 20% of adults evaluated [8]. The highest rate (>50%) was unsurprisingly found in the geriatrics ward and the lowest in surgical wards, with intermediate rates in both medical and orthopaedic wards (around 25%). When only older adults were examined in a nationwide study in Italy, the point prevalence of delirium was estimated to be approximately 23% [25]. The highest rates were detected in neurology and geriatrics wards. There are three caveats to consider from these studies. Firstly, a number of patients may be excluded because of untestability and lack of consent. Secondly, the relatively lower rate of delirium in surgical wards may be an artefact of the point prevalence estimation, especially if done on a weekend [8]. Surgery is a risk for delirium—the type of surgery, whether it was elective or emergency, and the duration of surgery appear to be important determinants of post-operative delirium [22]. Finally, both these studies excluded intensive care units (ICUs) [8, 25] and one excluded palliative care units [25]. The prevalence of delirium in ICU cohort studies can range from a low of 20–30% to as high as 70–80% [26], and in palliative care units, the delirium prevalence increases closer to death: 13.3–42.3% on admission, 26–62% during admission, and 58.8–88% in the weeks or hours preceding death [27]. This dramatic rise in delirium closer to death raises a pragmatic question—how do we distinguish between delirium as a part of dying and delirium as a sign of preventable death [28]? Prevalence estimates may rise further by 8–13% if subsyndromal delirium, a prognostically important milder state that does not meet the full diagnostic criteria, is included [29].

Clinical features and diagnosis

History taking and learning to interview and observe a patient who might not be very co-operative is critical to both the diagnosis of delirium and its differential diagnosis. Every effort must be made to obtain collateral information from the patient’s family members, caregivers, general practitioner, and past clinical records.

Delirium is an acute-onset condition. About half of older patients with delirium in hospitals already have it at admission, so this is an important part of the history to ascertain. The key questions are whether the current presentation of the older person *represents a change for them* and, if so, *the time course of that change*. Responses from family members such as ‘... this isn’t my mum’, or ‘... my father is off with the fairies’ should be taken seriously. It is also useful to find out if the patient had had a cognitive assessment in the past year, since most high-income countries now require periodic cognitive assessments for older people. In hospital, baseline cognitive assessment and change indicate delirium [30].

Once onset, delirium characteristically fluctuates, often in a diurnal pattern, within as little as 3 hours [31]. This can be missed if examinations are less frequent (for example, every 3 days) [32]. Experts rely on fluctuation of motor symptoms wherein changes to physical activity of the patient appear important [33]. This may be particularly helpful in diagnosing delirium superimposed on dementia, both in the hospital [34] and in nursing homes [35].

Delirium presents as a mental disorder; it typically shows gross disturbance of mental functions and consciousness. Schiff and Plum noted that the primary neuropsychological components of consciousness are arousal, attention, intention, memory, awareness, and mood/emotion [10]. Research on clinical features of delirium demonstrates impairments in all of these components of consciousness. In addition, there are often profound disturbances in both the form and content of thought and perception. Overall there is considerable fragmentation of the conscious experience, which was one of the meanings held by the phrase ‘clouding of consciousness’.

Generalized arousal is considered to be the most powerful and essential activity in any vertebrate nervous system [36]. Arousal is essential for the organism to be both aware and attentive [37]. In delirium, arousal is both diminished and heightened, as manifest when patients are hypoactive and hyperactive. Hypoactive and mixed subtypes are usually more common than the hyperactive subtype and more likely to be missed. Two-thirds of subtypes appear to maintain stability over time [38]. There is some evidence that arousal may predict both delirium and inattention [39]. Testing attention and other cognitive functions is difficult when arousal is reduced, so it is useful to become clinically adept at observing changes to arousal. Rating scales such as the modified Richmond Agitation and Sedation Scale (mRASS) [33] and the Observational Scale of Level of Arousal [39] may assist.

Attention is commonly impaired during clinical examination; global attention, when measured as the patient’s ability to participate in a conversation over a short period of time, is the most common impairment [40, 41]. Of the available tests of attention, months backwards, defined as the ability to name months backwards from December to July without error, appears to perform the best, both in hospitals [41] and in nursing homes [42]. These measures are easy to use by the bedside, but practice is essential in learning both to administer and to observe patients as they perform. An app is also available to assist in this process [43], although how it will be employed in routine practice is unclear [44]. To a certain extent, the ability to direct attention is an act of intention; however, intention has, as such, not been studied in delirium. The ability to direct the mind towards an object and the capacity to act on the object are typically impaired.

Awareness of both self and the environment is grossly impaired. While the diagnostic systems do not guide us in how this is to be either understood or measured, research into the subjective experience in delirium demonstrates this impairment to a startling degree. Patients talked of experiencing themselves as being in a vacuum or a torpor and/or slumbering and that the surroundings were experienced through a mist [1]. Time-orderedness of this awareness too was impaired; patients encountered a mix of events from past and present, and visualization interpreted as imagination or fantasizing in a borderline state. These experiences were typically frightening when experienced and, when remembered, evoked a variety of emotions, from feelings of suspiciousness to shame, and between 19% and 22% develop post-traumatic stress disorder [45]. Examining these experiences relies on developing nuanced interview and analytic skills.

Delirious people feel turbulent emotions, from anxiety and sadness to irritability and anger. Sadness and anxiety, along with diminished activity of the hypoactive subtype of delirium, prompt a diagnosis of depression in such patients and lead to inappropriate

treatment [46]. Psychotic symptoms are fragmented; judgements about, or perceptual misinterpretations of, the immediate external world are common, and when hallucinations occur, they are short-lasting and frightening. Thus, delusions, unlike those seen in schizophrenia, are liable to change and rarely systematized. Delusions and psychomotor agitation appear to predict the severity of distress after delirium [45]. The persistence of memories and distress may remind the clinician of delusions, but its certainty relates to the experience at the time and, unlike those seen in schizophrenia, is not an ongoing experience of the world. Hallucinations are typically visual and may occur in up to 50% of patients; rates are higher (nearly three-fourths) in patients referred to consultation–liaison psychiatry services [47]. It is clinical lore that delirium must be considered in an elderly person with first-onset visual hallucinations; however, one must be cautious in passively accepting it because it is not informed by research, and visual hallucinations are common in Lewy body dementias (LBDs).

Standard electroencephalography (EEG) is neither recommended for, nor feasible in, routine clinical practice. A recent study has shown that it may be possible to derive useful information from just two electrodes [48]. How this will influence routine practice has yet to be established.

Differential diagnosis

The differential diagnosis of delirium is influenced by the settings in which the patient is examined; in hospitals, dementias, depression, and alcohol use disorders (AUDs) are important to consider, whereas in nursing homes, dementias, behavioural and psychological symptoms of dementia (BPSD), and depression are likely more important. The task is made challenging because of the frequent co-occurrence of these disorders.

Dementia and cognitive impairment are consistently identified as risk factors for delirium. In approximately 50% of patients, delirium is superimposed on dementia [34]. The problem then is not just to differentiate delirium from dementias, but also to diagnose it when dementia is present; there appears to be no consensus among experts as to how to do this [49] (Table 39.2). Three issues must be considered. Firstly, there is considerable overlap of symptoms between delirium and those of dementias such as LBD and some rare forms of dementias such as those caused by infections and prions. Two-thirds of experts found it challenging to diagnose delirium superimposed on dementia with Lewy bodies (DLB) [49]. While estimates of prior probability in a setting is a useful guide to differential diagnosis, the risk of missed diagnoses and potential harm from treatment makes it important to ensure accuracy of diagnosis. Secondly, BPSD are not included in the diagnostic criteria for the most common dementias [AD and vascular dementia (VaD)], but these are common and add to the challenge of a delirium diagnosis. Finally, in a fifth of cases, delirium persists at 6 months after diagnosis [50]; where does delirium end and dementia begin?

Dementias can onset acutely [51], though the proportion of those that onset over hours to days might be small. Cerebrovascular disease, including VaD, is an important differential diagnosis because of possible acuity of onset and common co-occurrence. Around 11% of dementia patients in acute hospitals may have VaD [52]; while the frequency of strategic infarct VaD in this population is not known, it

Table 39.2 Prevalence and comparison between delirium and dementias

	Delirium		Dementias		BPSD		AD/mixed	VaD	DLB
Setting	Hospitals	LTC	Hospitals	LTC	Hospitals	LTC	Hospitals	Hospitals	Hospitals
Prevalence	17–30%	1.4–70%	3–63%	58%	62%	78%	80%	? 11%	? 3%
Onset	Acute (hours to days)		Typically insidious		Acute to subacute onset		Insidious	Acute to insidious	Insidious
Arousal	Impaired		Typically unimpaired		May be impaired		Typically unimpaired	May be impaired	Impaired
Attention	97%		Impaired		Impaired		Impaired	Impaired	Grossly impaired
Orientation	75%		Impaired		Impaired		Impaired	Impaired	Impaired
Memory	88%		Impaired		Impaired		Impaired	May not be in early stages	Impaired
Sleep–wake cycle	97%		May be impaired		6–11%		May be impaired	May be impaired	Impaired
Hallucinations	50%		May be present		0–18%		May be present	May be present	Present
Delusions	31%		May be present		9–40%		Present (later stages)	Present (earlier stages)	Present
Fluctuation	Present		May be present		May be present		May be present (20%)	May be present (35–50%)	Present (90%)
Course	Persistent in 20% at end of 6 months		Progressive		Persistent		Progressive	Stable to progressive	Progressive

may account for 10% of all VaD diagnoses at autopsy [53]. Delirium can also be present in 10–30% of patients with stroke [54]. The presence of focal neurological signs should trigger requests for brain imaging. When absent, repeat assessment focusing on arousal levels, attention, and focal higher cognitive signs can be helpful. Other dementias, typically those of infective causes or due to prions, can be acute in onset, but the prevalence is unknown. A high index of suspicion generated by experience of a curious mind is possibly vital.

LBD in general, but DLB in particular, has a clinical presentation that is most similar to delirium. Global cognitive impairment (in this case, dementia), fluctuation in cognition, with pronounced variations in attention and alertness, and visual hallucinations are core criteria for DLB [55]. The prevalence of DLB in hospital settings and in nursing homes is not known; it may be present in approximately 3% of inpatients [56], and 2% of patients with delirium during hospitalization were diagnosed with DLB at 3 months' follow-up [57]. Parkinson's disease, which is associated with both hallucinations and delirium, is perhaps more common in hospitals and nursing homes [58]. The time course over which symptoms evolve and the presence of Parkinsonian signs help differentiate. Treatment of hyperactive delirium may involve the use of dopamine antagonist drugs, such as haloperidol, which may be fatal in patients with DLB.

BPSD are common in dementias and especially so in nursing homes and perhaps also in hospitals; a recent study estimated that around 70% of hospitalized patients with dementia will show at least one BPSD [59]. The phenomenon of sundowning can mimic delirium, and delirium worsens BPSD [60]. BPSD tend to be persistent, so once again attempts to obtain a history from family members or staff at the nursing home are important in distinguishing delirium from BPSD.

Depression is common in hospitalized elderly patients [46], and delirium, depression, and dementia commonly co-occur in nursing homes [61]. Patients with hypoactive delirium and those with significant disturbance in mood and emotion can appear depressed on cross-sectional examination, leading to misdiagnosis. Efforts to obtain a history and, in the fast-paced environment of an acute ward, avoid conflating a symptom with a syndrome are important to

an accurate diagnosis. Depression onsets over days to weeks, rather than hours to days; severe melancholic depression can show fluctuation, but it is typically predictable, with characteristic worsening of symptoms in the morning; while sleep–offset insomnia is characteristic of severe depression, insomnia in depression can also be of sleep–onset and sleep–maintenance. However, it is rarely fragmented or reversed, as seen in delirium; when psychotic symptoms occur in depression, they tend to be delusions, which are typically delusions of poverty, guilt, and nihilism.

The number of people with substance use disorders aged 50+ years are likely to double by 2020 [62]. Almost 50% of older adults (≥ 65 years) and almost 25% of subjects over 85 years drink alcohol; AUDs afflict 1–3% of elderly subjects [62]. In addition, up to 30% of older patients hospitalized in general medicine wards and up to 50% of those hospitalized in psychiatric wards have AUDs. Standardized rating scales are recommended for the identification and prediction of withdrawal symptoms [62].

Late-onset schizophrenia and late-onset schizophrenia like psychosis are relatively rare. People with these disorders are less likely than young-onset schizophrenia to demonstrate cognitive symptoms [63]; indeed cognitive impairment is felt sometimes to exclude a diagnosis [64]. Where it does not, impairments in attention and memory are common [65]. Base rates of diagnoses are a useful guide to diagnostic reasoning.

In summary, careful history taking and interview, along with collateral information focused on premorbid cognition and behaviour and examination, are key, but no guarantee, to an accurate diagnosis.

Instruments

Given the rate of misdiagnosis of delirium, bedside use is as important a feature of a tool as it is for research. Two systematic reviews have examined the role of delirium assessment instruments [66, 67]. Wong *et al.* [66] reported that positive findings on the Global Attentiveness Rating (GAR), Memorial Delirium Assessment Scale (MDAS), Confusion Assessment Method (CAM), Delirium Rating

Scale Revised-98 (DRS-R-98), Clinical Assessment of Confusion (CAC), and Delirium Observation Screening Scale (DOSS) each had a likelihood ratio of >5 for diagnosing delirium. They determined that the Mini-Mental State Examination (MMSE) was the least useful for identifying patients with delirium [66]. The other brief cognitive screening instruments likely perform similarly. However, it is clinically relevant and important to conduct routine cognitive assessments, where possible, on all older patients admitted to hospital and those in post-acute care and nursing homes. Such instruments [for example, the Abbreviated Mental Test Score (AMTS)] might be helpful in the following ways in identifying delirium: (1) to detect dementia, possibly the most important risk factors for delirium, in hospitalized older patients [68]; (2) given its sensitivity, the MMSE may be useful in ruling out delirium [69]; (3) a change from baseline cognition may help predict delirium [30]; or (4) specific items such as disorientation to time and place on the MMSE on admission could predict delirium. Impairment in these two items classified nearly 90% of patients, and these two measures, along with visuoconstructional impairment, were each associated with either hypoactive or mixed subtype [70].

A problem when instruments are used in isolation is that they have to fit into hospital clinicians' available time. Even the CAM, which takes only 5 minutes to complete, may be too long for the busy clinician [66]. Besides, almost all instruments require training; in untrained clinicians, CAM has a low sensitivity [71–73]. Instruments may have to be suitably matched to clinicians using them. For example, the DRS-R-98 might be more suitable for use by suitably trained clinicians such as old age psychiatrists and geriatricians. On the other hand, the Nursing Delirium Screening Scale (Nu-DESC), which has shown good psychometric properties in two systematic reviews, might be a good observational tool for routine use by nurses [66, 67]. Two new instruments have taken on the challenge of being both brief and capable of wider use: 4AT [74] and RADAR (*Repérage Actif du Delirium Adapté à la Routine* or Recognizing Acute Delirium As Part of Your Routine) [35]. The 4AT has four items: (1) alertness; (2) four questions from the AMTS on age, date of birth, place (name of the hospital or building), and current year; (3) attention as tested by months of the year backwards; and (4) acute change or fluctuating course (<http://www.the4at.com/>). The RADAR has just three questions: 'When you gave the patient his/her medication: 1) Was the patient drowsy?; 2) Did the patient have trouble following your instructions?; 3) Were the patient's movements slowed down?' [35]. Of the two, the 4AT has so far shown a good balance between sensitivity and specificity when used by geriatricians [74] (Bellelli et al., 2014) and nurses without training in its use [75]. The RADAR had lower levels of both sensitivity and specificity, but participating nursing staff took only 7 seconds, on average, to complete the tool and almost all received it very well [35]. Additionally, it is important to note that the RADAR was tested across five nursing homes where the misdiagnosis of delirium is typically higher than in hospitals [76].

Natural history of delirium

Delirium is associated with an increased risk of post-discharge mortality, institutionalization, and dementia [77]. Hypoactive delirium, increased severity, and persistent delirium, pre-existing dementias, and depression may all be predictive of these negative outcomes [78].

Delirium has been for long thought of as a transient disorder; most modern studies demonstrated that this is not the case. One review found the combined proportions with persistent delirium at discharge, 1, 3, and 6 months to be approximately 45%, 30%, 25%, and 20%, respectively [50]. Persistence was associated with dementia, increasing numbers of medical conditions, increasing severity of delirium, hypoactive symptoms, and hypoxic illnesses [3]. It is unclear what proportion of these outcomes are attributable to factors other than delirium. Mortality in delirium may be mediated by the severity of illness and frailty in the short term [79] and through cognitive impairment in the long term [80]. Other negative outcomes may be mediated through persistence, which, in turn, is likely due to pre-existing dementia [78] and the presence of other geriatric syndromes [81]. Delirium, especially hypoactive delirium, is likely to predispose to deconditioning, falls, dehydration, pressure ulcers, and urinary retention, which, in turn, send the patient into a vicious spiral [81].

The outcomes of delirium from ICU settings are no less grim. Patients with delirium had significantly higher mortality during admission, longer durations of mechanical ventilation, and longer lengths of stay in the ICU and in hospital [82].

In nursing homes, symptoms of delirium predict incident delirium [83]. Baseline delirium and subsyndromal symptoms of delirium, depression, and dementia interact to lead to increased mortality and functional and cognitive decline [61].

Examination of outcomes of delirium requires further work. Adamis *et al.* [84] noted that recovery is not well defined for delirium; they proposed sustained improvement in cognitive function to define therapeutic outcomes in delirium. Following generally accepted nomenclature in psychiatry, they defined 'response' as when baseline cognitive function is re-established for at least one full day of assessment and 'recovery' when this baseline cognitive function is sustained for at least a week [84].

Aetiopathogenesis of delirium

Causality in medicine is commonly conceptualized, such that they can be reduced to biology, with preference for bottom-up explanations that focus on generative physiological mechanisms [85]. Outside of geriatrics and psychiatry, causality is commonly required to be parsimonious; multiple causes are eschewed. For the researcher, the attraction is the idea that a single cause can lead to a single treatment, and for the busy clinician, a clear direction for action. These ideas can be problematic when applied to the common and complex presentations of later life, including delirium.

Considering the pathogenesis of delirium, many causal hypotheses/models have been articulated [86]. A closer look reveals two broad categories: (1) those that reduce the cause of delirium to a single final common pathway operating in and through the brain; and (2) those that address complexity by other means. Complexity is usually addressed by attempting to either integrate two or more 'final common pathways' together or use a framework such as the vulnerability–stress model to either empirically derive or theorize a model. There is a varying degree of strength of assumption in these models as to whether the brain is the organ of dysfunction. A metaphorical understanding of delirium and related geriatric giants would consider the human organism as a complex system, however.

When complex systems fail, their highest-order functions fail first. In humans, consciousness, one of the higher-order functions, and its failure are signalled by delirium. In this metaphor, the brain is simply a bystander to a set of processes occurring throughout the body [37].

To be valid, the single common pathway theories should be able to describe the mechanisms that lead to the delirium in particular, and not something else, either dementia or one of the other complex presentations in older adults. These should also explain the occurrence of delirium subtypes, especially the occurrence of the mixed subtype of delirium. The more complex theories should not be setting-specific; they should be able to account for delirium in an older adult, regardless of the setting. They should also be able to describe the occurrence of delirium in older adults of varying levels of fitness within the same setting. Finally, they should serve utility.

Single final common pathway hypotheses

Oxidative stress

Engel and Romano [9], in their now classic paper, hypothesized that delirium could result from two processes: failure of function or failure of structure. In this schema, the former is reversible and the latter permanent, drawing to the distinction between transient delirium and permanent dementia. Presciently, they noted it was too early to 'regard these states as any more than different degrees or stages of similar processes'. Their hypothesis was that delirium resulted from low cerebral oxygen consumption. In its modern iteration, delirium is thought to result from brain damage resulting from oxidative stress [87]. Neopterin produced by microglia in the brain is a marker for both cell-mediated immunity and oxidative stress and was found to be higher in both the preoperative samples of CSF and the serum of delirious patients than in those with no delirium. Those with both delirium and chronic cognitive impairment had the highest levels of neopterin, and those with neither had the lowest [87]. In those without cognitive impairment, there was a correlation between delirium severity and neopterin levels. The association between obstructive sleep apnoea and delirium is seen as further evidence of the role of oxidative stress [88]. The fact that neopterin also has a role in cell-mediated immunity (though, in their study, the correlations persisted, even when those with infection and malignancies were removed from analysis) suggests more complex pathways. Importantly, elevated levels have been found in other neuropsychiatric disorders.

Neuroendocrine hypothesis

Kral hypothesized that delirium was the result of age-linked decline of stress resistance mediated through the hypothalamo-pituitary-adrenal (HPA) axis [89]. Some recent support for this hypothesis has come from a positive association between raised perioperative plasma cortisol concentrations post-coronary artery bypass graft surgery [90]. However, unlike other recent studies examining anticholinergic activity, this study did not adjust for confounders [91]. Moreover, intraoperative dexamethasone failed to reduce the incidence of post-operative delirium [92]. The important issue here is that impaired HPA activity has not only profound systemic effects, but also effects on the brain, and it is through their pro-inflammatory effects that they can be usefully integrated into a more complex hypothesis [93].

Cholinergic hypothesis

Tune *et al.* proposed the cholinergic hypothesis, based on the finding of an association between the use of anticholinergic drugs and post-operative delirium [94]. The hypothesis is attractive because of both the basal forebrain degenerative changes in dementias and the role that acetylcholine plays in arousal and attention. Much work has been done since the 1980s to prove the hypothesis by attempting to demonstrate associations between anticholinergic drug burden and serum anticholinergic activity and delirium. However, both an early [95] and recent studies cast doubt on this hypothesis [5, 91, 96, 97]. In one cohort study, anticholinergic drugs were not associated with an increased risk of delirium [96], while in another cohort study, the associations disappeared after adjusting for confounders [91]; in the first study examining CSF (and serum) anticholinergic activity, there was no association between either of these measures and delirium [97], and finally cholinesterase inhibitors have not demonstrated a role in preventing delirium [5]. Acetylcholine is but one important component in the modulation of attention and arousal [12]; disturbances in other neurotransmitters, such as dopamine, noradrenaline, GABA, and glutamate, are posited as well [86]. It is not that cholinergic systems have no role in delirium; instead they are likely to be part of more complex dysfunction that leads to delirium [98].

Melatonin hypothesis

Rooij and van Munster [99], noting the prominent disturbance of the circadian rhythm in the sundowning phenomenon seen in dementia and delirium, posited that melatonin deficiency triggers delirium and thus could be used to prevent it from occurring. The potential efficacy of melatonin in reducing symptoms of sundowning to this idea [100]; unfortunately, a large randomized clinical trial by the same group found no evidence for melatonin in reducing post-operative delirium [101]. Melatonin is implicated in the modulation of inflammation in the brain, and there are associations between sleep dysregulation and decreased proportions of natural killer cells, reduced lymphokine-activated killer activity, and reduced IL-2 production [86]. As with other pathways considered here, the picture points to complex interactions between inflammation, neurotransmitters, and neuroendocrine activity [86], which leads us to consider complex models that have attempted to integrate these findings in a systematic manner. Although additional investigations have been proposed, there is little evidence to recommend the use of melatonin at this time [102].

Complex models

Neuroinflammatory hypothesis

The most common hypotheses attempt to integrate theory and available data in different ways [98, 103, 104].

Pro-inflammatory cytokines generated in the periphery, such as interleukin 1 β (IL-1 β), tumour necrosis factor α (TNF α), and interleukin 6 (IL-6), communicate with the brain through several routes, including autonomic afferents, across the blood-brain barrier (BBB), and via the circumventricular region [103]. Increased TNF α is thought to activate microglia, which, in turn, release cytokines and prostaglandins. One postulate is that, with ageing and dementia, microglia are 'primed' due to loss of cholinergic inhibition resulting in their heightened response [98]. There is evidence that increasing severity of dementia may be associated with higher likelihood of

delirium [105]. This microglial priming and resulting uncontrolled inflammation causes further neurodegeneration leading to a vicious cycle of brain change [98]. Even though cytokines are known to be increased in delirium [106], this hypothesis, while explaining why neuroinflammation could be associated with dementia, does not quite explain the occurrence of delirium [98]. Cerejeira *et al.* [103] and Cunningham and MacLulich [104] go further, using an explicitly stated vulnerability–stress framework to provide mechanistically plausible accounts for the occurrence of delirium. In their comprehensive review, Cerejeira *et al.* [103] concluded delirium symptoms may be accounted for by the widespread dysregulation of brain homeostasis, neurotransmission, and neurophysiological functions, resulting ‘in a reduced capacity to interact with the environment and to integrate stimuli within the cognitive experience’. In a more nuanced analysis, Cunningham and MacLulich [104] stated that their model accounts for the characteristic symptoms of hypoactive delirium, but not for the presence of psychotic symptoms. Intriguingly, in a longitudinal study of community-dwelling older adults with AD, raised IL-6 was associated with hallucinations, but not with delirium [107].

Network disconnection hypothesis

The network disconnection hypothesis, also using the vulnerability–stress framework, proposes that acute breakdown of network connectivity within the brain results in delirium [86]. Two recent studies have attempted to characterize this hypothesized disconnection through fMRI and a within-patients design [108] and EEG using a between-patients design [109]. They both demonstrated disconnection, but one showed an increase in functional connectivity between the prefrontal cortex and the posterior cingulate cortex [108], while the other found reduced corticocortical connectivity [109]. Manshour and Avidan urge caution in interpreting these findings as evidence of disconnection given the assumptions made [110]. Post-operative delirium may be predicted by increased white matter hyperintensities (WMHs), offering a structural basis for this apparent functional disconnection [111], though in another study, WMHs did not predict post-operative delirium in those without dementia [112]. This latter group of researchers did find an association between diffusion tensor imaging abnormalities observed in the corpus callosum, cingulum, and temporal lobe and delirium [113], suggesting that disconnection may yet play an important role in delirium.

Multifactorial model

At the level of the human organism, Inouye’s multifactorial model is widely regarded. It too employs the vulnerability–stress framework, furnishing empirically derived factors to populate vulnerabilities and stressors [114]. It has clinical and pedagogic utility. The lack of temporal separation between, and lack of clarity of, vulnerabilities and stressors poses a problem, as does a failure to provide an explanation as to why delirium is caused. A recent study found pre-operative risk factors, such as impaired cognition, thus more clearly temporally separated vulnerabilities, clearly modify the response to post-operative factors, such as post-operative pain and opioid use, to result in delirium [115]. This model may not work well in nursing homes [116]. In addition, there is some evidence that deficit accumulation, and thus systems failure, may account for delirium [79], but this has not been tested more widely.

In summary, current models integrate available evidence and may explain at least one of the subtypes of delirium and provide a mechanism for accounting for the influence of age and pre-existing dementia in being a vulnerability to delirium. Most do not explain why the complex impairments lead to the characteristic symptoms of delirium, and not dementia, however. The multifactorial model and clinical and pedagogic utility may not be applicable outside hospital settings.

Treatment and management of delirium

The treatment and management of delirium are as much about prevention as it is about treating the condition once it has occurred. Management strategies that use single and multiple components, reflecting the multifactorial causation of delirium, have been trialled.

Multicomponent interventions typically include some combination of the following: staff education, orientation protocols, avoidance of sensory deprivation, multi-disciplinary team approach to care, sleep protocols, early mobilization, hydration, nutrition, medication reviews, oxygen delivery, and pain control [117]. The quality of evidence from the four randomised clinical trials reviewed in a recent systematic overview was considered to be very low [117]. There appears to be no evidence for efficacy of multicomponent interventions in the treatment of delirium. No new trials of multicomponent interventions in acute care appear to have been published after 2006 [118]; a pragmatic trial in post-acute care too failed to show an effect [119]. Does this mean that we should give up on treating delirium? What one of us wrote more than a decade ago is still relevant: ‘... the care provided to the intervention group is how most of us would like our loved ones to be cared for, with enough attention paid to them that health care professionals would at least recognize alterations in their mental state. The unattractive but real alternative is that these patients are consigned to a poor quality of care for ‘confusion’ that demoralizes families and health care professionals alike. Let me press the point further: to fail to recognize delirium is to practise with an unsatisfying disengagement with one’s patients’ lives’ [120].

Dopamine antagonists and other psychotropics are commonly used to treat delirium and agitation in acute hospitals. The (at least) four systematic reviews/meta-analysis published in 2015–2016 vary in their recommendations in using dopamine antagonist medications to treat delirium [121–124]. What is clear is that routine use of such medications cannot be recommended for the treatment of delirium. In routine use, the harms from this class of drugs outweigh any potential benefit. However, there will be times in a busy hospital ward when behavioural control of agitation is required for the safety of the patient and others. In each single case, a risk–benefit analysis must be done before using a dopamine antagonist. On the positive side, a majority of the studies show some benefit, in contrast to use of pro-cholinergic drugs or benzodiazepines [125]. Most treatment guidelines recommend haloperidol, and some include olanzapine [125]. The problem with haloperidol is that it is reputed to cause extra-pyramidal side effects (EPSEs), and it is not quite known how it helps. EPSEs may well be caused by higher doses; for example, in one recent clinical trial, the haloperidol dose, which is roughly equivalent to risperidone, was four times higher than the risperidone dose [126]. When used in equivalent doses (chlorpromazine equivalent dose of approximately 60 mg/day), haloperidol

(approximately 1 mg/day) was equally efficacious as newer dopamine antagonists without EPSEs [127]. The problem discovered in this trial was that the efficacy of all the dopamine antagonists tested was poor in those aged 75 years and over [127]. Benzodiazepines are not recommended in the treatment of typical delirium in an older person. However, they will need to be considered in cases where alcohol withdrawal is the cause of the delirium. In such cases, in order to avoid risks of oversedation, short-acting benzodiazepines should be considered. Lorazepam (1–2 mg orally or intramuscularly or intravenously every 4 hours) or oxazepam (30–60 mg orally every 4 hours for the first day, and then tapering the dose by 50% on days 2 and 3) are recommended [128].

If a dopamine antagonist is deemed necessary to use, then it is best to first trial haloperidol. The typical dosing should be 0.25 mg 3–4 times a day, resulting in stable drug levels from the outset. The important act is to review the use of the medication daily and to taper and cease it as soon as possible. Ideally, this would be part of a hospital routine to match the use of dopamine antagonist medications to an indication for their use.

In summary, multicomponent interventions continue to be important in ensuring older adults receive good quality of care during their hospitalization. Routine use of dopamine antagonist medications is not recommended for the treatment of delirium; they should be used when necessary to provide safe care in a hospital setting.

There is better evidence of effect for multicomponent interventions in the prevention of delirium. A recent Cochrane review found moderate-quality evidence that multicomponent interventions reduce the incidence of delirium, compared to usual care, with similar effect sizes across medical and surgical settings. However, the evidence was less for efficacy in patients with pre-existing dementia [5]. It is not clear which combination of components works best for patients and for patients in a given setting [117], but based on the very limited evidence from trials that used single components, it is possible that staff education, reorientation protocols, and geriatric consultations may be important components to include [117]. A pragmatic clinical trial in 283 older patients admitted for hip fracture repair found good adherence to pre-printed post-operative orders, but more importantly, significantly less delirium in the intervention group (33% vs 51% in controls) and a stronger effect in people with pre-existing dementia [129].

Multicomponent interventions are not without problems; it is unclear if they actually work in reducing delirium in the most frail [130], and implementation of *all elements* in a hospital setting *over time* may be problematic. This requires change in the thinking of what hospitals do, from the coal-face to the board [131]; a frail older adult-friendly hospital is likely to be friendly for all patients.

There is no evidence for the use of cholinesterase inhibitors, melatonin agonists, or dopamine antagonist medications in the prevention of delirium [5]. In the ICU setting, dexmedetomidine appears to reduce the incidence of delirium, agitation, and confusion in critically ill patients [132]. Placement of earplugs in patients admitted to the ICU, either in isolation or as part of a bundle of sleep hygiene improvement, appears to reduce the risk of delirium [133]. However, these short-term gains have to be considered against the finding that interventions do not reduce short-term mortality [134].

There is little evidence of systematic interventions in nursing homes [135]. In their review, Clegg *et al.* [135] found one large cluster randomized trial of a computerized system to identify medications

that may contribute to delirium risk and trigger a pharmacist-led medication review. This study showed a large reduction in delirium incidence, but not in other measures such as reduction in hospital admissions, mortality, or falls risk. Despite this, it is heartening to see the reduction in delirium incidence alone. While the system may not be either available or affordable in all countries, consideration for deprescribing is important. Canada has now established a deprescribing network, and information available on its website <http://deprescribing.org/> would be a useful resource to consider.

Closing remarks and future

Interest in delirium, both in research and policy, has dramatically increased in the past decade. This bodes well. However, despite this heightened interest, diagnostic error rate for delirium remains high and outcomes poor. Josef Strauss wrote his waltz *Delirien* for a medical ball; as beautiful as it is, after the first minute and 40 seconds, it contains little in its music to suggest the turbulence of delirium. Perhaps it is time for us to dance to a different tune for, and with, our patients.

Alzheimer's disease

Ivan Koychev and John Gallacher

Introduction

Worldwide, 47.5 million people have dementia. The total number of people with dementia is expected to reach 75.5 million by 2030 and 135.5 million by 2050 [1, 2]. In the UK, dementia has become the leading cause of death in women and is second to heart disease for men [3]. The most common cause of dementia is Alzheimer's disease (AD), being implicated in up to 70% of dementia cases [4]. The tragic combination of symptoms present in AD has a profound emotional and resource-intensive impact on patients, family, friends, and carers.

Clinical features

Typical early symptoms include absent-mindedness, difficulty recalling names and words, difficulty learning new information, disorientation in unfamiliar surroundings, and reduced social engagement. Atypical, non-amnesic forms also exist where the initial presentation is dominated by visual agnosia (posterior cortical atrophy), word-finding difficulties (logopenic—primary progressive aphasia), or dysexecutive syndrome (presents as fronto-temporal dementia phenocopy). As the disease progresses, there is marked memory loss and loss of other cognitive skills, including a reduced vocabulary and less complex speech patterns. This may be accompanied by mood swings, apathy, a decline in social skills, and the emergence of psychotic phenomena. Advanced AD is characterized by monosyllabic speech, psychotic symptoms, behavioural disturbance, loss of bladder and bowel control, and reduced mobility. Nevertheless, due to the mixed nature of dementia pathologies, the differential diagnosis of AD is inexact. For example, AD frequently occurs in the presence of vascular changes, indicating a coexisting vascular dementia. Without imaging and neurocognitive test evidence, the early stages in atypical AD may not be distinguishable from other neuropathologies. The lack of certainty is reflected in the NINDS-ADRDR diagnostic category of 'probable AD' [5]. Post-mortem examination reveals that AD brains are characterized by the aggregation and accumulations of inter-neuronal amyloid (described as amyloid plaques) and intra-neuronal tau (described as neurofibrillary tangles) proteins.

There are two separate AD expressions, based on their age of onset and underlying genetics. In early-onset AD, also known as

dominantly inherited or familial AD (fAD) due to its high heritability, symptoms can begin in a person's late 20s through to their 50s. Late-onset AD, also known as sporadic AD (sAD), has more varied genetic determinants, but they individually and collectively have less impact. In sAD, there is a greater influence of environmental risk factors such as exercise, alcohol consumption, and obesity. In sAD, symptoms rarely occur before the age of 65. Although the range and complexity of causal factors may be greater in sAD, the disease processes are sufficiently similar for both to result in comparable symptomatology and neuropathology. This has allowed fAD to be used as a model for sAD [6].

Current convention set by the National Institute on Aging-Alzheimer's Association Workgroup differentiates core clinical and research diagnostic criteria [7]. In clinical practice, the diagnosis of probable AD requires the presence of dementia (either amnesic or non-amnesic in terms of affected cognitive domain) that is of insidious onset, represents a deterioration from the individual's baseline, and is not more likely to be accounted for by another cause (for example, other types of dementia or other neurological or medical comorbidities). The term mild cognitive impairment (MCI) has additionally been introduced to recognize states of pre-dementia where cognitive impairment does not interfere to a significant extent in the patient's function. The research AD criteria see the addition of two sets of biomarkers: pathophysiology and neuronal injury. The former is defined by the presence of AD pathology (low CSF A β -42 levels or positive PET amyloid imaging). The major neuronal injury biomarkers are elevated levels of CSF tau, reduced temporo-parietal glucose uptake, as measured by ¹⁸F-fluorodeoxyglucose PET, and disproportionate atrophy in the temporal and parietal lobes using structural neuroimaging. The current recommendation is that the biomarker-enhanced AD diagnosis is not used in routine clinical practice, as the core clinical criteria have good diagnostic accuracy for the majority of patients, while the biomarker criteria require further validation and standardization across laboratories.

Epidemiology

fAD accounts for less than 5% of AD cases, and due to its heritability, most cases are easily identified [8]. Characterizing the prevalence, incidence, and risk factor profile of sAD, however, is more

challenging due to the subtle and insidious onset of symptoms, the stigma associated with a dementia diagnosis, and the limited availability of diagnostic tools. Accurate diagnosis, particularly in the early disease stages, is difficult and requires (preferably serial) structural and molecular brain imaging, as well as CSF analysis. These highly specialized data are rarely available in population studies, being confined to clinical studies.

In a systematic review of 45 studies of sAD, with 20 studies eligible for meta-analysis of participants aged 60+ years, the overall prevalence was 4%, ranging from 1.5% in India to 20% in Israel. In community settings, the prevalence was 3%, while in institutional settings, the prevalence ranged between 10% and 23%. Age-specific prevalence of sAD increases from around 1% at age 60 years to 2% at age 65, 5% at age 70, 10% at age 75, and 20% at age 80 to rates of around 30% at age 90 [9, 10].

In a systematic review of 30 studies, with 11 studies eligible for meta-analysis of participants aged 60+ years, the pooled annual incidence of sAD was 1.6%. All studies in this meta-analysis were in community settings, with estimates ranging between 0.7% in an Italian study to 3% in an American study. Age-specific incidence rates go from around 0.2% at 65 years to 6% at 90 years [9]. A more sophisticated analysis, adjusting for competing morbidities and attrition, but using non-specified dementia as an outcome, confirms these systematic review estimates [11].

Until the age of 85, AD incidence rates for men and women are comparable [12]. Beyond the age of 85, incident AD is lower in men, although vascular dementia risk in men rises. The resulting balance of risk is for an overall increased risk of incident dementia in women at older age. The extent to which this is due to greater female survival is unknown.

A comparison of dementia across 20 years (1989–2008) in the UK shows a recent and modest decline in annual incidence from 2% to 1.7% [13]. This is more pronounced in men and is attributed to an improvement in lifestyle over this period. Although these numbers refer to dementia, given the mixed pathology of many dementias, similar changes are unlikely not to be reflected in sAD. This drop in incidence, although encouraging, will do little to ameliorate the population impact of sAD. Due to the increasing numbers of older people, the overall numbers of sAD cases will continue to rise. Similar trends are found elsewhere [14]. These findings are consistent with the fall in AD after the age of 98 found in post-mortem studies [15].

Neuropathology

AD is a protein abnormality resulting in relentlessly progressive neurodegeneration. The molecular biology underlying AD is complex and incompletely understood. Interest has focused on the two main brain protein accumulations that are characteristic of AD: amyloid and tau. The β -amyloid protein (A β) is prone to aggregation when it fails to fold into the three-dimensional structure that is essential to its function. The misfolded A β monomers progressively aggregate, forming oligomers, then fibrils, and then into relatively disordered clumps of fibrils known as plaque. Tau protein stabilizes extracellular clumps, which are essential to a number of cellular processes. It has a number of phosphorylation sites. Hyperphosphorylation at these sites inhibits microtubule assembly

and sequesters normally phosphorylated tau, causing microtubule disassembly. Hyperphosphorylated tau self-assembles into paired helices and straight filaments, which aggregate as tangles.

These accumulations of misfolded proteins are intracellular tangles of protein processing abnormalities. Although these endpoints are unlikely to represent the initial neuropathological triggers, with time (and increasing age), accumulation of misfolded proteins may result in further cellular changes to oxidative and inflammatory pathways, leading to energy failure, axonal transportation failure, synaptic dysfunction, and neuronal death.

Genetics

The genetic variants causing fAD are found in the β -amyloid precursor protein (*APP*), presenilin-1 (*PSEN1*), and presenilin-2 (*PSEN2*) genes [16]. These genes are located on chromosomes 21, 14, and 1, respectively. Of the 30 known coding mutations in the *APP* gene, 25 result in over-production of A β , resulting in AD. Most of these variants are highly penetrant, that is, almost all individuals carrying the variant will develop AD. One variant (A673T) reduces A β production and is protective against AD [17]. *PSEN1* and *PSEN2* contribute to the γ -secretase complex, which processes APP. The *PSEN1* and *PSEN2* genes each contains ten coding exons, several variants of which increase the production of the longer forms of A β , that is, those which are more likely to misfold.

The genetics of sAD are more complex, involving a greater variety of genes, each with lower penetrance. The apolipoprotein E (*APOE*) gene is the strongest genetic risk factor for sAD [18]. Of the three common alleles, $\epsilon 4$ is associated with a higher risk of AD relative to $\epsilon 3$, while $\epsilon 2$ is associated with a lower risk relative to $\epsilon 3$ [19]. The three alleles are expressed unevenly in the general population, with 60–90% being $\epsilon 3$ carriers, 10–20% carrying $\epsilon 4$, and 0–20% $\epsilon 2$ [20]. A single $\epsilon 4$ allele confers a 3-fold greater risk, while two $\epsilon 4$ alleles confer a 12-fold greater risk. *APOE* binds to A β and is involved on the clearance of A β from the brain. Genome-wide association studies (GWAS) have identified other genetic variants related to AD risk [21–23]. These genes affect a wide range of mechanisms. Although these risk variants can be relatively common in the general population (3–50%), their individual contribution to AD risk is small. Although the specific AD-related functionality of the risk variants is largely unknown, likely areas of action can be identified. Reduced expression of the clusterin gene (*CLU*) is associated with a higher risk of AD, clusterin being involved in A β clearance [16]. Variants in the ATP-binding cassette transporter A7 (*ABCA7*) gene that reduce gene expression are associated with an increased AD risk. *ABCA7* deletion facilitated the processing of APP to A β by increasing the levels of the β -site APP cleaving enzyme 1 (*BACE1*) [16]. Several genes have been associated with the immune response (*CR1*, *CD33*, *MS4A*, *TREM2*). The relationship between the immune response and AD is complex, but in general, upregulation of the immune response is associated with a raised AD risk. A further constellation of AD risk genes is associated with endocytosis (*BIN1*, *PICAML*, *CD2AP*, *SORL1*). Endocytosis is critical to many aspects of neuronal health, including APP processing (*BIN1*), A β clearance (*PICALM*), synapse formation (*CD2AP*), and APP cleavage and *APOE* uptake (*SORL1*). Although each of these GWAS-identified genes contributes only a small degree of AD risk, in combination,

Fig. 40.1 (see Colour Plate section) Risk genes for Alzheimer's disease identifying the primary mechanism, risk conferred, and population allele frequency.

Adapted from *Biol Psychiatry*, 77(1), Karch CM, Goate AM, Alzheimer's disease risk genes and mechanisms of disease pathogenesis, pp. 43–51, Copyright (2015), with permission from Society of Biological Psychiatry.

the risk increases. Although the patterns of association are complex, put simply, if APOE is included in the polygenic risk estimate, comparison of the extremely high and extremely low polygenic risk score groups can predict AD with >80% accuracy [24–26]. The range of risk genes is summarized in Fig. 40.1 (adapted from Karch and Goate [16]), giving the primary mechanism, risk conferred, and population allele frequency.

Mechanisms

That sAD is genetically heterogeneous suggests it is unlikely that a single mechanism will fully explain the variety of protein–protein interactions underlying the disease. AD may best be considered as a multifactorial disorder—a common outcome from multiple neuropathologic pathways. A parsimonious and necessarily simplistic working model would be the expression of amyloid and tau protein folding abnormalities which not only exert direct neurotoxic effects, but also promote an innate immune response, leading to synaptic failure, neurodegeneration, and apoptosis. Tau and amyloid may have a synergistic impact on the immune response, serving to accelerate neurodegeneration. Injury to the neurovascular unit may increase susceptibility to AD through large-vessel atheroma and disruption to the blood–brain barrier. Finally, the systematic spread of amyloid and tau suggests that extracellular misfolded amyloid and tau protein may ‘seed’ protein misfolding in surrounding cells.

Beta amyloid

AD-specific initiating events include A β processing [27]. A β is an albumoid (albumin-like) peptide synthesized from APP. A β peptides are natural products of metabolism. A β is formed by the processing of APP by sequential enzymatic cleavage involving α , β , and γ -secretase. There are six known isoforms of A β , which vary in length from 36 to 43 peptides [4]. The amyloid hypothesis is that the longer isoforms, that is, A β \geq 42 peptides, which are more self-aggregating, are over-produced intracellularly throughout life in fAD and gradually rise extracellularly with age due to faulty clearance mechanisms in sAD. From this perspective, both fAD and sAD point to APP processing as being the trigger for AD.

Transmembrane APP processing

APP produced within the cell is cleaved, as it passes through the cell membrane (Fig. 40.2). Non-amyloidogenic cleavage of APP begins with α -secretase cleavage of APP, leading to the release of the fragment sAPP α into the intercellular space; sAPP α contributes to synapse formation and repair. sAPP α includes part of the A β sequence and so precludes the formation of A β . The remaining APP (in the form of the C83 fragment), still tethered to the cell membrane, is cleaved by γ -secretase, releasing P3 fragment into the intercellular space and the APP intracellular domain (AICD) back into the cell.

Amyloidogenic cleavage begins with β -secretase activity, leading to the release of a shortened fragment (sAPP β) into the extracellular space, leaving the A β peptide intact. The remaining APP (in the form of the C99 fragment), still tethered to the cell membrane, is

Fig. 40.2 (see Colour Plate section) Schematic of amyloidogenic and non-amyloidogenic APP processing pathways.

cleaved by γ -secretase, releasing $A\beta$ into the intercellular space and AICD back into the cell. γ Mitochondrial mass changes occur in the AD brain -secretase cleavage proceeds in a number of steps, beginning with ϵ -cleavage releasing either $A\beta_{48}$ or $A\beta_{49}$, which are then processed, leading to the release of extracellular $A\beta$ [28].

Newly cleaved monomeric $A\beta$ aggregates into oligomers, which, in turn, become fibrils and then plaques. Plaque formation is a dynamic process, with individual oligomers aggregating and disaggregating. Relatively diffuse plaques occur in normal ageing. In AD, plaques are $A\beta_{42}$ rich, more frequent, and more compact, consisting of a central core of amyloid fibrils. Apart from stimulating an inflammatory response, it is difficult to see how plaques affect cell function, and plaque formation may be thought of as a compensatory mechanism to isolate harmful species. That plaques are surrounded by dystrophic neurites and astrocytes suggests they are not entirely inert, and the dynamic nature of $A\beta$ aggregation suggests that it is the presence of aggregating oligomers that is neurotoxic and stimulates an immune response. Extracellular oligomeric $A\beta$ has been shown to interfere with synaptic function, adversely affecting long-term potentiation (LTP). This, in turn, downregulates the translation of neurotransmitters at the synapse, leading to the withdrawal of dendritic spines. In the case of the hippocampus, this effectively inhibits new memories from forming and established memories being retained.

For fAD, genetic variants that are related to AD risk increase the level of either $A\beta_{42}$ or the $A\beta_{42}/A\beta_{40}$ ratio. For sAD, the key genetic risk factor is APOE. In the brain, most APOE is expressed by astrocytes. Although its function and activity are not fully understood, APOE has an affinity for $A\beta$, binding to form a protein complex. APOE alleles vary in their $A\beta$ binding ability, with $E2 > E3 > E4$. The production of $A\beta$ does not appear to vary according to APOE genotype. The lack of variation in production, combined with variation in binding, suggests that for sAD, it is the amyloid clearance mechanism that is not operating efficiently [18]. This is consistent with evidence that in AD, CNS $A\beta$ is lower, suggesting that $A\beta$ is being retained in the brain.

Intracellular APP processing

APP in the cytosol is also processed within the cell, although this process is less well understood. Several studies have demonstrated that α - and β -secretases are present in the ER, enabling APP cleavage [29, 30]. As in the plasma membrane, α - and β -secretases compete with each other for intracellular APP cleavage; this competition modulates the production of $A\beta$. It has also been shown that γ -secretase activity is located predominantly in a specialized subcompartment of the ER—the mitochondria-associated membrane (MAM). MAM is an intracellular lipid, raft-like structure intimately involved in cholesterol and phospholipid metabolism and is physically and biochemically connected to mitochondria. The area of close apposition between mitochondria and MAM is substantially enlarged in AD. Release of $A\beta$ from the ER into the cytosol and exposure of $A\beta$ to mitochondria suggest intracellular neurotoxic mechanisms.

Mitochondrial mass changes occur in the AD brain. Although the total amount of mitochondria may increase, in hippocampal neurons, there is a decline in the number of intact mitochondria and an increase in the number of degraded mitochondria. A case can be made that the brain of AD subjects show perturbed mitochondrial function and a subsequent compensatory response. The bioenergetics evidence has led to the mitochondrial cascade hypothesis, where mitochondrial dysfunction initiates the preferential production of intracellular $A\beta_{42}$. However, the balance of evidence is in favour of APP processing as an initiating event and that an effect of mitochondrial function on intracellular $A\beta$ is subsequent to the initial production of $A\beta$ oligomers.

Tau

Tau is more closely associated with cognitive performance than $A\beta$ [31–33], and porcine evidence suggests tau is required for $A\beta$ -mediated toxicity [34]. Furthermore, extracellular and intracellular $A\beta$ do not immediately explain the development of the tau-based neurofibrillary tangles that are characteristic of AD [35].

Tau is a soluble protein found abundantly in neurons and is one of three microtubule-associated proteins (MAPs) which promote the assembly and stability of microtubules in the neuron, microtubules being essential to axoplasmic flow which is critical for neuronal activity. The ability of tau to support microtubule structure is dependent on the level of phosphorylation [36]. Optimal phosphorylation occurs with the phosphorylation of around 30 of the 85 potential sites. Hyperphosphorylated tau has several cytotoxic effects. As the number of phosphorylated sites increase beyond 30, tau loses the ability to bind with microtubules. Hyperphosphorylated tau also sequesters normal tau and other MAPs from the microtubule lattice into the cytosol. This destabilizes the microtubule, leading to disassembly. Microtubule network dysfunction leads to loss of axonal transportation and neurodegeneration. Apart from affecting normal microtubule function, hyperphosphorylated tau is associated with conformational changes, leading to misfolding and increased aggregation. As with mature A β plaques, mature neurofibrillary tangles are relatively inert, suggesting that it is monomeric and oligomeric hyperphosphorylated tau that is cytotoxic, that is, it is the soluble species, rather than the neurofibrillary tangle itself [37].

A link between tau phosphorylation and APP processing in the cell membrane has been shown, although the full pathway is not clear [36]. In stem cell models, changes in tau production and tau phosphorylation are associated with APP processing through β - and γ -secretase activity. Inhibition of β -secretase reduced tau levels and phosphorylation, while inhibition of γ -secretase was associated with increased tau and tau phosphorylation [29]. Modulation (enhancement) of γ -secretase was associated with reduced tau production. Limiting β -secretase function reduces the release of APP-C99, while limiting γ -secretase function reduces the release of both APP-C99 and APP-C83 (Fig. 40.2). Enhancing γ -secretase function increases the release of APP-99 and APP-83, which accumulate in the cell. These findings suggest that tau production and tau phosphorylation occur as part of an APP processing pathway, which is independent of extracellular A β levels. How phosphorylated tau affects cell function is largely unknown. One possible mechanism is a gradual loss of axonal function through the disassembly of microtubules, leading to an immune response and apoptosis. APOE4 is associated with increased tau phosphorylation [38]. Although the mechanisms are unclear, that APOE4 acts independently on both tau and A β opens the possibility that tau and A β may act synergistically to accelerate neurodegeneration.

Immune response

Several strands of evidence suggest a general upregulation of the immune response, associated with a raised AD risk. Genetic evidence for an immune response to plaque comes from the overexpression of genes (*Trem2*, *CRI*, *CD33*) that are associated with plaque phagocytosis [39–42]. The co-location of plaque with astrocytes and other glial elements and the presence of inflammatory and complement cascade components implicate an innate and adaptive immune response to the presence of plaque. This response is likely to be subsequent to the triggering events surrounding APP processing but serves to accelerate AD pathology. Although the immune response may be targeted at plaque removal, by microglial phagocytosis, for example, it is unlikely not to affect the surrounding neurons. The associated increasing concentrations of reactive oxygen species and inflammatory cytokines, for example, will affect the function and

integrity of the plasma membrane. As described, the increased susceptibility to AD, associated with an upregulated immune response, may be largely a response to abnormal APP processing. However, it may be that upregulation provides a cellular environment that also facilitates abnormal APP processing.

Synaptic failure

Although proteinopathy may initiate neurodegeneration, AD is functionally a reflection of synaptic failure leading to neuronal loss [43]. Synaptic loss is more prevalent in the vicinity of A β plaques, suggesting plaques are a source of synaptotoxic molecules [44]. Hippocampal synapses begin to decline in patients with mild cognitive impairment in whom the remaining synaptic profiles show compensatory increases in size. In mild AD, there is a reduction of about 25% in the presynaptic vesicle protein synaptophysin. With advancing disease, synapses are disproportionately lost, relative to neurons, and this loss is the best correlate with clinical symptoms of dementia. Experimental application and expression of A β , especially oligomers, impair synaptic plasticity by altering the balance between LTP and long-term depression (LTD) in favour of LTD. LTP refers to the increase in dendritic spine development, while LTD causes spine shrinkage and collapse, thus reducing the number of dendritic spines [45]. At high concentrations, oligomers may suppress basal synaptic transmission. From *in vitro* studies, A β is associated with disruption of the release of presynaptic neurotransmitters and post-synaptic glutamate receptor ion currents [46, 47]. For example, A β binds to α -7 nicotinic acetylcholine receptors, impairing the release of acetylcholine and the maintenance of LTP. Although a reduction in LTP is found in normal ageing, it may be that A β triggers synaptic deficits earlier.

Circulatory and metabolic factors

Vascular injury and the resulting parenchymal inflammation perpetuate the cycle of protein misfolding. Although cases of 'pure' AD are recognized, most AD cases are mixed, combining features of both AD and vascular disease [4]. This has led to an increased interest in the neurovascular unit—the close anatomical and functional relationship between the cellular components of the brain [48]. A β is toxic to endothelial and smooth muscles cells and compromises the A β influx and efflux mechanisms of the blood–brain barrier [49]. A further factor is the reduced cerebral blood flow typically found in AD [50]. The extent to which this reflects reduced demand or inadequate supply is moot.

Metabolic factors focus on the insulin signalling pathway. Glucose intolerance and type 2 diabetes are risk factors for AD. Several models have been proposed to explain the increased insulin resistance underlying these associations [51]. These focus on deregulated insulin signalling affecting the energy available to the cell, increased inflammatory response, increased A β production, and compromised synaptic transmission. However, the direction of causality involved in these associations is unclear.

Propagation

Mechanisms underlying the spread of AD pathology, typically beginning in the entorhinal cortex have focused on the prion hypothesis, which is that the process is dependent on the nucleating properties of misfolded protein and the transmission of misfolded protein between cells [52, 53]. In this model, misfolded protein acts

as a template for further misfolding, accelerating the misfolding process. If the misfolded protein is released into the extracellular space and endocytosed into a neighbouring cell, the misfolding process is transmitted independently of the receiving cell's intrinsic ability to misfold the protein [54, 55]. In AD, there is evidence that both A β and tau can be transmitted between cells. This 'prion' model does not replace the basic trigger mechanism of APP processing. It is likely that populations of cells, subject to proteolytic 'stresses' (genetic or otherwise), independently produce misfolded protein and that the seeding of these proteins further distributes pathology.

Treatment

Significant advances in the understanding of AD pathophysiology and corresponding investment in the development of potential disease-modifying treatment have so far not led to effective aetiological therapy, with several notable failed agents. The only licensed treatment of AD is therefore symptomatic, with two drug classes available: acetylcholinesterase inhibitors (donepezil, rivastigmine, and galantamine) and the NMDA receptor antagonist galantamine. The former are licensed for mild to moderate AD, while memantine can be used in moderate to severe AD. The most recent guidelines recommend a combination between the two classes in moderate and severe AD cases [56]. The expected benefit is stabilization of cognitive decline for a period of 6–12 months, with, on average, nine patients needed to be treated for one of them to experience significant benefit (that is, number needed to treat of 9). Despite the modest immediate benefits associated with these drugs, they appear to have some additional effects in those treated long term. In the Donepezil and Memantine in Moderate to Severe Alzheimer's Disease (DOMINO) study, Howard and co-authors examined the effects of continuing symptomatic treatment beyond the stage of moderate to severe dementia; a sample of patients on stable donepezil dose were randomized to: (1) continue the drug; (2) discontinue the drug; or (3) switch to, or add, memantine. In this study, the group that discontinued symptomatic treatment had faster cognitive decline and worse functional outcomes [57] and were admitted to care more quickly [58]. These results led to the current consensus guideline that 'cholinesterase inhibitors should not be stopped just because the point of severe dementia has been reached' [59].

The transition of prodromal and subclinical AD is accompanied by the emergence of a variety of behavioural and psychological symptoms of dementia (BPSD). These include depression (comorbidity of AD and depression in up to 50%), psychosis, agitation, aggression, sleep disturbance, wandering, apathy, and a variety of socially inappropriate behaviours. Some of these symptoms affect practically all patients with dementia at some point of the illness and are a major cause of loss of independence, carer burden, and early placement into nursing care [60]. Current guidelines advocate the use of non-pharmacological strategies to prevent and address problem behaviours in dementia [61]. Pharmacological treatment of aggression through sedation is limited to acute settings to prevent injury with long-term use of dopamine antagonists, which is being actively discouraged due to a 3-fold elevation in risk for cerebrovascular events. Drugs for psychosis, such as risperidone, offer some efficacy in terms of improving recurrent agitation and psychosis symptoms, which warrants careful consideration of risk/benefits.

SSRIs may be a better alternative, with evidence of citalopram and sertraline, in particular, for beneficial effects on agitation and psychosis. Also, long-term treatment with a drug for depression should be a consideration where there is comorbid depression, although the evidence for efficacy is weak [60]. Careful risk/benefit consideration is also applicable here, given the higher likelihood of SSRIs causing hyponatraemia and gastrointestinal bleeding in the elderly.

Care

The care for individuals with dementia is a major societal challenge, with an estimation of care costs in the United States alone standing at \$203 billion in 2013 and expected to rise to \$1.2 trillion in 2050 [63]. This is due to individuals with dementia requiring significantly higher levels of care than other chronic conditions. This level of need, as a rule, leads to care in nursing homes, with four-fifths of all residents suffering from dementia. Still, the majority of dementia patients are being looked after by their families in their homes. Such informal care is associated with significant carer strain, with higher levels of stress, less time for social interaction, and high prevalence of dropping out of work or otherwise missing job opportunities, relative to carers of other chronic conditions [63]. Carers are also at significantly higher risk for psychological problems (for example, depression risk is 3–39 times higher than age-matched controls [64]) and physical deterioration (carers experiencing stress have a 60% higher risk of mortality over 4 years, relative to those who do not report stress [65]). Informal care, however, is and will remain critical to the sustainability of looking after dementia. Long-term strategies therefore focus on reducing carer burden through complex interventions, focusing on education, training, practical support, and respite. A typical intervention lasts 8–12 weeks and includes individual or family counselling, case management, education on strategies for managing behaviours, and environmental modifications. Such interventions result in improvement of carer mental health and increase the time to institutionalization by up to a year [66].

Prevention

Prevention of sAD has been identified by the WHO and G8 as a key element in the strategy to counter the dementia epidemic. Economic analyses have shown that delaying the onset of the disease by even 1 year would reduce its prevalence by up to 11%, while a delay of 5 years would halve it [67].

Risk factors

A number of risk factors for sAD have been identified. Non-modifiable risk factors can be used for targeting therapies in appropriate groups. The best established non-modifiable risk factors for sAD are age, genetics, and female sex. These are discussed in the relevant Epidemiology and Genetics sections of this chapter. Modifiable risk factors are the logical focus of prevention strategies. Attributing population risk estimates, that is, the proportion of the population for whom a risk factor has caused a disease, is particularly challenging for sAD. Apart from most risk factor studies focusing on non-specific dementia as an outcome, rather than sAD, the major modifiable risk factors for sAD (lifestyle, comorbidities,

education) are unlikely to impact sAD independently of each other. Nevertheless, an overall estimate is that between a third and a half of all sAD cases are attributable to modifiable risk factors [68].

Lifestyle risk factors, such as exercise, diet, smoking, excessive alcohol use, and associated cardiovascular risk, are the main focus of prevention programmes in sAD. This focus predicated a life course approach to dementia prevention, as these risk factors frequently represent chronic exposures and exposure at some life stages may be more harmful than at others.

Cardiovascular factors

The major modifiable cardiovascular risk factors (hypertension, diabetes, obesity) increase the likelihood of not only the vascular subtype of dementia, but also sAD. This is due to the two conditions frequently sharing neurodegenerative pathologies—it is likely that cardiovascular disease potentiates sAD pathology through disruption of the blood–brain barrier and atherosclerotic, inflammatory, and/or thrombotic mechanisms. Hypertension was identified as a major risk factor through cohorts such as the Goteborg Longitudinal Study [69] and the Honolulu Asia Aging Study [70]. They demonstrated a strong relationship between mid-life hypertension and dementia in later life, but also that a decline in blood pressure levels frequently precedes the development of sAD. This had previously led to the distorted view that low blood pressure predisposes to sAD. Direct evidence of sAD-protective effects of long-term blood pressure control is currently lacking, despite significant evidence of the benefit of blood pressure therapies on overall mortality and morbidity [71]. Late-life diabetes has been consistently linked to both sAD and vascular dementia. Trials exploring the protective effect of strict diabetic control on cognition had conflicting results; this may have been due to tighter control being associated with cognitive benefits, but also increasing the risk of hypoglycaemic episodes, a known risk factor for dementia onset [72]. The evidence for up to 50% increase in sporadic dementia risk by mid-life diabetes comes from health record studies, for example an American study of 8845 patient records [73]. While obesity and associated hypercholesterolaemia in middle age have not been shown to directly increase the risk for sAD [72], it is nonetheless a rational target for prevention, given their established role as cardiovascular risk factors. In later life, perhaps counterintuitively, body mass index reduction precedes the development of sAD by 5–15 years [74]. Current research therefore demonstrates the importance of addressing cardiovascular risk factors from a life course perspective, with emphasis on mid-life risk factor control.

Alcohol and smoking

Smoking is a major risk factor for sAD and the only one with a good level of evidence for the protective effect of intervention. Specifically, current smokers have a 50% increase in their sAD risk, relative to never-smokers. The effect appears to be mediated by a direct effect on amyloid metabolism (reduction in microglia-mediated amyloid clearance), as well as the well-described effect of increasing cardiovascular risk. It is plausible that the true risk for sAD is underestimated due to the greatly reduced life expectancy associated with smoking—analyses aiming to account for the missing smokers support this. In addition, heavy smokers who survive to old age are likely to be biologically unusual individuals who have a variety of protective factors against cardiovascular risks that may also confer

protection against sAD. Importantly, smoking cessation leads to a reduction of sAD risk to the level of never-smokers [72], which is hugely encouraging for prevention programmes.

The association with alcohol consumption is less clear. A recent meta-analysis demonstrated a modest protective effect for moderate drinkers vs abstainers, while heavy drinkers had comparable risk with abstainers [72]. This 'J'-shaped curve, reminiscent of that found between alcohol and cardiovascular disease, likely reflects several competing mechanisms. These include the 'sick-quitter' effect where higher-risk individuals stop drinking prior to the onset of symptoms, the underreporting of alcohol consumption at high levels of intake, and under-representation of high-risk individuals with high alcohol of intake. Although plausible protective mechanisms for a protective effect of moderate alcohol on the cerebrovascular system exist, population-based 30-year follow-up imaging evidence showed no benefits of light drinking, with hippocampal atrophy rising dose-dependently [75].

Physical exercise and cognitive stimulation

Regular exercise is recommended as a means of reducing cardiovascular, as well as broader health, risk and therefore has the potential for indirectly reducing sAD risk. In addition, exercise improves cerebral perfusion, has anti-inflammatory properties, improves synaptic function, and stimulates neurogenesis [76]. It also has a social and cognitive element, which is protective in terms of mental health more broadly. A systematic review of the effects of physical effects on sAD risk in older adults showed a 50% sAD risk reduction in those exercising regularly [77]. Interpretation of these data, however, is limited by the possibility that lower physical activity may be part of the dementia prodrome, either through apathy or through broader functional impairment (reverse causality).

Similarly, cognitively stimulating activities are of great interest as potential protective strategies. The available studies point to a consistent reduction of sAD risk in older adults who engage in intellectually challenging activities vs passive activities such as watching TV. These effects suffer from the same limitation as physical exercise where a gradual reduction in engagement with intellectual activities may be the first sign of incipient dementia. Some evidence, however, exists linking intellectual activity in early and mid life and a reduced risk for sporadic dementia (Rush Memory and Aging study Project [78]). Whether the benefits of cognitive stimulation are due to a slowing of pathology or an improved efficiency of remaining function due to training is unclear.

Psychological factors

Psychiatric disorders are of particular interest in relation to prevention of sAD, given their high prevalence across the lifespan and the availability of effective psychological and pharmacological treatments. There is a robust link between depression in late life and the incidence of sporadic dementia, whereby having depression increases nearly 2-fold the risk of developing dementia [72, 79]. Having depression also increases the risk of transitioning from MCI to dementia [80]. The interpretation that late-life depression is a risk factor for depression was discounted recently by the 28-year-long follow-up Whitehall II cohort study [81]. It is instead more likely that low mood forms part of the dementia prodrome or that the two conditions share a common cause. The same study discounted a role for mid-life depression as a risk factor for sAD, even where it was of

a recurrent/chronic nature. Personality factors, schizophrenia, and other psychiatric factors have been investigated, but the evidence for a link with sAD is so far lacking [72]. While this shows that treating depression is unlikely to delay the onset of sAD, the well-established deleterious effects of depression on memory, sleep, and social functioning makes treating depression in the stage of established cognitive impairment an important clinical consideration.

Education and occupational attainment

Higher educational and occupational attainments have consistently been implicated as protective for developing dementia in later life. For education, a recent meta-analysis reported an approximately 40% risk reduction for high vs low education attainers [72]. Similarly, there was an 80% increased risk for dementia in low-paid workers, although a significant part of the variance appeared to be accounted for by their level of education [72]. The protective effects of education may be due to prolonged period of learning, stimulating the development, or being the result, of larger brain volume or neural networks of greater complexity. These potential physical and functional factors could be related to a greater capacity to compensate the underlying sAD pathology and thus delay the onset of clinical symptoms (the 'cognitive reserve' theory). Equally, an inborn characteristic of the nervous system that is protective of sAD may also increase the capacity to learn at a young age and thus predispose to longer education.

Future trends

The importance of conducting effective primary and secondary prevention of sAD has led to the development of population-based programmes specifically designed to translate sAD risk factor research into public health benefit. The clustering of lifestyle risk factors in sAD lends itself to complex interventions where several risk factors are addressed simultaneously. The Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER) is one of the first such initiatives aimed at secondary prevention [82]. FINGER recruited non-demented individuals in the 60–77 years range who had an elevated dementia risk score (based on age, sex, education, blood pressure, BMI, cholesterol levels, and physical activity), as well as a minor degree of cognitive impairment. This therefore selected an ultra-high-risk population for dementia and allowed the trial of a multi-domain intervention involving changes to nutrition, physical activity, education, and cognitive training. The intervention group's cognitive outcomes improved at 25–150%, compared to the control group (health advice only). Future studies would need to demonstrate the benefit of such interventions on the key public health outcome—time to dementia onset. A further key question to be addressed is the extent to which addressing risk factors in mid life results in effective primary prevention of sAD. However, indirect evidence of this effect is already available through the observed decline in the projected dementia incidence rate—a trend attributed to improved cardiovascular risk control [11].

Despite the huge societal gains that are likely to accrue from risk factor control, it is likely that disease-modifying treatments will be required to affect the global burden of dementia. The realization that the disease process starts decades before the first symptoms has led to a number of initiatives aimed at identifying the condition either

at its preclinical (that is, a state with evidence of sAD pathology) or prodromal (that is, a state of minimal symptoms and sAD pathology) stages.

Development in these disease stages rests on the increased knowledge of mechanisms for the development of new compounds, access to biomarkers for risk stratification for targeting treatments to those who will benefit the most, the development of more sensitive outcome measures allowing benefits to be more efficiently detected, and a trials-ready infrastructure enabling new compounds to be tested more rapidly. These challenges are increasingly being met through large-scale collaborative platform science projects. In relation to mechanisms, these include the UK Dementia Research Institute (<https://ukdri.ac.uk/>). For biomarker development, there is the Deep and Frequent Phenotyping Study [83], while for risk stratification and trials, there are the Dementias Platform UK (<https://www.dementiasplatform.uk/>), the European Prevention of Alzheimer's Dementia Consortium (EPAD) (<http://ep-ad.org/>), and the American-based Global Alzheimer's Platform Foundation (<http://globalalzplatform.org/>). Powerful digital technologies are also being harnessed for sAD research, including the Dementias Platform UK (<https://www.dementiasplatform.uk/>), the European Medical Informatics Framework (<http://www.emif.eu/>), and the Real world Outcomes across the Alzheimer's Disease spectrum for better care: Multi-modal data Access Platform (ROADMAP) project for the assessment of real-world evidence in sAD (<http://roadmap-alzheimer.org/>).

Arguably, a culture shift in the public perception of AD and dementia in general will be required before full benefit of preventative and treatment strategies will be realized. Moving from dementia to a framework of brain health would help de-stigmatize cognitive decline, empower the public to take greater responsibility for prevention, and encourage society at large to generate inclusive solutions for maintaining functional independence. To reimagine dementia care in terms of brain health centres, rather than memory clinics, would not be an idle reverie.

Frontotemporal dementias

Akitoshi Takeda and Bruce Miller

Introduction

Arnold Pick first reported in 1892 a case of dementia with symptoms of aphasia and atrophy of the frontal and temporal lobes [1]. By the 1920s, the clinicopathological entity named Pick's disease had been established [2]. It was soon realized that many patients with progressive degeneration of the frontotemporal regions did not have classical Pick bodies. In 1994, the Lund–Manchester groups developed a consensus to delineate the clinical and neuropathological criteria for what they called frontotemporal lobar degeneration (FTLD) [3]. The criteria encompassed each of the major clinical syndromes of FTLD: frontotemporal dementia (FTD) [currently called behavioural-variant FTD (bvFTD)], progressive non-fluent aphasia, and semantic dementia. These criteria have been replaced by the international criteria for FTD [4–14] and primary progressive aphasia (PPA) [5–27].

Epidemiology

FTD is recognized as one of the leading causes of early-onset dementia and typically presents in people in their late fifties. The onset of symptoms is usually between the fourth and eighth decades, but cases that begin in the third and ninth decades are seen. About 10% of FTD cases present in patients aged less than 45 years, and about 60% of FTD cases present in those aged between 45 and 64 years [6]. Approximately 30–50% of cases are familial, and 10–15% of FTD cases appear to be associated with an autosomal dominant pattern of inheritance. The prevalence of FTD in individuals between 45 and 64 years of age is estimated to be 2–22 per 100,000 but varies widely, ranging from 4–31 per 100,000 in Europe [4] and 15–22 per 100,000 in the United States [6] to 2–9.5 per 100,000 in Japan [5, 7]. The estimated incidence of FTD is between 2.7 and 4.1 per 100,000 person-years, based on population studies from the United States and Europe [4]. Regarding the gender distribution of FTD, some studies have reported a significantly higher prevalence among men, whereas other studies have reported almost the same prevalence in men and women [4]. The median survival after onset is 6.0–11.8 years [8–10]. In FTD subtypes, semantic dementia has longer median survival (12 years) [9], while FTD and motor neuron disease (FTD-MND) has the shortest median survival (3 years) [8, 11].

Classification

FTD is a neurodegenerative disorder that primarily affects the frontal and temporal lobes and leads to distinct clinical syndromes. FTD is classified into three clinical variants, according to the FTD consensus criteria: (1) bvFTD, which is characterized by early and significant changes in behaviour, emotion, personality, and executive control; (2) non-fluent-variant PPA (nfvPPA), which is characterized by progressive deficits in speech, grammar, and word output; and (3) semantic-variant PPA (svPPA), which is a progressive disorder of semantic knowledge and naming. Some patients present with features of both FTD and amyotrophic lateral sclerosis (ALS)/MND (ALS/MND). In addition, behavioural and cognitive symptoms of progressive supranuclear palsy (PSP) and cortico-basal syndrome (CBS) often overlap with FTD. These clinical syndromes are closely linked to specific molecular pathologies that affect the frontal and temporal lobes [12] (Fig. 41.1).

A new classification for cognitive disorders (including dementia) was established in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5). FTD is referred to as a frontotemporal neurocognitive disorder (NCD) in DSM-5. Frontotemporal NCDs are subdivided into mild or major frontotemporal NCD, according to the severity of cognitive impairment. Frontotemporal NCD is characterized by the progressive development of behavioural and personality changes and/or language impairments. According to the DSM-5 criteria, the prerequisite for a diagnosis of behavioural-variant frontotemporal NCD is a progressive decline in social cognition and/or executive abilities. In addition, three or more of the following behavioural features must be present: behavioural disinhibition, apathy/inertia, loss of empathy, perseverative/ritualistic behaviour, and hyperorality/dietary changes. The diagnosis is categorized as 'possible' or 'probable' frontotemporal NCD, according to the severity of cognitive and functional impairment. If there is supporting evidence from genetic mutations or neuroimaging, the diagnosis is described as probable; otherwise, it is designated as possible [13]. The behavioural variant and three language variants (agrammatic/non-fluent, semantic, and logopenic) exhibit distinct patterns of brain atrophy and some distinctive forms of neuropathology. The necessary criteria must be met to make a diagnosis of either the behavioural or the language variant, but many individuals present with features of both.

Fronto-temporal dementias

Behaviour	Language	Motor
<u>bvFTD</u> Behavioural symptoms Disinhibition Loss of empathy Apathy, etc. FTLD-tau, FTLD-TDP FTLD-FUS	<u>nvPPA</u> Apraxia of speech Agrammatism FTLD-tau FTLD-TDP	<u>CBS</u> Parkinsonism Cortical sensory deficit Limb apraxia FTLD-tau FTLD-TDP
<u>FTD-MND</u> Behavioural symptoms Motor neuron disease FTLD-TDP FTLD-FUS	<u>svPPA</u> Anomia Word comprehension deficit FTLD-tau FTLD-TDP	<u>PSPs</u> Parkinsonism Supranuclear vertical gaze palsy Postural instability FTLD-tau FTLD-TDP

Fig. 41.1 Clinical and pathological spectrum of frontotemporal dementias. Frontotemporal dementia encompasses three canonical syndromes: behaviour syndrome, language syndrome, and motor syndrome. These clinical syndromes can overlap in the disease course.

Despite recent advances in the characterization of bvFTD, the diagnosis of the syndrome remains challenging. Some patients with bvFTD are misdiagnosed as having psychiatric disorders or Alzheimer's disease (AD). In the absence of definitive biomarkers, clinical diagnostic criteria are more important in the diagnosis of bvFTD. The International Behavior-variant FTD Criteria Consortium (FTDC) developed revised guidelines for the diagnosis of bvFTD in 2011. A diagnosis of bvFTD is categorized as 'possible', 'probable', or 'definite' bvFTD, based on this hierarchical classification system, with support from radiological findings, genetic studies, and neuropathological data. The FTDC criteria have been changed by prescribing specific criteria for diagnosis, while excluding patients with biomarkers for AD or other neurodegenerative disease [14].

Behavioural-variant frontotemporal dementia

The most pronounced behavioural symptoms of bvFTD are loss of empathy, apathy, and disinhibition, which typically precede any obvious cognitive impairment. Therefore, bvFTD can be mistaken for depression or other psychiatric disorders in the early stages. In bvFTD, behavioural changes can lead to job loss and financial problems. The families of patients with bvFTD report high levels of distress from the very early stages, compared with families of patients who have AD [15]. Most behavioural symptoms are caused by disruptions to the brain networks involved in emotions and social function. Patients with bvFTD show loss of empathy towards family and other people. They cannot interpret the emotional state of other people and show decreased responsiveness to emotions (emotional blunting). Family members of patients with bvFTD often describe their loss of empathy as selfish or self-centred. Loss of empathy is associated with human brain networks that include the medial orbitofrontal cortex (OFC), anterior temporal lobe, and anterior insula, and these regions match those affected by the pattern of

atrophy characteristic of bvFTD [16, 17]. The loss of empathy seems to be lateralized to the right anterior temporal lobe, OFC, and anterior insula [16, 18].

Apathy is defined as loss of interest or emotion and loss of motivation [19], and in patients with bvFTD, this presents as reduced interest in work, hobbies, and hygiene that leads to a decline in personal hygiene. Apathy is associated with atrophy of the anterior cingulate cortex (ACC) and ventromedial superior frontal cortex [20]. The ACC (especially the dorsal ACC) also plays an important role in both the motor and cognitive domains. The dorsal ACC is involved with the supplemental motor area in the planning of complex movements. ACC lesions can cause dramatic reductions in spontaneous speech and movement (akinetic mutism) in extreme cases [21]. In terms of the cognitive domain, the dorsal ACC and dorsolateral prefrontal cortex are associated with executive functions such as set maintenance.

Disinhibition is a distinctive feature of bvFTD, and the OFC plays an important role in modifying behaviour, depending on the principle of receiving rewards and avoiding punishment [22]. Avoiding inappropriate behaviour is a key component of successful social functioning. The OFC is one of the earliest regions affected in bvFTD, and its atrophy leads to disinhibition [22]. Dysfunction of the right OFC in bvFTD manifests as marked behavioural disinhibition [20], which is associated with inappropriate behaviours such as hugging or kissing strangers, urinating in public, or telling sexual jokes. Behavioural disinhibition may also manifest as impulsivity such as reckless driving, excessive purchasing of unnecessary items, or criminal behaviour such as shoplifting. Loss of insight is defined as a lack of awareness of mental symptoms due to frank denial or unconcern for the consequences [23]. Patients with bvFTD show even more severely diminished insight into their symptoms and overestimate their performance. Loss of insight is associated with ventromedial and frontopolar prefrontal atrophy [23].

Alterations in eating behaviour occur in patients with bvFTD, including changes in appetite and food preferences. Patients with bvFTD tend to display sugar cravings and binge eating, often associated with significant weight gain. Changes in food preferences are due to dysfunction in neural networks that include the hypothalamus, right insula, bilateral nucleus accumbens, and OFC [24]. Binge eating is associated with loss of function in the right ventral insula, striatum, OFC, thalamus, and anterior cingulate [24, 25]. In terms of neuropsychological testing, patients with bvFTD tend to show deficits in executive function, although visuo-spatial function, and often episodic memory, is relatively spared, compared with AD [26].

Language-variant frontotemporal dementia

PPA is a progressive language disorder that is often associated with disproportionate atrophy of the left frontal and temporal lobes, and is classified as language-variant frontotemporal NCD in DSM-5 [13]. Language dysfunction is the main symptom for the first 2 years of the illness. Deficits in language production, object naming, syntax, or word comprehension are apparent during conversation or in speech and language assessments [27]. Patients with language-variant frontotemporal NCD present with PPA with gradual onset, with three subtypes being commonly described—semantic-variant, agrammatic/non-fluent-variant, and logopenic-variant—and each variant has distinctive features and corresponding neuropathology [27]. nfvPPA and svPPA are associated with FTD, and logopenic-variant PPA is associated with AD. ‘Probable’ is distinguished from ‘possible’ frontotemporal NCD by the presence of causative genetic factors (such as mutations in the gene coding for microtubule-associated protein tau) or by the presence of a distinctive pattern of atrophy or reduced activity in frontotemporal regions on structural or functional imaging [13].

Non-fluent-variant primary progressive aphasia

nfvPPA is characterized by non-fluent and effortful speech production, and agrammatism (omission or misuse of grammar) is usually, but not always, present. Agrammatism and effortful speech are core symptoms of nfvPPA [27]. Apraxia of speech (AOS) is also common in nfvPPA. AOS causes inconsistent speech sound errors such as distortions, insertions, deletions, substitutions, and transpositions of speech sounds. Word-finding difficulties are relatively mild, compared with svPPA. Single-word and object comprehension are relatively spared, although patients can have mild anomia that may be more pronounced for verbs than for nouns. Deficits in syntax comprehension are evidenced by impairments in sentence comprehension, initially only for the most difficult syntactic constructions [27]. nfvPPA is associated with atrophy predominantly in the left inferior frontal and insular regions, which is necessary for making a diagnosis of the imaging-supported non-fluent variant. Clinically, nfvPPA patients exhibit few behavioural changes.

Semantic-variant primary progressive aphasia

Patients with svPPA present with deficits in comprehension and word-finding abilities (anomia) due to impairments in semantic knowledge; however, these patients retain a fluent expressive speech pattern, with correct use of grammar. Anomia and single-word comprehension deficits are the core features [27]. These

deficits reflect a gradual loss of semantic knowledge, which is observed irrespective of modality. Anomia tends to be more pronounced for nouns than for verbs or pronouns. Semantic deficits are usually present for most categories (that is, tools, animals, and people), although rare cases have been described with greater, or even selective, deficits for people and animals. A common feature among svPPA patients is surface dyslexia and dysgraphia, impairments in which words with atypical spelling or pronunciation are regularized. Anatomically, svPPA is associated with atrophy in the ventral and lateral portions of the bilateral anterior temporal lobes, although damage is usually greater on the left side. The clinical presentation of predominantly right-sided semantic dementia cases is heterogenous and includes inappropriate behaviour, loss of knowledge about familiar faces, loss of empathy, and/or semantic deficits [28].

Motor symptoms

In patients with FTD syndromes that overlap with MND, behavioural and cognitive symptoms can develop before, after, or simultaneously with motor symptoms. Patients with FTD often present with parkinsonism, including bradykinesia, rigidity, tremor, and/or postural instability. The prevalence of parkinsonism in FTD varies from 12.5% to 30% [29]. Early parkinsonism is observed in 16% of FTD patients [30], with bradykinesia being the most common manifestation in 84% of patients, followed by a parkinsonian gait (71%), rigidity and postural instability (35.5%), and resting tremor (6.5%) [31]. PSP and CBS are two atypical parkinsonian syndromes demonstrating cognitive and behavioural features that overlap with FTD. Patients with FTD often have concomitant ALS/MND. In some instances, FTD precedes ALS by many years; in other instances, ALS occurs before FTD. The incidence of FTD in patients with bulbar-onset ALS is reported to be as high as 48% [32]. Although 10–15% of patients with FTD develop MND [32, 33], there is an even higher prevalence of ‘subclinical’ MND, with evidence from electromyography (EMG) of MND or mild motor signs such as fasciculations in 30–60% of patients with FTD [32, 33]. Among the FTD variants, MND arises frequently in patients with bvFTD, and less often in patients with svPPA or nfvPPA.

Genetics

Approximately 40% of FTD cases have a family history, and 10–15% of FTD cases show an autosomal dominant pattern. Mutations have currently been associated with bvFTD in genes encoding the following proteins: chromosome 9 open reading frame 72 (C9ORF72), microtubule-associated protein tau (MAPT), granulin (GRN), transactive response DNA-binding protein 43 (TARDBP, otherwise known as TDP-43), fused in sarcoma (FUS), valosin-containing protein (VCP), and charged multivesicular body protein 2b (CHMP2B) [34] (Table 41.1). Mutations in C9ORF72, MAPT, and GRN account for the majority of familial FTD cases [35].

C9ORF72

The C9ORF72 mutation results in a recently identified hexanucleotide repeat expansion on chromosome 9 [36]. The largest proportion of familial FTD (about 25%) is caused by

Table 41.1 Clinical and neuroimaging features of hereditary frontotemporal dementia

	Prevalence	Mean age of onset	Clinical presentation	Atrophy pattern
<i>C9ORF72</i>	25% of familial FTD	45 years	bvFTD ALS FTD-MND Parkinsonism	Symmetrical frontal atrophy with temporal and parietal involvement Thalamus and cerebellar atrophy
<i>MAPT</i>	2–11% of familial FTD	49 years	bvFTD PPA CBS PSP	Symmetric anteromedial temporal lobe atrophy
<i>GRN</i>	20% of familial FTD	58 years	bvFTD PPA CBS PSP	Asymmetric frontal, temporal, and parietal lobe atrophy
<i>FUS</i>	3% of familial FTD-MND	46 years	FTD-MND ALS	Frontal and temporal atrophy
<i>VCP</i>	1–2% of familial FTD-MND	57 years	bvFTD FTD-MND Inclusion body myopathy Paget's disease of the bone	Frontal, temporal, and parietal lobes, especially prefrontal and superior temporal cortices
<i>TARDP</i>	1.3% of familial FTD-MND	63 years	FTD-MND ALS	Frontal and temporal atrophy
<i>CHMP2B</i>	1% of familial FTD-MND	58 years	bvFTD FTD-MND	Frontal and temporal atrophy
<i>TBK1</i>	0.5–4% of ALS	67 years	FTD-MND ALS nfvPPA svPPA CBS	Asymmetric anterior temporal atrophy and frontal involvement

pathogenic expansions of *C9ORF72* [35]. Cases with *C9ORF72* mutations are characterized by underlying TDP-43 pathology [36]. The most common clinical phenotypes associated with *C9ORF72* mutations are bvFTD, ALS, or both. *C9ORF72* mutations are the most common genetic cause of familial FTD and ALS [37]. Thirty to 50% of patients with *C9ORF72* expansions present with hallucinations and delusions [36].

MAPT

The microtubule-associated protein tau is encoded by *MAPT* and plays an important role in microtubule assembly and stabilization in neurons. *MAPT* mutations account for between 2% and 11% of familial FTD cases [34]. An *MAPT* mutation was identified as the first causative genetic mutation in several families with FTD and associated parkinsonism in 1998 [38]. *MAPT* mutations are associated with an underlying tauopathy. Clinically, cases with *MAPT* mutations usually present with bvFTD and may include parkinsonism. PPA syndromes, including nfvPPA and svPPA, can also be seen in patients with *MAPT* mutations [39]. Variability in the normal haplotypes of *MAPT* has also been associated with an increased risk for the development of the syndromes PSP and CBS that overlap with FTD [40].

GRN

GRN encodes granulin, a secreted protein that may function in inflammation, wound repair, and cell cycling [41]. The neuropathology of patients with *GRN* mutations is characterized by tau-negative, TDP-43-positive inclusions. *GRN* mutations account for up to 20% of familial FTD cases and are occasionally seen in sporadic cases

[42]. *GRN* mutations are found in 24.7% of FTLD-TDP cases [41] and are associated with an earlier age of symptom onset and an earlier age of death, compared with FTLD-TDP patients without *GRN* mutations [41]. The clinical presentation of patients with *GRN* mutations is bvFTD, with nfvPPA or CBS seen less frequently [34]. Episodic memory deficits occur in 10–30% of those with *GRN* mutations and may lead to the clinical diagnosis of an amnesic variant of MCI, with parietal deficits similar to AD [42]. *GRN* mutations are seldom seen in association with MND [41].

Others

Mutations in the genes encoding five other proteins, including VCP, CHMP2B, TARDBP, FUS, and TBK-1, have been identified in a minority of cases [34]. *VCP* mutations result in a rare syndromic combination of bvFTD with inclusion body myopathy and Paget's disease of bone (known as IBMPFD). Pathologically, *VCP* mutations have TDP-43 type D pathology [43]. *CHMP2B* mutations are a genetic cause of FTD linked to chromosome 3 (FTD-3), which was originally identified in a large Danish family. The phenotype of *CHMP2B* mutations is usually a behavioural syndrome similar to bvFTD, although several cases with FTD-MND have been described [44]. *TARDBP* mutations on chromosome 1 have been reported in FTD and FTD-MND cases [45], and are found in 5% of those with familial ALS [42]. *FUS* mutations were originally described in familial ALS, accounting for 3% of cases [46]; however, most FTD cases with *FUS* pathology are sporadic and do not have *FUS* mutations [47]. Finally, recent studies suggest that loss-of-function mutations in *TBK1* (encoding TANK-binding kinase 1) can cause FTD-MND. In addition, svPPA and nfvPPA can be manifestations

of *TBK1* mutations and should be considered in patients with PPA associated with ALS.

Semantic and non-fluent aphasic variants, secondarily associated with ALS, are predominant FTLT phenotypes in *TBK1* carriers [48, 49].

Pathology

To distinguish the neuropathology from the clinical diagnosis, the term FTD is used for the clinical syndrome, whereas the term FTLT is used when referring to the neuropathological classification [50]. AD pathology can be responsible for bvFTD syndrome, although if the international research criteria for this disorder are applied carefully, this is rare [51]. One pathological finding of FTLT is regional atrophy of the frontal and temporal cortices, with neuronal loss and microvacuolation predominantly involving the superficial cortical layers II and III [52]. FTLT is a neuropathologically heterogeneous disorder, which can be divided into two major subtypes, according to the characteristic pattern of abnormal protein deposition: FTLT with tau-positive inclusions (FTLT-tau) subtype and FTLT with ubiquitin-positive and TDP-43-positive subtype. FTLT-FUS is seen in a small minority of tau-negative, ubiquitin-positive cases [12] (Table 41.2).

FTLT-tau

FTLT-tau accounts for 36–50% of all cases of FTLT, according to different pathological series, and varies widely across the different FTD syndromes [35]. The defining characteristic of FTLT-tau is the accumulation of filamentous aggregates of pathological tau in neurons, astrocytes, and oligodendrocytes, which are collectively known as tauopathies (Fig. 41.2a–c). Primary tauopathies include Pick's disease, FTD with *MAPT* mutations (FTDP-17), PSP, CBD, argyrophilic grain disease (AGD), and neurofibrillary tangle dementia (NTD). The most common primary tauopathy is CBD, accounting for 35% of cases, followed by PSP with 31%, Pick's disease with 30%, and AGD accounting for the remaining 4% of all cases of FTLT-tau [12]. Pick's disease is characterized by the presence of Pick bodies, cytoplasmic inclusions composed primarily of three-repeat isoforms of abnormal tau protein (Fig. 2a). PSP, CBD, and AGD are tauopathies with predominantly four-repeat tau isoforms. There are very good clinicopathological associations between FTLT-tau as a group, particularly for PSP. nfvPPA is usually a primary tauopathy, with CBD accounting for approximately 50% of cases with PSP and Pick's disease also seen [12, 53]. At our institution, University

of California, San Francisco, approximately one-third of all bvFTD cases are due to tau.

FTLT-TDP

TDP-43 is a ubiquitously expressed nuclear protein that functions as a repressor of transcription. It also regulates gene expression and splicing. FTLT-TDP is represented in about 50% of all cases of FTD [35]. TDP-43 pathology is seen in sporadic and familial cases of FTLT involving mutations in the genes for GRN and VCP, and in FTD with or without MND and the C9ORF72 hexanucleotide repeat, as well as familial and sporadic cases of ALS [52]. Four major subtypes of FTLT-TDP are recognized (types A, B, C, and D), based on the pattern of cytoplasmic or intranuclear pathology [54] (Fig. 2d) (Table 41.2).

FTLT-FUS

FTLT-FUS accounts for about 10% of all bvFTD cases [35, 55]. The majority of tau-negative/TDP-43-negative, ubiquitin-positive FTLT cases have positive immunohistochemical staining for the FUS protein, thus distinguishing a third category of FTLT neuropathology that includes the categories formerly called atypical FTLT with ubiquitinated inclusions (aFTLT-U), basophilic inclusion body disease (BIBD), and neuronal intermediate filament inclusion disease (NIFID) [55]. This last entity is characterized by sporadic, early-onset (<40 years) bvFTD or FTD-MND [35].

Others

The FTLT-other category is reserved for diseases in which the major protein associated with the disease entity remains unknown [12]. FTLT without inclusions (FTLT-ni) is diagnosed when there is histological evidence of frontotemporal neuronal loss and gliosis, but no presence of any inclusions by immunostaining. FTLT with immunohistochemistry against proteins of the ubiquitin proteasomal system (FTLT-UPS) is diagnosed when there are ubiquitin or p62 immunoreactive inclusions that are negative for tau, alpha-synuclein, alpha-internexin, TDP-43, and FUS [12]. The majority of FTLT-UPS cases are associated with *CHMP2B* mutations [12, 44].

Investigations

Neuroimaging

Structural MRI shows distinct patterns of atrophy in FTD. Brain atrophy in FTD predominantly affects the frontal or temporal lobes, and atrophy of the ACC and frontal insular cortex are particularly characteristic of FTD, while medial and posterior temporo-parietal and occipital lobe atrophy is indicative of AD, rather than FTD [56]. The genetic forms of FTD have their own typical patterns of atrophy. GRN mutations are more likely to show strongly asymmetrical atrophy, predominantly affecting one hemisphere and involving the inferior frontal, temporal, and inferior parietal lobes [34]. *MAPT* mutations are associated with a more symmetrical pattern of atrophy, localized predominantly in the anterior temporal lobes and also involving the OFC [34]. With *C9ORF72* mutations, thalamic, and sometimes cerebellar, atrophy is a distinguishing feature, and a slightly more generalized pattern of atrophy is evident than with the other genetic forms of FTD.

Table 41.2 Correlations between clinical presentation, pathology, and genetics in frontotemporal dementia

	Common clinical presentation	Associated gene mutation

FTLT-UPS	bvFTD, FTD-MND	CHMP2B

Fig. 41.2 (see Colour Plate section) Histological features of FTLD-tau and FTLD-TDP. (a) Pick's disease. Pick bodies (lower inset) in the inferior temporal gyrus. (b) Cortico-basal degeneration. Astrocytic plaque (circle) and neuronal cytoplasmic inclusions (arrow and upper inset) in the precentral gyrus. (c) Progressive supranuclear palsy. Tufted astrocyte in the sensorimotor cortex. (d) FTLD-TDP type B. Neuronal cytoplasmic inclusions (arrow and lower inset) and neuropil threads (arrowheads and upper inset) in the middle frontal gyrus. Immunostains are phospho-tau (a–c) and TDP-43 (d). All scale bar represents 10 µm.

PET imaging is also useful for distinguishing AD and FTD. In FDG-PET studies, a pattern of hypometabolism in the frontal, anterior temporal, and anterior cingulate cortices characterizes FTD, while hypometabolism in the temporoparietal and posterior cingulate cortices characterizes AD [57]. Amyloid imaging may also be useful to distinguish FTD from AD. The novel PET tracer ^{11}C -PiB selectively binds to amyloid plaques and identifies cortical lesions affected by AD pathology [58]. A variety of tau tracers are being tested in patients with AD [59]. Tau imaging could potentially differentiate between AD, FTLD-tau, and FTLD with ubiquitinated inclusions, although at least with the svPPA form of FTD where TDP-43 is usually the underlying pathology, tau imaging markers have proven disappointing.

Functional connectivity network mapping using resting state fMRI is a novel technique for identifying specific brain networks. In patients with bvFTD, intrinsic connectivity within the salience network is decreased, while increased activity is seen in the default mode network. By contrast, the opposite pattern of intrinsic connectivity is seen in AD [60].

In vivo biomarkers

To date, no serum or CSF biomarkers have been identified that distinguish patients with FTD from normal controls. Similarly, there

is no biomarker that enables the differentiation of FTD subtypes. By contrast, biomarkers that help to differentiate AD from FTD are well accepted. tau, phosphorylated tau (pTau181), and A β 42 in combination help to differentiate FTD from AD [61]. A β 42 in the CSF is reduced, and tau and pTau181 are increased in AD, compared with FTD. Combined CSF analysis of the ratios of A β 42/A β 40 [62], total tau/A β 42, or phosphorylated tau/A β 42 [63] can be used to improve the diagnostic accuracy and enable AD to be differentiated from FTD.

Differential diagnosis

A careful history, which includes the progression of behavioural changes and family and social history, is one of the most effective ways to distinguish FTD from other dementias. Performance on neuropsychological testing, laboratory studies, and neuroimaging also help to differentiate FTD from other causes of dementia such as inflammation or infectious disease. Among the subtypes of FTD, the differential diagnosis of early bvFTD is the most challenging. The possibility of AD needs to be considered, especially the behavioural/dysexecutive variant that also affects the frontal lobes. Some 10–40%

of patients clinically diagnosed with bvFTD have subsequently been found to have AD pathology on amyloid PET or post-mortem evaluations [64], although our recent studies suggest that bvFTD diagnosed in an expert centre is almost never due to AD pathology. Patients with behavioural variant AD showed worse memory deficits than those with bvFTD but did not differ from patients with typical AD, while their executive function was more impaired, compared to patients with bvFTD and typical AD [64].

Another important differential diagnosis is late-onset psychiatric disease. In the early stage of bvFTD, behavioural changes, including disinhibition, apathy, and compulsive behaviour, can occur in the absence of neurological signs or cognitive impairment. These behavioural changes in bvFTD can overlap with specific psychiatric disorders. The initial diagnosis in 6% of patients with bvFTD is schizophrenia, schizoaffective disorder, bipolar disorder, depression, or an unspecified psychotic state [65]. A few forms of genetic bvFTD have been associated with psychotic symptoms. Patients with bvFTD and *C9ORF72* mutations often exhibit psychosis as a dominant presenting problem, resulting in initial diagnoses of obsessive-compulsive disorder, schizophrenia, or bipolar disorder [36]. Patients with bvFTD and *GRN* mutations also present with psychiatric manifestations, including bulimia, personality changes, sexual disinhibition, ritualistic behaviours, and paranoia [66].

There is a subset of bvFTD patients in whom disease progression following clinical diagnosis does not appear to occur despite a clear history from caregivers of initial personality and behavioural changes. These patients are said to suffer from bvFTD phenocopy syndrome [67]. Patients with phenocopy syndrome should be distinguishable because they do not show a functional decline or imaging changes [14]. As the long-term prognosis is good, it seems less likely that phenocopy syndrome is caused by a neurodegenerative disorder [14]. Recent work suggests that some phenocopy subjects carry a genetic form of bvFTD [68].

Treatment and care

Currently, no disease-modifying treatments can alter the course of FTD. Therefore, pharmacological treatments have focused on the modulation of behavioural and cognitive symptoms of FTD [35, 69]. Recent randomized controlled trials have shown that cholinesterase inhibitors, galantamine, and memantine, which are effective for treating cognitive or behavioural symptoms in AD patients, have no efficacy in patients with FTD [69, 70]. Some drugs for depression, including SSRIs and trazodone, have shown efficacy in improving the behavioural symptoms of bvFTD such as disinhibition, depression, compulsive behaviour, and carbohydrate cravings [35, 70]. A few studies have shown that olanzapine is effective for aggression, agitation, and psychosis, although the adverse events associated with dopamine antagonists include parkinsonism [69, 70].

To manage the behavioural symptoms of bvFTD, environmental modification and education for caregivers are also necessary. Educating caregivers about the best non-pharmacological behavioural strategies, identification of triggers for problematic behaviours, and increasing their coping skills have shown success in reducing caregiver stress and improving caregiver tools for managing behavioural symptoms [70, 71]. Resources, such as The Association

for Frontotemporal Degeneration, and the development of strategies to maintain emotional and physical safety have been shown to minimize caregiver burden [70].

Prion disease

Akin Nihat, TzeHow Mok, and John Collinge

Introduction

Human prion diseases, also known as subacute spongiform encephalopathies, have been traditionally classified into Creutzfeldt–Jakob disease (CJD), Gerstmann–Sträussler syndrome (GSS) (also known as Gerstmann–Sträussler–Scheinker disease), and kuru, although this has largely been superseded by aetiological categorization. Although rare, with an annual incidence of 1–2 per million worldwide (accounting for 1 in 5000 deaths in the UK), remarkable attention has been focused on these diseases. This is because of the unique biology of the transmissible agent, or prion, and also because bovine spongiform encephalopathy (BSE), an epidemic bovine prion disease, was transmitted to humans as variant CJD (vCJD), leading to fears of a significant public health threat through dietary exposure.

The transmissibility of the human diseases was first demonstrated with the transmission of kuru and then CJD in 1966 and 1968, respectively, [1, 2] by intracerebral inoculation of brain homogenates into chimpanzees. Transmission of GSS followed in 1981. The prototypic prion disease is scrapie, a common naturally occurring disease of sheep and goats, recognized in Europe for over 200 years and present in sheep flocks of many countries. Scrapie was demonstrated to be transmissible by inoculation in 1936 [3], and the recognition that kuru, and then CJD, resembled scrapie in its histopathological appearances led to the suggestion that these diseases may also be transmissible [4]. Kuru reached epidemic proportions among the Fore linguistic group in the Eastern Highlands of Papua New Guinea and was transmitted by consumption of human tissues at mortuary feasts. Since the cessation of cannibalism in the 1950s, the disease has declined, but a few cases were still occurring into the 2010s as a result of long incubation periods, which may exceed 50 years [5].

The term Creutzfeldt–Jakob disease was introduced by Spielmeyer in 1922, bringing together the case reports published by Creutzfeldt and Jakob. Several of these cases would not meet modern diagnostic criteria for CJD; indeed, it was not until the demonstration of transmissibility allowing diagnostic criteria to be refined that a clear diagnostic entity developed. Prion diseases of both humans and animals are associated with the accumulation in the brain of disease-related isoforms of a host-encoded protein known as prion protein (PrP), and all share common histopathological features: the classical triad of spongiform vacuolation (affecting any part of the cerebral grey

matter), astrocytic proliferation, and neuronal loss, accompanied by PrP deposits which may form amyloid plaques.

Aetiology

According to the widely accepted ‘protein-only’ hypothesis, prions are devoid of significant nucleic acid and consist of multichain assemblies of misfolded, host-encoded PrP, a cell surface glycoprotein expressed in most tissues, but at its highest levels in the CNS. Cellular PrP (PrP^C) is present in all vertebrates and highly conserved in mammals. Prions are thought to propagate by acting as a template to recruit PrP monomers in an autocatalytic process of seeded protein polymerization and fission, mimicking propagation of a biological pathogen. Biophysical experiments established that PrP^C, rich in α -helical structure, needs to largely unfold in order to adopt the β -sheet-rich structure of the infectious amyloid form, arguing that prions propagate by recruitment of at least partially unfolded PrP. Disease-related PrP isoforms have been classically referred to as PrP^{Sc} (for the scrapie form of PrP), which was originally defined by its partial resistance to proteolytic digestion. However, it is now established that there are multiple disease-related forms of PrP, some of which are protease-sensitive, and the term PrP^{Sc} should not be used synonymously with prion infectivity.

Human prion diseases have three distinct aetiologies: (1) autosomal dominant inheritance, whereby coding mutations in the PrP gene (*PRNP*) result in PrP^C predisposed to form seeds; (2) sporadic CJD, following the spontaneous production of seeds as a rare stochastic event and representing the large majority of CJD cases; and (3) acquired by environmental exposure to prions. While this aetiological triumvirate was thought unique, it is now being widely considered whether this is relevant to much more common diseases. Notably, the principal neurodegenerative diseases are all associated with accumulation of misfolded proteins; they also occur primarily as sporadic conditions, but with rare inherited forms generally associated with mutations in the genes encoding or processing the relevant accumulating proteins or peptides. Recent data are challenging the assumption that these conditions do not have acquired forms, with a developing interest in understanding whether the so-called ‘prion-like’ mechanisms are involved, notably in Alzheimer’s disease [6].

The human PrP gene (*PRNP*) is a single-copy gene located on the short arm of chromosome 20. A turning point in understanding

human prion diseases was the identification of mutations in *PRNP* in familial CJD and GSS in 1989. The first mutation to be identified in *PRNP* was in a family with CJD and constituted a 144-bp insertion into the coding sequence [7]. A second mutation was reported in two families with GSS, and genetic linkage was confirmed between this missense variant at codon 102 and GSS, confirming that GSS was an autosomal dominant Mendelian disorder [8]. Current evidence suggests that around 15% of prion diseases are inherited and over 40 coding mutations in *PRNP* are now recognized.

A common PrP polymorphism at residue 129, where either methionine or valine can be encoded, is a key determinant of genetic susceptibility to acquired and sporadic prion diseases—the large majority of which occur in homozygous individuals [9, 10]. This protective effect of *PRNP* codon 129 heterozygosity is also seen in some of the inherited prion diseases.

Prion strains and transmission characteristics

Although devoid of a nucleic acid genome, prions exist as multiple strains which can be serially propagated in laboratory animals and produce distinct patterns of disease. Strains are associated with specific types of PrP^{Sc}, and it is thought they represent structurally distinct seeds that are able to recruit host PrP^C into their discrete polymeric forms. Understanding how a protein-only infectious agent could encode such phenotypic information has been of considerable biological interest and represents a non-Mendelian form of transmission.

Prion strain diversity appears to be encoded by differences in PrP conformation and pattern of glycosylation [11]. Molecular strain typing approaches, based on these characteristics, have allowed the identification of multiple types among CJD cases. Two classifications are in use; no internationally agreed classification has yet emerged, and it is likely that additional PrP^{Sc} types or strains will be identified [12, 13]. According to the London classification, four main types of PrP^{Sc} are recognized—sporadic and iatrogenic CJD being of PrP^{Sc} types 1–3, while all variant CJD cases are associated with a distinctive type 4 PrP^{Sc} [11, 12].

Transmission of prion diseases between different mammalian species is limited by a so-called ‘species barrier’. Early studies of the molecular basis of the species barrier argued that it principally resided in differences in PrP primary structure between the inoculating species and the host. Transgenic mice expressing hamster PrP were, unlike wild-type mice, highly susceptible to infection with hamster prions [14]. That most sporadic and acquired CJD occurred in individuals homozygous at *PRNP* polymorphic codon 129 supported the view that prion propagation proceeded most efficiently when interacting PrP^{Sc} and PrP^C were of identical primary structure [12]. However, it has been long recognized that prion strain type affects ease of transmission to another species. Interestingly, with BSE prions, the strain component to the barrier seems to predominate, with BSE not only transmitting efficiently to a range of species, but maintaining its transmission characteristics, even when passaged through an intermediate species with a distinct PrP gene [15]. The term ‘transmission barrier’ is therefore preferable [15]. Both the PrP amino acid sequence and strain type affect the three-dimensional structure of glycosylated PrP, which will presumably, in turn, affect the efficiency of the protein–protein interactions thought to determine prion propagation.

Mammalian PrP genes are highly conserved. Presumably only a restricted number of different PrP^{Sc} conformations (that are highly

stable and can therefore be serially propagated) will be permissible thermodynamically and will constitute the range of prion strains seen in mammals. While a significant number of different PrP^{Sc} conformations may be possible among the range of mammalian PrPs, only a subset of these would be allowable for a given single mammalian PrP. Substantial overlap between the favoured conformations for PrP^{Sc} derived from species A and species B might therefore result in relatively easy transmission of prion diseases between these two species, while two species with no preferred PrP^{Sc} conformations in common would have a large barrier to transmission (and indeed transmission would necessitate a change of strain type). According to such a *conformational selection model* [16] of a prion transmission barrier, BSE may represent a thermodynamically highly favoured PrP^{Sc} conformation that is permissive for PrP expressed in a wide range of different species, accounting for the remarkable promiscuity of this strain in mammals. Contribution of other components to the transmission barrier is possible and may involve interacting co-factors which mediate the efficiency of prion propagation, although no such factors have yet been identified.

Additional data have further challenged our understanding of transmission barriers [17], the assessment of which has relied on the development of a clinical disease in inoculated animals. However, it is now clear that *subclinical prion infections* are sometimes established on prion inoculation of a second species [18]. Such animals harbour high levels of prion infectivity but do not develop clinical disease during a normal lifespan. The existence of such subclinical carrier states of prion infection has important potential animal and public health implications and argues against direct neurotoxicity of prions. Indeed, recent studies have demonstrated uncoupling of prion propagation and neurotoxicity [19].

The transmission barrier between cattle BSE and humans cannot be directly measured but can be modelled in transgenic mice expressing human PrP^C, which produce human PrP^{Sc} when challenged with human prions. While these transgenic mouse models have been able to faithfully propagate human prion strains [11, 20, 21] and recapitulate the characteristic neuropathology of vCJD [22], there are important caveats in extrapolating from such animal models to human susceptibility. However, these studies have found a much higher infection rate in transgenic mice expressing human PrP M129 than mice expressing human PrP V129 when challenged with either BSE or vCJD prions, and demonstrated that BSE prion infection can produce disease phenotypes resembling sporadic CJD and also novel prion strain phenotypes. Most recently, these studies have argued that the vCJD phenotype may only be expressed in the presence of the M form of human PrP [23]. While implying that only those humans expressing PrP M129 may develop the vCJD phenotype, this does not mean that VV individuals are completely resistant to BSE prion infection—but rather that if infected, they would show a different phenotype [23]. Modelling of susceptibility of the MV genotype suggests that several different phenotypes may be possible when infected with BSE or vCJD prions [24].

Clinical features and diagnosis

Human prion diseases can be divided aetiologically into inherited, sporadic, and acquired forms, which largely share one or more core clinical features: progressive cognitive deterioration, ataxia,

myoclonus, and pyramidal or extra-pyramidal motor signs. Focal cognitive deficits (for example, executive or memory impairment) may present in isolation for weeks or months, as can isolated ataxia. There is inevitably progression to global cognitive dysfunction, and the common pre-terminal clinical state is akinetic mutism.

Nevertheless, there is wide phenotypic variability both between and within aetiological groups. Indeed, kindreds with inherited prion disease that segregate the same mutation can manifest remarkably diverse clinical presentations. Approximately 85–90% of human prion disease cases in the UK are sporadic, and psychiatric symptoms in the form of agitation, anxiety, hallucinations, or depression are present in the majority early in disease course. A subset of patients develop a more discrete psychiatric syndrome, such as florid psychosis, and may first present to psychiatric services without common motor features.

Broadly, prion disease should be considered in all cases of early-onset or rapidly progressive dementia or ataxia. Significant clinical overlap exists with other neurodegenerative syndromes, including Alzheimer's disease, dementia with Lewy bodies, and fronto-temporal dementia. A definite diagnosis can only be made via neuropathological examination, commonly post-mortem (or with a confirmed *PRNP* mutation in inherited prion disease). However, the rapid advancement in diagnostic markers, in particular diffusion-weighted MRI and CSF prion seeding assays for sporadic prion disease, coupled with the availability of *PRNP* genotyping, now permits accurate ante mortem diagnosis in the large majority of cases. Brain biopsy is now rarely required and is usually reserved for cases with highly atypical features or a strong suspicion of a treatable mimic. The key clinical features and investigations for the diagnosis of prion disease are given in Box 42.1.

Sporadic CJD

The onset is usually in the 45- to 90-years age group, peaking around 65 years. Sporadic CJD (sCJD) classically presents with rapidly progressive multifocal dementia, myoclonus, and gait ataxia. The condition typically progresses over weeks to akinetic mutism and death, often in 2–3 months; around 70% of cases die in under 6 months and 90% by 1 year. Prodromal features such as headache, fatigue, or weight loss are reported in about a third of cases; the other key features of sCJD include pyramidal and extra-pyramidal signs and visual signs. For case classification for epidemiological purposes, the appropriate clinical picture, in combination with at least one typical investigation finding (MRI, EEG, or CSF), would allow ante mortem classification as *probable* sCJD, without histological confirmation (Box 42.1). Probable CJD is almost always (>95%) confirmed as definite if autopsy is performed.

Routine blood investigations are usually within the normal range and, even when abnormal, possess no particular value diagnostically. MRI brain with diffusion-weighted sequences has emerged as the most sensitive non-invasive diagnostic tool for sCJD [25]; sCJD patients typically demonstrate restricted diffusion in the basal ganglia and thalami and cortical ribboning, but the regional combinations vary from case to case (Fig. 42.1). Signal hyperintensity on T2-weighted and FLAIR sequences in the corresponding regions may also be present, but this is less striking. CSF examination is essential to exclude other causes of rapid cognitive decline, and both cell count and routine biochemistry remain normal in sCJD cases.

Box 42.1 Diagnosis of prion disease

Sporadic CJD (MRI-CJD diagnostic criteria [25])

I. Clinical signs (*rapidly progressive dementia** with additional features)

- Myoclonus.
- Cerebellar or visual signs.
- Pyramidal or extra-pyramidal signs.
- Akinetic mutism.

II. Tests

- Periodic sharp waves complexes on EEG.
- 14-3-3 protein detected in CSF.
- High signal abnormalities in caudate nucleus/striatum, or at least two cortical regions (temporal/parietal/occipital), either in diffusion-weighted imaging (DWI) or fluid attenuation inversion recovery (FLAIR) MRI sequences.
- Positive RT-QuIC in CSF or other tissues

Probable sCJD

- Rapidly progressive dementia and two of I and at least one of II. Progressive neurological syndrome and positive RT-QuIC in CSF or other tissues

Possible sCJD

- Rapidly progressive dementia and two of I and duration of less than 2 years.

Iatrogenic CJD

- Progressive predominantly cerebellar syndrome and behavioural disturbance in a recipient of human pituitary hormones (growth hormone or gonadotrophin). Limb dysaesthesiae is also a frequent feature.
- Probable CJD with exposure to a recognized iatrogenic CJD risk factor: human pituitary hormones; human dura mater graft; corneal graft from a recipient with definite/probable human prion disease; exposure to neurosurgical instruments used in a case with definite/probable human prion disease.
- Incubation periods may be over 40 years from exposure.
- MRI findings are similar to those seen in sporadic CJD; EEG periodic sharp waves are rarely seen.
- CSF 14-3-3 protein can be detected in approximately half of cases; RTQuIC can also be positive, but sensitivity is much reduced, compared with sporadic CJD.

Variant CJD

- Progressive neuropsychiatric syndrome: depression, anxiety, withdrawal, delusions.
- Peripheral sensory symptoms (pain or dysaesthesiae), cerebella ataxia, and myoclonus/chorea/dystonia often precede dementia.
- Mostly young adults, with a longer disease course (>6 months).
- EEG: non-specific slow waves, CSF 14-3-3 may be elevated or normal.
- MRI: pulvinar sign present in approximately 90% (particularly FLAIR sequence) but may be a late feature and not pathognomonic.
- Tonsil biopsy: characteristic PrP immunostaining and PrP^{Sc} on western blot.

Inherited prion disease

- Varied clinical syndromes between and within kindreds: consider in all pre-senile dementias and ataxias, irrespective of family history.
- *PRNP* analysis: diagnostic, codon 129 genotype may predict age at onset in pre-symptomatic testing.

* This is typically 6 months or less, but there is high variability; approximately 10% have a duration of >2 years. No other cause identified, including no pathogenic *PRNP* mutations.

Incorporates data from Lloyd, S., Mead, S., & Collinge, J. (2011). Genetics of prion disease. In *Prion Proteins* (pp. 1–22). Springer Berlin Heidelberg.

Fig. 42.1 Typical MRI features of sporadic CJD (sCJD), variant CJD (vCJD), and iatrogenic CJD. (a) Diffusion-weighted (DW) imaging showing the basal ganglia, thalamic, and hippocampal tail increased signal in sCJD, with corresponding restriction (b) in apparent diffusion coefficient (ADC) sequence. (c) and (d) DW and ADC images in sCJD, showing cortical ribboning and restricted diffusion. (e) FLAIR image in vCJD showing the pulvinar sign (thalamic high signal more prominent than in the basal ganglia). (f) DW image in iatrogenic CJD, showing high signal in the motor strip.

The presence of protein 14-3-3, raised S100B levels, and highly elevated total tau levels in the CSF are useful adjunctive tests for sCJD. However, they have been superseded by the development of the real-time quaking-induced conversion (RT-QuIC) assay in recent years. RT-QuIC is an amyloid-seeding assay that uses repeated mechanical sample shaking and incubation to amplify prion seeds in patient CSF, using recombinant PrP as a substrate and a fluorescent thioflavin T readout. A positive CSF RT-QuIC possesses a comparable sensitivity to a positive protein 14-3-3 in the CSF, but more importantly it has a specificity for sCJD approaching 100% [26]. The RT-QuIC assays seeded by nasal brushings and, more recently, skin from sCJD patients also yield high sensitivities and specificities approaching (and reaching) 100%, although neither of these have yet been incorporated into routine clinical practice [27, 28]. EEG in sCJD may show characteristic pseudoperiodic sharp wave activity, but this is demonstrated in less than 50% of patients [25], the large majority of whom are *PRNP* codon 129 MM. To some extent, demonstration of a typical EEG is dependent on the number of serial EEGs performed.

Neuropathological confirmation of sCJD is by demonstration of the classical spongiform change, neuronal loss, astrogliosis, and positive PrP immunohistochemistry. PrP amyloid plaques are usually not present in sCJD, although protease-resistant PrP^{Sc} types 1–3 can be demonstrated by immunoblotting of brain homogenates

(molecular strain typing; see Aetiology, p. 414). *PRNP* analysis is important to exclude pathogenic mutations. By definition, there is no family history in these cases, although rarely mutations are seen due to late-onset disease or non-paternity. It is possible some cases might arise from somatic mutation of *PRNP* or unidentified environmental exposure to human or animal prions.

Atypical forms of sCJD

Atypical forms of sCJD with distinct clinical syndromes and durations of survival are well recognized. Those with the so-called ataxic variant of sCJD present with slowly evolving gait ataxia in the initial months before the onset of cognitive impairment. These individuals are typically *PRNP* codon 129 MV and have a longer duration of illness, with a good proportion living beyond 2 years from the time of symptom onset. In the Heidenhain variant of sCJD, which affects individuals who are *PRNP* codon 129 MM, cortical visual symptoms and signs predominate in the early course of the illness, while memory remains intact; patients can progress rapidly to cortical blindness and death in as short as 4 weeks from symptom onset, often accompanied by severe agitation.

Other clinical syndromes at presentation encountered in sCJD patients include pure cognitive syndromes, neuropsychiatric syndromes, cortico-basal syndrome, and stroke-like syndromes;

the former two can progress slowly with late emergence of typical sCJD signs and are frequently mistaken for Alzheimer's disease and behavioural-variant fronto-temporal lobar degeneration, respectively.

Acquired prion diseases

While human prion diseases can be transmitted to experimental animals by inoculation, they are not contagious in humans. Documented case-to-case spread has only occurred during endocannibalistic practices (kuru) or following accidental inoculation with prions during medical or surgical procedures (iatrogenic CJD).

Kuru

Kuru reached epidemic proportions among the Fore linguistic group and their neighbours in the Eastern Highlands of Papua New Guinea [29]. It predominantly affected women and children, as they were the principal participants in the practice of consuming dead relatives at mortuary feasts, as a mark of respect and mourning.

The clinical course typically lasts between 1 and 2 years and begins with a constitutional prodrome of headaches and limb and joint pain, followed by progressive cerebellar ataxia, often with other features such as tremor, diplopia, dysarthria, social withdrawal, and depression. Patients subsequently develop global dementia and frequently pyramidal and extra-pyramidal motor signs.

Kuru incidence has been in decline since its peak in the 1950s, following the cessation of endocannibalism in the late 1950s, and the last recorded case was 2012. However, the study of kuru continues to reveal valuable insights, the most recent being the identification of the protective G127V polymorphism in kindreds at the epicentre of the kuru epidemic. This polymorphism appeared to provide complete protection against kuru [30], and this was supported by transgenic mouse modelling and inoculation experiments which showed that mice expressing human PrP 127V were completely resistant to all known human prion strains [31].

Iatrogenic CJD

Iatrogenic transmission of CJD has occurred by accidental inoculation with human prions as a result of medical procedures. Such iatrogenic routes include the use of inadequately sterilized neurosurgical instruments, dura mater and corneal grafting, and use of human cadaveric pituitary-derived growth hormone or gonadotrophin. It is of considerable interest that cases arising from intracerebral or optic inoculation manifest clinically as classical CJD, with rapidly progressive dementia, while those resulting from peripheral inoculation, most notably following pituitary-derived growth hormone exposure, typically present with a progressive cerebellar syndrome and are, in that respect, somewhat reminiscent of kuru. Unsurprisingly, the incubation period in intracerebral cases is short (less than 2 years for depth electrodes and neurosurgery), as compared to peripheral cases (typically 15 years or more). There is evidence for genetic susceptibility to iatrogenic CJD with an excess of codon 129 homozygotes [9] (see Aetiology, p. 414).

Variant CJD

The appearance of an unusual form of CJD in the UK was heralded by a spate of cases in teenagers and young adults in 1995–1996, with

a surprisingly consistent, but unique, histological pattern [32]. There was considerable concern over the possibility that they might suggest a link with BSE. These cases were named 'new variant' CJD, and eventually 'variant' CJD (vCJD), although it was clear that they were also rather atypical in their clinical presentation; in fact, most cases did not meet the accepted clinical diagnostic criteria for probable CJD.

Direct experimental evidence that vCJD is caused by BSE was provided by molecular analysis of human prion strains and transmission studies in transgenic and wild-type mice (see Aetiology, p. 414), with the most likely explanation being exposure to specified bovine offal (notably CNS tissues) prior to the ban on its inclusion in human foodstuffs in 1989. While it is now clear that vCJD is caused by infection with BSE prions, it is unclear why this particular age group should be predominantly affected.

vCJD has an insidious clinical onset, and its early features are highly non-specific. The clinical presentation is often with behavioural and psychiatric disturbance, commonly depression, but also anxiety, social withdrawal, and behavioural change, complex unsustained delusions, and visual and auditory hallucinations. Initial referral is consequently often to a psychiatrist. Persistent limb or face dysaesthesiae and pain are also prominent early features. In most cases, neurological features are not apparent until some months into the clinical course, whereby a progressive cerebellar syndrome develops with gait and limb ataxia. Overt dementia then occurs, with inevitable progression to akinetic mutism. Myoclonus is seen in most patients, and chorea is often present, which may be severe in some patients. The age at onset ranges from 12 to 74 years, with a mean of around 28 years. Clinical course is usually prolonged, compared to sCJD (9–35 months, median 14 months).

The EEG is abnormal, most frequently showing generalized slow wave activity, but without the pseudoperiodic pattern seen in sCJD cases. CSF 14-3-3 protein may be elevated or normal. Neuroimaging by CT is either normal or shows only mild atrophy. The most useful non-invasive investigation in advanced cases is magnetic resonance neuroimaging, in which FLAIR hyperintensity has been demonstrated in the pulvinar nuclei of the thalamus, designated the 'pulvinar sign', in 91% of vCJD cases [33]. The pulvinar sign is not exclusive to vCJD but can also be seen in sCJD, paraneoplastic limbic encephalitis, idiopathic intracranial hypertension, status epilepticus associated with cat-scratch disease, Alper's disease, and post-infectious encephalitis. The absence of the pulvinar sign does not exclude a diagnosis of vCJD, and in fact, the MRI in older patients with histologically confirmed vCJD seems less likely to possess the pulvinar sign [34]. Remarkably, up until early 2016, all definite cases of vCJD have been of the *PRNP* codon 129 MM genotype; a case of vCJD in an individual who is *PRNP* codon 129 MV was previously described, but the first case of pathologically confirmed vCJD in whom the *PRNP* codon 129 genotype was MV was reported in 2017 [35]. MRI features in this case were reminiscent of sCJD; the pulvinar sign was absent. Crucially, this patient did not fulfil diagnostic criteria for probable or possible vCJD in life.

Tonsillar biopsy is a sensitive and specific diagnostic procedure for vCJD and obviates the need for brain biopsy, based on the presence of prion replication in lymphoreticular tissue prior to neurological onset [36–39]. Tonsillar PrP^{Sc} is uniformly present in clinically affected cases of vCJD, but not in other forms of prion disease. Prior to tonsil biopsy, *PRNP* analysis is essential to rule out pathogenic mutations, which may clinically mimic vCJD.

Several biofluid-based techniques have been in development for diagnostic use in vCJD. The blood-based direct detection assay (DDA) exploits the steel binding affinity of prions with a capture matrix, coupled with immunodetection; this had a sensitivity of 71% and a specificity of 100% and is available at the UK National Prion Clinic [40]. More recently, the protein misfolding cyclic amplification (PMCA) assay, which is analogous to the RT-QuIC technique but uses repetitive cycles of sonication, instead of shaking and western blot as a readout, has been adapted with success for historical vCJD blood and urine samples. The sensitivities and specificities achieved were between 90% and 100%, but neither has yet been applied in routine clinical practice or for screening purposes [41–43].

The neuropathological appearances of vCJD are striking and relatively consistent. While there is widespread spongiform change and gliosis and neuronal loss, most severe in the basal ganglia and thalamus, the most remarkable feature is abundant ‘florid’ PrP amyloid plaques (in which the plaques are surrounded by vacuoles) in the cerebral and cerebellar cortices. Western blot analysis of brain tissue demonstrates PrP^{Sc} type 4, which is pathognomonic of vCJD.

Important lessons predicting the evolution of vCJD epidemiology can be drawn from kuru research and large-scale studies of archived appendix tissue in the UK. Firstly, kuru studies highlighted the profound effect of *PRNP* codon 129 genotype on incubation period with individuals who are 129 MV, having incubation periods which can exceed 50 years [5]; a similar effect of codon 129 genotype on incubation period is also seen in iatrogenic CJD cases secondary to human cadaveric growth hormone [44]. Secondly, screening of archived appendix studies led to estimates that approximately 1 in 2000 of the UK population carry subclinical vCJD infection [45]. While numbers of vCJD cases have steadily fallen since their peak in 2000, it is possible that a second wave of cases may occur in 129 MV individuals. Furthermore, given the atypical clinical features of the MV vCJD case and results from animal modelling studies (see Aetiology, p. 414), assiduous autopsy surveillance may be required to establish the true extent of BSE-related human prion disease, some of which might present as sCJD.

Secondary (iatrogenic) vCJD

The prominent lymphoreticular involvement raised early concerns that vCJD may be transmissible by blood transfusion. Indeed the tissue distribution is similar to that of ovine scrapie where prionemia has been demonstrated experimentally. In 2004, two transfusion-associated cases of vCJD prion infection were reported among a small cohort of patients identified as having received blood from a donor who subsequently developed vCJD. One patient had a typical clinical course of vCJD, although the diagnosis was not made until autopsy, and had the *PRNP* codon 129 MM genotype. The second, who died of an unrelated condition, was found to have prion infection at autopsy. This patient had the *PRNP* codon 129 MV genotype, which is associated with relative resistance to prion disease. Subsequently, two further patients have been diagnosed with vCJD during life from this group of 23 known surviving recipients of implicated blood. That four of 23 patients have been infected, three dying of vCJD, in each case following transfusion with a single unit of implicated red cells, suggests the risk to recipients of blood from a silently infected donor is substantial. The incubation period in the clinical cases was 6–7 years. Since 2003, all known recipients of implicated blood have been notified of their status. Over 6000

individuals in the UK have been exposed to blood products prepared from large donor pools containing blood from a donor who went on to develop vCJD. None of these individuals, predominantly haemophiliacs, have yet developed vCJD.

Inherited prion diseases

Approximately 10–15% of human prion disease cases are inherited in an autosomal dominant fashion. Over 40 pathogenic mutations are reported in the human PrP gene (Fig. 42.2) and consist of: (1) point mutations within the coding sequence, resulting in amino acid substitutions in PrP or the production of a stop codon resulting in the expression of a truncated PrP; (2) insertions encoding additional integral copies of an octapeptide repeat present in a tandem array of five copies in the normal protein [octapeptide repeat insertion (OPRI)]; and (3) insertions or deletions resulting in a frameshift mutation. Some reportedly pathogenic mutations may, in fact, represent benign or risk-conferring polymorphisms [46].

Phenotypes can be widely variable, even within kindreds; hence, *PRNP* analysis should be considered in all early-onset dementing or ataxic disorders and is available from the UK National Prion Clinic (see Further information, p. 421). Brief details of the more commonly seen types are given in the following sections. For a more comprehensive review, see reference [47].

P102L (commonly presenting as Gerstmann-Sträussler-Scheinker syndrome)

This is the most common mutation seen in the UK, usually presenting as GSS, as originally described in 1936 in a family, prior to the discovery of *PRNP* mutations [48]. Progressive ataxia is the dominant clinical feature, with dementia, pyramidal features, and lower limb dysaesthesiae occurring later. The mean age of onset is 49 years (range 25–70), and the mean clinical duration 4 years. Rarely, the clinical course is shorter and can closely mimic sCJD.

Octapeptide repeat insertion mutations

The first PrP mutation reported was a 6-OPRI mutation, found in a small UK family with familial CJD [7], now known to form part of the largest known kindred with an inherited prion disease caused by an OPRI mutation. Kindreds segregating for pathogenic mutations encompassing 4–9 and 12-OPRI mutations are described (see, for example, [49–52]). Insertions of 1–3 OPRI repeats have been rarely reported, often with clinical and neuropathological features indistinguishable from sCJD [53]; it remains to be seen whether these reflect true pathogenic mutations or benign polymorphisms in the context of sporadic disease.

The 6-OPRI mutation is the most commonly seen in the UK; the initial presentation is usually of cortical cognitive deficits such as apraxia, acalculia, language impairment, frontal dysexecutive features, and episodic memory loss. Physically, there is a varying combination of cerebellar ataxia and dysarthria, pyramidal signs, myoclonus, and occasionally extra-pyramidal signs, chorea, and seizures. A well-described behavioural prodrome can include personality disorder, aggression, hypersexuality, and impulsivity, often manifesting in childhood or long before any overt neurodegenerative syndrome; patients are frequently in contact with the criminal justice system prior to diagnosis [54]. The mean age of onset is 34 years

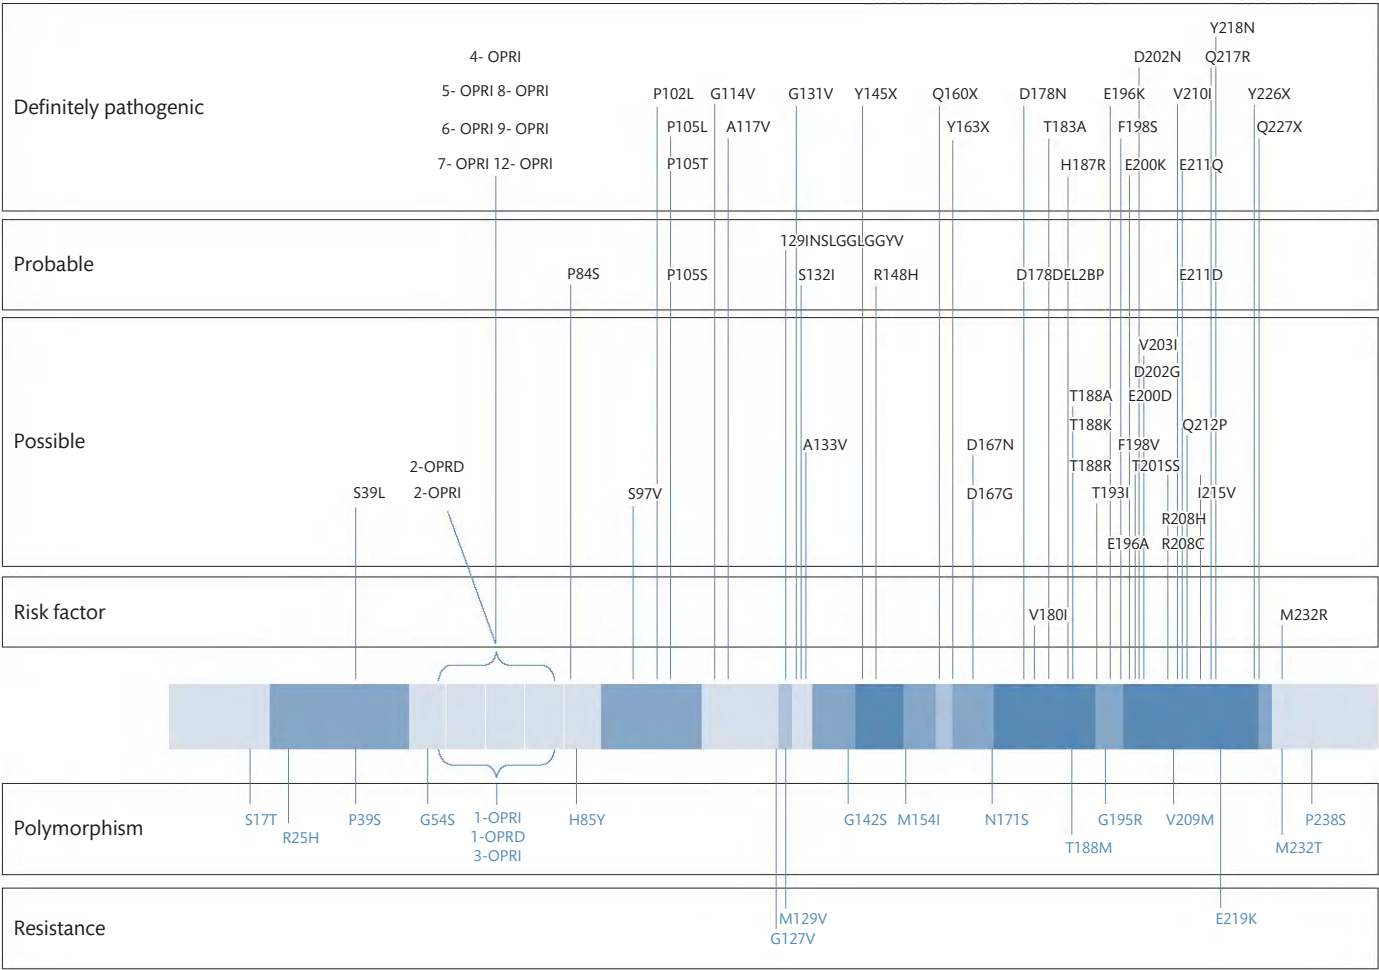

Fig. 42.2 Pathogenic mutations (above) and polymorphic variants of the human prion protein gene.

(range 20–53), with a mean clinical duration of 8–10 years. Codon 129 heterozygotes have an age of onset of approximately 10 years later than homozygotes [51].

A117V

This mutation has been described in families from France, the United States, and the UK [55]. The clinical features are of progressive cortical dementia that can often present as expressive language dysfunction. There is associated Parkinsonism, which may predominate in the early stages and mimic Parkinson’s disease. Pyramidal signs, pseudobulbar features, and cerebellar ataxia are also seen. The mean age of onset is 39 years, and the mean clinical duration of around 4 years.

D178N (fatal familial insomnia)

The D178N mutation has been documented widely in kindreds throughout Europe [56, 57], and the clinical phenotype is modified by the codon 129 status of the mutant allele. When the mutation is encoded on a methionine 129 allele, the clinical picture is usually of fatal familial insomnia (FFI); the cardinal feature is insomnia, often with a preceding period of inattentiveness. There may be initially compensatory daytime somnolence that masks early symptoms. Autonomic features invariably develop, including hypertension, excessive salivation, hyperhidrosis, diurnal pyrexia, and impotence.

Hallucinations are a frequent feature, and with progression, there is ataxia, dementia, and myoclonus. The mean age of onset is 50 years (range 20–72). When the codon 178 mutation occurs on a valine 129 allele, the clinical picture closely mimics sCJD [58], as do MRI diffusion-weighted imaging sequence appearances, albeit with a more prolonged course of about 15 months.

E200K

This mutation is the most common cause of inherited prion disease worldwide, particularly in closely segregated communities, for example in Chile and Slovakia, and among Sephardic Jews in Libya and Israel [59, 60]. The clinical picture and imaging findings are indistinguishable from sCJD, although there is often peripheral neuropathy, and seizures are more frequently seen. The mean age at onset is a little earlier than in sCJD, at around 61 years, but there is a wide range of 31–78 years in the UK. The clinical duration is, on average, 5 months.

Y163X (PrP systemic amyloidosis)

First described in 2013 in a large family from the south of England, this truncation mutation usually manifests in the fourth decade with insidious diarrhoea, nausea, autonomic disturbance, neurogenic bladder, and recurrent urinary infections, followed much later by length-dependent axonal neuropathy and cognitive decline. The clinical course is progressive over approximately 20 years, and

pathology is remarkable for the extent of peripheral prion amyloid deposition, primarily in the gut, in addition to the CNS [61].

Pre-symptomatic and antenatal testing

Direct gene testing allows unequivocal diagnosis in patients with inherited forms of the disease and pre-symptomatic testing of unaffected, but at-risk, family members, as well as antenatal testing after appropriate genetic counselling. Pre-implantation genetic diagnosis and transfer of unaffected embryos via *in vitro* fertilization (IVF) were successfully used to remove the risk of inherited prion disease in the offspring of a parent carrying the F198S mutation in the United States [62].

Because age of clinical onset in some mutations is affected by *PRNP* codon 129 genotype, it is often possible to determine within a family whether a carrier of a mutation will have an early or late onset of disease. However, biomarkers indicating a more specific age of onset are sorely needed and are the focus of determined investigation.

Most of the common mutations appear to be fully penetrant; however, experience with some is extremely limited. In some families, for example with E200K or D178N (FFI), there are examples of elderly unaffected gene carriers who appear to have escaped the disease; the wide age of onset may indicate complete penetrance at a very advanced age, which may not be practically relevant for many patients. Recent work comparing the expected incidence of clinical disease with the frequency of reportedly pathogenic mutations in large control populations suggests the penetrance of several to be 10% or lower; at this level, they may be better classified as risk-conferring variants [46], with important implications for genetic counselling discussions.

Genetic counselling is essential prior to pre-symptomatic testing. A positive PrP gene analysis has important consequences for other family members, and it is preferable to have discussed these issues with others in the immediate family before testing. Following the identification of a mutation, the wider family should be referred for genetic counselling. It is vital to counsel both those testing positive for mutations and those untested but at-risk that they should not be blood or organ donors and should inform surgeons, including dentists, of their risk status prior to significant procedures, as precautions may be necessary to minimize the risk of iatrogenic transmission.

Treatment

All recognized prion diseases are invariably fatal, following a progressive course. There have been few robust therapeutic trials in human prion disease. These are challenging due to the combination of difficulty recruiting adequate patient numbers, a paucity of validated outcome measures beyond mortality, and widely variable disease patterns in the absence of longitudinal natural history data. Many of these barriers to meaningful controlled clinical trials have now been largely overcome [63, 64].

A double-blind RCT of flupirtine, a non-opioid analgesic, suggested some benefit in cognitive scores, but not mortality, albeit in a small sample size and with borderline statistical significance [65]. A patient preference trial (PRION-1) of quinacrine, an anti-malarial agent, in 107 patients with prion disease did not significantly alter

the disease course [66]. A more recent randomized, double-blind, placebo-controlled trial of doxycycline, an antibiotic with positive reports in previous observational studies, similarly did not show any effect on disease progression or mortality [67]. The effects of a variety of other agents have been reported anecdotally or in small case series, including pentosan polysulfate, a glycosaminoglycan administered to a handful of patients with vCJD, with anecdotal reports of some longer disease courses [68].

More recently, many groups have turned their attention to targeting the PrP itself; interference with PrP^C expression in the adult brain is without serious effect and blocks the onset of neurological disease in animal models [69]. Anti-PrP monoclonal antibodies, or small molecules that interfere with the conversion of PrP^C to PrP^{Sc}, appear to slow or arrest the disease course in mouse models of CJD if given prophylactically, during the incubation period [70]. They represent a promising therapeutic avenue in humanized form. New methods for early diagnosis—and their timely use—will therefore be vital, as arresting prion propagation will not reverse neuronal cell loss, which may be considerable by the time a clinical diagnosis is typically reached.

Symptom management is crucial and, for specific indications, can be highly effective. Myoclonus is generally of cortical origin and responds well to levetiracetam, or a benzodiazepine (commonly clonazepam), or sodium valproate at normal therapeutic doses. Visual hallucinations can be managed with a centrally acting anticholinesterase such as donepezil, and aggression or agitation with a dopamine antagonist, such as risperidone or quetiapine, or benzodiazepines; extra-pyramidal symptoms are common in prion disease, and the risk of these should be taken into account when prescribing (see Chapter 64 for details).

Patients and their families require early and consistent support, given the likely rapid pace of clinical change and the variety of functional deficits in cognition, mobility, toileting, and behaviour. Good community or residential nursing care is essential, and the involvement of a palliative care team is often of great benefit. Supportive medical therapies, such as parenteral nutrition, may prolong survival, with no appreciable improvement in quality of life.

Dementia with Lewy bodies

Anto P. Rajkumar and Dag Aarsland

Introduction

Dementia with Lewy bodies (DLB) is the second most common neurodegenerative dementia [1]. Lewy bodies are abnormal aggregates of several proteins that form eosinophilic spherical neuronal intracytoplasmic inclusions. Lewy bodies are found in the cerebral cortex, brainstem, various subcortical structures, and peripheral nervous system. Clinical manifestations of DLB include cognitive impairment, extra-pyramidal symptoms, neuropsychiatric symptoms, and autonomic dysfunction.

DLB has been known by other names, which include diffuse Lewy body disease, Lewy body dementia, dementia associated with cortical Lewy bodies, senile dementia of Lewy body type, and the Lewy body variant of Alzheimer's disease [2]. The current consensus is that 'Lewy body dementia' term includes DLB and Parkinson's disease dementia (PDD) [3]. DLB and PDD are clinically differentiated only by the timing of onset of dementia and Parkinson's disease (PD), using an arbitrary 1-year rule. PDD starts at least 1 year after well-established PD, but people with DLB develop dementia before, concurrently, or within 1 year of onset of Parkinsonism. Some people with DLB never develop Parkinsonism. Once both dementia and Parkinsonism are well established, DLB and PDD seldom differ clinically. As increasing evidence suggests common pathophysiological processes underlying the two disorders [3], DLB and PDD can also be viewed together as a single nosological continuum [4]. However, this chapter focuses only on DLB, and Chapter 44 presents PDD in detail.

Brief history

Fritz Heinrich Lewy, later known as Frederic Henry Lewey, first reported eosinophilic intracytoplasmic inclusions in 1912, while he was studying the neuropathology of PD in the team of Alois Alzheimer at Munich University. He observed the inclusions in the dorsal vagal nuclei and substantia innominata of people with PD, but he concluded that the inclusion bodies are not pathognomonic of PD [5]. Konstantin Tretiakoff, a Russian neuropathologist, coined the term 'Corps de Lewy' (Lewy bodies) and presented it as one of the major hallmarks of PD pathology in 1919. Lewy also observed swellings of axon cylinders of the neurons with the inclusions, and

they were called 'Lewy neurites' later. The interest in Lewy bodies was renewed in 1960 when Bethlem and Den Hartog Jager diligently documented the distribution of Lewy bodies in the central and autonomic nervous systems. Later, Haruo Okazaki reported in 1961 autopsies of two people with progressive dementia and rigidity, who had widely disseminated Lewy bodies in their cerebral cortex.

Over the next two decades, Kenji Kosaka and other researchers from Japan reported autopsies of more than 20 people, who clinically presented with varying degrees of extra-pyramidal symptoms, cognitive impairment, and neuropsychiatric symptoms and had variable distribution of Lewy bodies in their brainstem and cerebral cortex. They proposed the term 'Lewy body disease' in 1980 and classified it into brainstem, transitional, and diffuse types. Yoshimura reported more autopsies of people with the diffuse type and proposed the term 'diffuse Lewy body disease' in 1983 [6]. Hansen and Perry reported more autopsies from North America and Europe, respectively, in 1990. Their studies have confirmed that diffuse Lewy body disease is not rare and that at least 15–20% of older people with dementia have Lewy bodies. Later, more autopsies that found Lewy bodies almost exclusively in the cerebral cortex were reported. The first international workshop on DLB was held in Newcastle in the UK in 1995, and the consensus guidelines for the clinical and pathological diagnosis of DLB were published in 1996. Maria Spillantini identified the major component of Lewy bodies as α -synuclein in 1997. The Third International Workshop on DLB was held in 2003, and the revised consensus diagnostic guidelines for DLB were published in 2005. The fourth consensus report of the DLB Consortium and the revised criteria for the clinical diagnosis of DLB was published in 2017. Studies investigating the epidemiology, pathophysiology, clinical diagnosis, and management of DLB have been exponentially increasing over the past two decades, and this chapter attempts to provide a brief overview of this expanding knowledge base.

Epidemiology

Robust data on the prevalence and incidence of DLB remain sparse. However, DLB is no longer considered to be a rare disorder, and its prevalence is second only to Alzheimer's dementia (AD) among older adults with neurodegenerative dementia. A recent systematic review, including 22 studies that investigated the prevalence and/or

incidence of DLB, has reported that the incidence rates ranged from 0.5 to 1.6 per 1000 person-years among the community-dwelling older adults aged 65 years and above [7]. 3.2–7.1% of all incident dementias are due to DLB. The incidence of DLB is nearly twice more common in men than in women. The prevalence of DLB has been reported from 0.02 to 0.06 per 1000 adults younger than 65 years of age, and from 0.3 to 6.5 per 1000 older adults aged 65 and above. Studies that included only people older than 70 years have reported the prevalence of DLB as from 8.6 to 33.3 per 1000 people, and one study that included only people older than 81 years has reported the prevalence as 63.5 per 1000 people. The mean prevalence of DLB is 4.2% in community studies, and it is 7.5% in clinical samples.

DLB remains underdiagnosed in many clinical settings, so the prevalence of DLB could be higher than the reported estimates [8, 9]. Studies including detailed neurological examinations, neuroimaging, and screening for rapid eye movement (REM) sleep behaviour disorder (RBD) have reported the prevalence of DLB as high as 24%. Advancing age, hypertension, dyslipidaemia, and a past history of depression and anxiety have been reported to increase the risk of DLB. People with DLB reportedly have poorer quality of life than those with AD. Quality of life in DLB has been directly associated with the independency in instrumental activities of daily living and inversely associated with neuropsychiatric symptoms, especially apathy and delusions [10]. People with DLB may utilize more health resources, and their costs of care are reportedly higher than those of people with AD [11].

Pathology

Neuropathology

Subcortical and cortical Lewy bodies differ in their appearance and immunohistochemical staining. Subcortical Lewy bodies have the characteristic appearance of dense eosinophilic cores, surrounded by concentric lamellar bands and pallid halos. They can be visualized by immunohistochemical staining for α -synuclein and ubiquitin. Cortical Lewy bodies do not have the surrounding halo. They can be visualized by immunohistochemical staining for ubiquitin, but less than one-third of cortical Lewy bodies can be detected by α -synuclein immunostaining [12]. Lewy neurites are abnormal neuronal projections, including aggregates of α -synuclein and other proteins. They are more extensively distributed in various cortical and subcortical regions than the Lewy bodies, and they can be visualized by immunohistochemical staining for α -synuclein and ubiquitin. They are believed to represent earlier stages of neurodegeneration and to lead to synaptic dysfunction when they are present in the presynaptic terminals.

It remains uncertain whether Lewy bodies play a neurotoxic or neuroprotective role [3]. Moreover, the relationship between cortical Lewy body burden and the clinical severity of DLB is not linear. However, a pathological classification system including three subtypes of DLB has been proposed on the basis of a semi-quantitative scoring system assessing the pattern of distribution of Lewy bodies and Lewy neurites. Brainstem-predominant DLB has Lewy pathology principally within the substantia nigra, dorsal nucleus of the vagus, and the locus caeruleus. Limbic or transitional DLB includes Lewy pathology in the anterior cingulate and transtentorial

cortices. The third subtype—neocortical or diffuse DLB—has disseminated Lewy pathology in the cerebral cortex, with or without involvement of the brainstem. Braak has introduced a pathological staging system for PD, and he has suggested caudorostral progression of Lewy pathology that starts from the brainstem and then spreads to the neocortex. Some people with DLB may follow the caudorostral progression of Lewy pathology, but many do not follow this kind of spread. Hence, the importance of Braak staging is limited to DLB, and an additional ‘cerebral’ subtype of DLB has been proposed.

Eighty to 90% of older adults with DLB have varying degrees of coexisting Alzheimer’s-like pathology. They often have diffuse β -amyloid plaques, but neocortical neurofibrillary tangles are less common in DLB. The neocortical type of DLB is more likely to have substantial coexisting Alzheimer’s-like pathology. Increasing evidence support that β -amyloid deposition also contributes to the pathology of DLB. Loss of cholinergic neurons in the basal nucleus of Meynert and decreased cortical choline acetyltransferase indicate that the deficits in cholinergic neurotransmission are common in DLB. Such deficits occur earlier and are more severe in DLB than in AD. Minor cerebrovascular lesions are found in around 30% of older adults with DLB, but their contribution to DLB pathology is uncertain. Depletion of dopaminergic neurons and deficits in GABA and serotonergic neurotransmission have been reported in older adults with DLB [1].

Neuroimaging

Neuroimaging of people with DLB not only helps to enhance our understanding of the underlying pathology, but also has direct clinical implications [13]. Structural neuroimaging in DLB with MRI often reveals diffuse, but relatively mild global, grey matter atrophy with relatively preserved medial temporal lobes, when compared to people with AD. However, if there is substantial coexisting Alzheimer’s-like pathology, medial temporal lobes may not be spared. The volume of the substantia innominata and putamen may be less in DLB than in AD. Atrophy in the temporal, occipital, and parietal lobes is often more pronounced in DLB than in PDD. Diffusion tensor imaging (DTI) studies have documented the loss of parieto-occipital white matter tracts in DLB, when compared with people without cognitive impairment [14]. Several studies have investigated DLB using magnetic resonance spectroscopy (MRS) [15]. They have documented reduced *N*-acetyl aspartate/creatine ratio in the centrum semiovale, occipital grey matter, and temporal lobes in DLB, when compared to healthy controls. Findings on choline/creatine ratios in DLB have been inconsistent. A recent study has reported that people with mild cognitive impairment (MCI) and lower *N*-acetyl aspartate/creatine ratio in their posterior cingulate cortex were significantly more likely to develop AD, but not DLB [16].

¹²³I-2 β -carbomethoxy-3 β -4-iodophenyl-*N*-3-fluoropropyl nortropane single-photon emission computed tomography (¹²³FP-CIT SPECT) can demonstrate low dopamine transporter uptake in the basal ganglia in people with DLB. This can distinguish DLB from AD, before one develops clinically observable extra-pyramidal symptoms. This has been evaluated in a multi-centre phase III trial, and it has been incorporated in the DLB Consortium revised criteria for the clinical diagnosis of DLB [17]. SPECT studies investigating regional cerebral blood flow by using radionuclides, such

as ^{99m}Tc hexamethylpropyleneamineoxime, have reported global cortical hypoperfusion in DLB, when compared to healthy controls, and occipital hypoperfusion in DLB, when compared to people with AD. PET studies using ^{18}F -fluorodeoxyglucose (FDG) have confirmed occipital hypometabolism in DLB, when compared to AD. An association between the frequency of visual hallucinations and occipital hypometabolism in DLB has been reported. Besides, metabolism in the posterior cingulate cortex is relatively preserved in DLB, when compared to AD, and this 'posterior cingulate island sign' can distinguish DLB from AD. Amyloid PET studies have documented variable degrees of cortical β -amyloid ligand binding in DLB. β -amyloid deposition is usually more in DLB, when compared to healthy controls and people with PDD, but it is relatively less than that in AD [18]. A recent tau PET study that employed ^{18}F -labelled AV-1451 ligand has demonstrated variable tau pathology, especially in the inferior temporal gyrus and precuneus, in people with DLB [19]. Cholinergic PET studies have reported reduced cortical and thalamic acetylcholinesterase activity in DLB. ^{123}I -metaiodobenzylguanidine (MIBG) scintigraphy can demonstrate the involvement of the autonomic nervous system in DLB. Reduced myocardial MIBG uptake due to the involvement of post-ganglionic cardiac sympathetic nerves can distinguish DLB from AD very accurately, and it has been recently included in the diagnostic criteria for DLB [20]. Fig. 43.1 presents representative coronal MRI, FDG PET, and ^{123}FP -CIT SPECT images in DLB and AD.

Molecular biology

Lewy bodies are complex structures, and they are made of at least 90 distinct molecules [21]. They comprise α -synuclein, α -synuclein binding proteins, such as tau, agrin, synphilin-1, 14-3-3, and microtubule-associated proteins, and synphilin-1 binding proteins such as parkin, dorfin, and glycogen synthase kinase-3 β . They include proteins from the ubiquitin proteasome system, such as ubiquitin, ubiquitin-activating enzyme, ubiquitin-conjugating enzyme, ubiquitin C-terminal hydrolase, ubiquitin ligase, proteasome, and proteasome activators, and from the autophagosome lysosome system such as glucocerebrosidase, LC3, GATE-16, and NBR1. Many aggresome-related proteins, such as γ -tubulin, HDAC6, and pericentrin, several cellular stress response proteins including heat-shock proteins, clusterin, glutathione peroxidase, heme oxygenase-1, αB -crystallin, and superoxide dismutase 1 and 2, and various protein phosphorylation and signal transduction proteins including calcium/calmodulin-dependent protein kinase II, cyclin-dependent kinase 5, G-protein coupled receptor kinase 5, leucine-rich repeat kinase 2 (LRRK2), and phospholipase C- δ , are found in Lewy bodies. Lewy bodies include mitochondria-related proteins, such as cox IV, cytochrome C, and PTEN-induced putative kinase 1 (PINK1), cell cycle proteins, such as cyclin B and retinoblastoma protein, and cytoskeletal proteins, such as neurofilament, and tubulin. Several cytosolic proteins, including amyloid precursor protein, calbindin, choline acetyltransferase, chromogranin A, synaptophysin, synaptotagmin, tyrosine hydroxylase, and vesicular monoamine transporter 2, immunoglobulins, and lipids are present in Lewy bodies [21].

It is widely accepted that aggregation of α -synuclein is the key initial step in the formation of Lewy bodies [12]. DLB, along with PD and multiple system atrophy, is recognized as a primary α -synucleinopathy. Made of 140 amino acids, α -synuclein normally

exists as an unfolded protein without a typical secondary structure or as a stable folded tetramer. It is principally localized in the presynaptic terminals of neurons. Molecular functions of α -synuclein remain uncertain, but they may include trafficking of synaptic vesicles, formation of SNARE complexes that mediate the fusion of vesicles with their target membranes, regulation of synaptic vesicle recycling, and regulation of presynaptic release of several neurotransmitters, including dopamine [22]. Presynaptic α -synuclein aggregation leads to synaptic dysfunction that may explain the neurodegeneration in DLB. Conformational changes and aggregatory properties of α -synuclein have been extensively investigated over the last decade. α -synuclein is susceptible to undergo various post-translational modifications, such as phosphorylation, ubiquitination, nitration, oxidation, and sumoylation [23]. Such post-translational modifications, binding with polyamines, and cross-linking by tissue transglutaminase promote oligomerization of α -synuclein; this leads to the formation of protofibrils and mature aggregates [24]. α -synuclein oligomers and protofibrils are neurotoxic. However, the formation of Lewy bodies with other proteins may protect the involved neurons and prolong their survival [12]. There are at least two more alternatively spliced isoforms of α -synuclein. α -synuclein that has 126 amino acids (α -synuclein 126) is less prone for aggregation, but α -synuclein that has 112 amino acids (α -synuclein 112) has increased propensity for aggregation [25].

α -synuclein oligomers can be released into the extracellular space either by exocytosis or by the formation of exosomes, which are 30–100 nm-sized extracellular vesicles [26]. Exosomes carry a complex cargo of proteins, lipids, and nucleic acids from the brain to the peripheral systems, and they lead to cell-to-cell transport of several biologically active molecules, including α -synuclein. An increasing number of cell culture, animal, and post-mortem studies have shown that exogenous α -synuclein can instigate Lewy pathology in the recipient cells, and the possibility of prion-like propagation of α -synuclein in DLB has been hypothesized [27]. Extracellular α -synuclein can activate neighbouring microglia and astrocytes. Possible mechanisms of microglial activation by α -synuclein, and consequent chronic neuroinflammation in DLB, have been studied over the past decade [28]. Activated microglia release pro-inflammatory cytokines, such as interleukin-1 β , interleukin-2, interleukin-6, and tumour necrosis factor- α , nitric oxide, and reactive oxygen molecules and trigger an apoptotic process of affected neurons [29]. Besides, the ubiquitin proteasome system and the autophagy lysosome pathway are the two most essential pathways that repair or degrade several abnormal neuronal proteins, including α -synuclein. Accumulating evidence suggests that these two pathways are dysfunctional in DLB and that such deficits lead to an increased release of extracellular α -synuclein and an uncontrolled propagation of associated pathology. β -glucocerebrosidase 1 (GCase), a lysosomal hydrolase, has received special attention recently [30]. Lysosomal dysfunction, secondary to GCase deficiency, may lead to misprocessing and aggregation of α -synuclein [31]. GCase deficiency also contributes to mitochondrial dysfunction [32], and other mitochondria-related proteins, such as parkin and PINK1, are involved in the pathology of DLB. Mitochondrial energy metabolism dysfunction increases the vulnerability of neurons to oxidative damage [33], and α -synuclein pathology can directly damage mitochondria [34].

Genetics

Although DLB is mostly sporadic, there is evidence for familial aggregation of DLB [35]. A genome-wide linkage study in an autosomal dominant family with autopsy confirmed DLB has mapped the chromosomal locus for DLB at 2q35–q36 [36]. *SNCA* codes for α -synuclein, and *SNCA* triplications and missense mutations have been associated with DLB [37]. *GBA* (glucosylceramidase beta) encodes GCase, and the genetic associations between DLB and polymorphisms in *GBA* have been replicated by several studies [38–40]. A large multi-centre study has reported that pathogenic

GBA mutations increase the risk of DLB by more than eight times and that they are associated with an earlier age of onset of DLB and disease severity [39]. A recent study has found that the pathogenic *GBA* mutation carriers have significantly less GCase activity in their brain [41]. Another large study that investigated 788 people with DLB and 2624 controls has reported false-discovery adjusted statistically significant genetic associations of DLB with *APOE*, *SNCA*, and *SCARB2* (scavenger receptor class B member 2) [42]. Along with *GBA* and *SCARB2* mutations that lead to lysosomal dysfunction, two more lysosome-related genes *SMPD1* and *MCOLN1* have

been associated with Lewy pathology [41]. Available evidence suggests that *APOE* $\epsilon 4$ allele increases the risk of DLB and that *APOE* $\epsilon 2$ allele reduces the risk and delays the onset of DLB by 4 years [43]. Evidence supporting the associations between DLB and other AD-related genes, such as *APP* and *PSEN1*, are weak [37]. The first genome-wide association study (GWAS) investigating DLB was published in January 2018. It estimated 36% heritability of DLB, and it confirmed the associations between DLB and variants in *APOE*, *SNCA*, and *GBA* [43a].

Gene expression studies in DLB have confirmed the importance of alternative splicing of α -synuclein and the differential expression of the isoforms. Increased expression of α -synuclein 112 and decreased expression of α -synuclein 126 in post-mortem frontal cortical samples from people with DLB have been reported [25]. A study investigating the expression of all small ribonucleic acids (RNAs) in post-mortem temporal cortical samples of people with DLB did not find any differentially expressed small RNA. However, another study that investigated post-mortem anterior cingulate cortical samples from people with DLB using next-generation RNA sequencing technology has documented 490 differentially expressed genes, including many downregulated genes, which are implicated in neurogenesis, myelination, and regulation of nervous system development [44]. Another study that investigated the primary visual cortex post-mortem, using gene expression microarrays, has reported that several genes, associated with GABAergic neurotransmission, were differentially expressed in people with DLB who experienced recurrent complex visual hallucinations. Lower levels of DNA methylation in the *SCNA* intron 1 has been found in the peripheral leucocytes of people with DLB, but studies evaluating the epigenetics of DLB remain sparse [45].

Other biological correlates

Theta and delta wave activity and frequency variation in EEG, especially in the posterior leads, are more frequent in DLB than in AD and PDD [46]. Quantitative EEG may predict conversion of MCI to DLB accurately. RBD is a core clinical feature of DLB. Video polysomnographic investigation of people with DLB has revealed increased sleep latency, reduced sleep efficiency, and altered non-REM sleep architecture. Several studies have investigated potential biomarkers of DLB in the CSF for helping an early and accurate clinical diagnosis, as well as for monitoring prognosis and treatment effectiveness [47]. A meta-analysis including 13 studies and 2728 people has established that α -synuclein concentration in the CSF is significantly lower in DLB than in AD [48]. Akin to AD, CSF β -amyloid 1-42 concentration is often reduced in DLB and has been shown to predict a more rapid cognitive decline in DLB [49]. However, CSF tau and phosphorylated tau concentrations are less in DLB than in AD. The oxidized form of β -amyloid 1-40 in the CSF is higher in DLB than in PDD and healthy controls. CSF levels of homovanillic acid, 5-hydroxyindoleacetic acid, 3-methoxy-4-hydroxy phenylethyleneglycol levels, and neurosin, as well as cocaine and amphetamine-regulated transcript, have been reported to be less in DLB than in AD. Other CSF studies have reported elevated levels of neurofilaments, calcium, and magnesium, as well as reduced levels of soluble neuron glia 2 in DLB [47]. Studies evaluating potential biomarkers of DLB in other biological fluids remain sparse. Unlike AD, serum fatty acid-binding protein levels are elevated in DLB. Preliminary evidence suggests elevated serum

magnesium levels in DLB. Although Lewy pathology often involves minor salivary glands, reliable salivary biomarkers for DLB have not been found so far.

Diagnosis

Although a definite diagnosis of DLB can be confirmed only by neuropathological verification, a probable or possible diagnosis of DLB can be made clinically. DLB is currently diagnosed by using either the DLB Consortium revised criteria for the clinical diagnosis of DLB [50] or the DSM-5 diagnostic criteria for major neurocognitive disorder with Lewy bodies. ICD-10 does not include specific diagnostic criteria for DLB.

The DLB consortium criteria

DLB diagnoses are missed more often than not in clinical settings when standard diagnostic criteria are not used routinely. A large study that evaluated the accuracy of clinical diagnoses of DLB, in comparison with autopsy findings, has reported 95% specificity, but only 32% sensitivity [51]. The third DLB Consortium revised criteria for the clinical diagnosis of DLB have been reported to increase the clinical diagnoses of probable DLB by nearly 24%. [Table 43.1](#) presents the current revised criteria for the clinical diagnosis of probable and possible DLB [50]. Meeting the general criteria for dementia is essential for the diagnosis of possible or probable DLB. Two of the four core clinical features (fluctuating cognition, recurrent visual hallucinations, RBD and spontaneous Parkinsonism) are sufficient for a diagnosis of probable DLB, and only one of them is sufficient for a diagnosis of possible DLB. If one or more of the indicative biomarkers is present in the presence of one or more core clinical features, probable DLB can be diagnosed. A diagnosis of probable DLB cannot be made on the basis of indicative biomarkers alone. In the absence of any core clinical features, one or more indicative biomarkers are sufficient for a diagnosis of possible DLB. Possible DLB is an unstable diagnosis, and some develop probable DLB, whereas others develop AD or other diseases. The revised criteria list supportive clinical features and supportive biomarkers that are commonly present in DLB, but their diagnostic specificity are uncertain. Hence, these supportive features do not have any diagnostic weighting. There are ongoing endeavours to improve the sensitivity of the criteria without compromising their specificity.

DSM-5 diagnostic criteria

As the term 'dementia' is replaced by the term 'major neurocognitive disorder' in DSM-5, DLB is called 'major neurocognitive disorder with Lewy bodies' (NCDLB). The DSM-5 diagnostic criteria for probable and possible major NCDLB mirrors the 2005 version of third DLB Consortium revised criteria for the clinical diagnosis of DLB, but there are a few differences between the two. Three core features (fluctuating cognition, recurrent visual hallucinations, and spontaneous Parkinsonism) are included, and RBD and severe neuroleptic sensitivity are mentioned as two suggestive features in DSM-5. The neuroimaging biomarker demonstrating low dopamine transporter uptake in the basal ganglia is not included in DSM-5, and this may compromise the sensitivity of the criteria further. At least two core features or one core feature with one or two suggestive features

Table 43.1 The DLB Consortium revised criteria for the clinical diagnosis of probable and possible DLB

Feature of DLB	Criteria
Essential feature	Dementia that is defined by progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Prominent or persistent memory impairment may not occur in the early stages but is usually evident with progression. Deficits on tests of attention, executive function, and visuo-spatial ability may be especially prominent
Core clinical features	<ol style="list-style-type: none"> 1. Fluctuating cognition with pronounced variations in attention and alertness 2. Recurrent visual hallucinations that are typically well formed and detailed 3. Spontaneous features of Parkinsonism 4. REM sleep behaviour disorder that may precede cognitive decline
Supportive clinical features	Severe sensitivity to antipsychotic agents, postural instability, repeated falls, syncope or other transient episodes of unresponsiveness, severe autonomic dysfunction, hypersomnia, hyposmia, hallucinations in other modalities, systematized delusions, apathy, anxiety, and depression
Indicative biomarkers	<ol style="list-style-type: none"> 1. Reduced dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET 2. Abnormal (low uptake) ¹²³Iodine-MIBG myocardial scintigraphy 3. Polysomnographic confirmation of REM sleep without atonia
Supportive biomarkers	<ol style="list-style-type: none"> 1. Relative preservation of medial temporal lobe structures on CT/MRI 2. Generalized low uptake on SPECT/PET perfusion/metabolism scan with reduced occipital activity with or without the cingulate island sign on FDG-PET imaging 3. Prominent posterior slow-wave activity on EEG with periodic fluctuations in the pre-alpha/theta range
A diagnosis of DLB is less likely	<ol style="list-style-type: none"> 1. In the presence of a physical illness or brain disorder including cerebrovascular disease sufficient to account in part or in total for the clinical picture 2. If Parkinsonism only appears for the first time at a stage of severe dementia
Temporal sequence of symptoms	DLB should be diagnosed when dementia occurs before or concurrently with Parkinsonism. The term PDD should be used to describe dementia that occurs in the context of well-established Parkinson's disease. In clinical settings, the term that is most appropriate to the clinical situation should be used, and generic terms such as Lewy body disease are often helpful. In research studies in which distinction needs to be made between DLB and PDD, the existing 1-year rule between the onset of dementia and Parkinsonism for DLB continues to be recommended

Adapted from Neurology, 89(1), McKeith IG, Bradley F, Boeve BF, et al., Diagnosis and management of dementia with Lewy bodies: fourth consensus report of the DLB Consortium, pp. 88-100. Copyright (2017), with permission from American Academy of Neurology

are needed to diagnose probable major NCDLB. Only one core feature or one or two suggestive features are needed to diagnose possible major NCDLB. Besides, there is no consensus on the definition of prodromal or pre-dementia phase of DLB, but DSM-5 has introduced probable and possible mild neurocognitive disorder with Lewy bodies. Nosological validity of these two diagnostic categories remains uncertain. DSM-5 has also provided further coding for major NCDLB with or without behavioural disturbance. However, DSM-5 does not include a list of supportive features of NCDLB but mentions many supportive features as 'diagnostic markers' with uncertain diagnostic weighting.

Clinical presentation

As the initial clinical presentation of DLB varies widely, people with DLB may first present to primary care, psychiatric, neurology, internal medicine, or emergency services. DLB may initially present with memory impairment, impairment of other cognitive functions, visual hallucinations, psychosis, depression, fall, syncope, loss of consciousness, acute confusion, sleep disorders, autonomic dysfunction, or extra-pyramidal symptoms. Such heterogeneous clinical presentation contributes to the underdiagnosis of DLB in clinical settings. DLB is not clinically diagnosed, until people develop cognitive impairments that are severe enough to interfere with their functions. People with DLB have varying degrees of cortical and subcortical neuropsychological deficits. People with DLB often have greater impairment of their attention, visuo-spatial skills, and executive functions than people with AD [52]. DLB usually presents with recurrent episodes of confusional states on

a background of progressive cognitive deterioration. Fluctuating cognition with pronounced variations in attention and alertness is a core feature of DLB. Fluctuating cognition is present in 50–75% of people with DLB but is difficult to elicit reliably in the clinical setting. Scales, such as clinician assessment of fluctuation, the one-day fluctuation assessment scale, the Mayo fluctuations composite scale, and the dementia cognitive fluctuation scale, may help, but they need further validation and they are seldom used routinely. Visuo-spatial impairment occurs more frequently and earlier in DLB than in AD. Executive function deficits in DLB include impairments in cognitive flexibility, planning, abstraction, conceptualization, judgement, self-monitoring, and reinforcement learning. Episodic memory and verbal memory impairments are often less severe in DLB than in AD. Recognition of information is better preserved than recall in DLB, and this indicates impaired retrieval mechanisms in DLB.

Spontaneous Parkinsonism may occur in 60–92% of people with DLB [53], and 25–50% of people with DLB may have them at the time of their diagnoses. Missing the clinical diagnosis of DLB is more likely in those lacking clinically observable extra-pyramidal symptoms. Detailed neurological examination and scales, such as the unified PD rating scale, facilitate the detection of extra-pyramidal symptoms in DLB. Extra-pyramidal symptoms in DLB often include bilaterally symmetrical limb rigidity, symmetrical postural tremor, bradykinesia, facial impassivity, axial rigidity, and shuffling gait. Prominent tremors, asymmetrical resting tremors, and asymmetrical limb rigidity are less common in DLB [2]. ¹²³FP-CIT SPECT and PET neuroimaging can demonstrate reduced dopamine transporter uptake in the basal ganglia, before the occurrence of clinically observable extra-pyramidal symptoms. A meta-analysis including

four studies and 419 people has reported that $^{123}\text{FP-CIT}$ SPECT has 86.5% sensitivity and 93.6% specificity to diagnose DLB [54]. $^{123}\text{FP-CIT}$ SPECT is not necessary once Parkinsonism is well established clinically. Missing a clinical diagnosis of DLB and the presence of associated psychotic symptoms often set the stage for revealing severe sensitivity to dopamine antagonist drugs in DLB. Challenge with a dopamine antagonist must not be used for the diagnosis of DLB, because of the associated risks.

Almost 85% of people with DLB experience recurrent complex visual hallucinations that usually feature people, children, and animals [53]. The images are often vivid, colourful, well formed, three-dimensional, and mute. Visuoperceptual deficits predispose people with DLB to experience visual hallucinations [55]. A combination of faulty perception of environmental stimuli, impaired recollection of prior experience, and intact generation of images may lead to visual hallucinations. Studies that evaluated the neurocognitive processes underlying visual hallucinations in DLB have proposed a disconnection between the prefrontal cortex and the visual cortex, as well as improper activation of the inferior temporal cortex [56]. Hallucinations involving other modalities are less common. People with DLB may have other neuropsychiatric symptoms, including apathy, paranoid delusions, depression, anxiety, and aggression [57]. Besides, RBD is a parasomnia that presents with a lack of motor inhibition during REM sleep, leading to potentially harmful simple or complex dream-enacting vocalizations and motor behaviours. Although a formal diagnosis of RBD can be confirmed only by polysomnography, diligent history taking and standardized questionnaires, such as the Mayo sleep questionnaire, can elicit RBD reliably in clinical settings. The prevalence of RBD among people with DLB has been suggested to be as high as 77%, and RBD often precedes the onset of DLB by several years. Additionally, autonomic dysfunction, including orthostatic hypotension, and carotid sinus hypersensitivity are common in DLB, and they may lead to constipation, urinary incontinence, syncope, and falls.

Differential diagnosis

Differentiating DLB from other conditions with overlapping clinical presentations is essential for accurate diagnosis and appropriate management, and for minimizing the use of dopamine antagonists. Differential diagnosis of DLB include AD, PDD, vascular dementia, fronto-temporal dementia, other dementias, delirium, PD, adverse effects of anti-parkinsonian medications, progressive supranuclear palsy, multiple system atrophy, cortico-basal degeneration, other neurodegenerative diseases, prion diseases, complex partial seizures, late-onset psychosis, and psychotic depression. Diligent history taking, neurological examination, neuropsychological assessments, neuroimaging, EEG, and CSF biomarkers aid to clarify diagnostic dilemmas [53]. Fluctuating cognition and RBD are likely to be missed, unless specifically asked for, and eliciting them is vital for an accurate clinical diagnosis of DLB. If fluctuating cognition is the principal clinical presentation, a detailed systemic examination and investigations for potential causes for delirium should be carried out. Polypharmacy and associated adverse effects in older adults can mimic many clinical features of DLB. Hence, a comprehensive medication review is essential.

AD is the most common clinical misdiagnosis of people with DLB. The neuropsychological profiles of AD and DLB differ, and people with DLB may perform relatively worse on tests of attention, working memory, figure copying, spatial judgement, and set-shifting. SPECT and PET can help differentiating DLB from other dementias by revealing low dopamine transporter uptake in the basal ganglia and occipital hypoperfusion, as well as hypometabolism. $^{123}\text{FP-CIT}$ SPECT may be positive in fronto-temporal dementia, but associated occipital hypometabolism favours the diagnosis of DLB. A meta-analysis including eight studies and 346 people has reported that MIBG scintigraphy can differentiate DLB from other dementias, with 98% sensitivity and 94% specificity [20]. CSF biomarkers may not help the differential diagnosis of DLB, but they may predict a more severe clinical course. Besides, DLB may initially present only with neuropsychiatric symptoms, so it should be considered as one of the differential diagnoses for all older adults presenting with late-onset psychosis, especially if they have associated cognitive deficits or extra-pyramidal symptoms.

Clinical course

Pathological processes underlying DLB may begin several years earlier than their clinical manifestations. A heterogeneous, potentially long prodromal phase of DLB is widely recognized but has been poorly defined so far. RBD is likely to be the most common feature of prodromal DLB. Many longitudinal studies have confirmed the association between idiopathic RBD and later DLB diagnosis [58]. Features of prodromal DLB may include MCI, subtle neuropsychological deficits, olfactory dysfunction, dysautonomia, constipation, hypersalivation, mild extra-pyramidal symptoms, and neuropsychiatric symptoms. Among people presenting with MCI, non-amnesic deficits, fluctuating cognition, visual hallucinations, extra-pyramidal symptoms, EEG changes, low dopamine transporter uptake in the basal ganglia, reduced myocardial MIBG uptake, occipital hypoperfusion, and occipital hypometabolism have been associated with progression to DLB. The clinical onset of DLB is often insidious. Typical clinical course is gradually progressive, and the rate of cognitive decline is similar to that of AD. Initial studies have suggested that DLB and AD do not differ in their prognosis, but recent evidence indicates a worse prognosis for DLB. Longitudinal studies evaluating the courses of DLB and AD have associated DLB with an increased risk of mortality [59], shorter median survival time, and earlier admission to nursing homes by nearly 2 years [60]. DLB also places a high burden on the caregivers, even compared to AD [61]. *APOE* $\epsilon 4$ allele has been associated with a rapid decline in DLB, and increased CSF tau levels have been associated with shorter survival in DLB.

Management

Good clinical management of DLB begins with an early accurate diagnosis. As treatments that can alter the progression of DLB pathology are not currently available, contemporary management focuses on symptomatic treatment, treatment of comorbidity, and providing holistic supportive care. Patients, their families, and carers need to be educated about the nature of the illness and should be involved in

Table 43.2 Summary of available pharmacological options for DLB

Symptoms	Medications
Cognitive symptoms	Donepezil* Rivastigmine Galantamine Memantine
Hallucinations and delusions	Donepezil Rivastigmine Memantine Clozapine Quetiapine Pimavanserin Olanzapine (poorly tolerated)
Depression	Antidepressant medications
Anxiety	Antidepressant medications
REM sleep behaviour disorder	Rivastigmine Memantine Melatonin Clonazepam
Restless legs syndrome	Gabapentin
Excessive daytime sedation	Modafinil/armodafinil
Postural hypotension	Fludrocortisone
Urinary incontinence	Trospium

* Level I evidence is available.

all clinical decisions. Individualized care plans should be formulated after comprehensive assessments of the needs, risks, disability, and wishes of people with DLB. Well-co-ordinated multi-disciplinary management involving general practitioners, psychiatrists, neurologists, psychologists, nurses, physiotherapists, occupational therapists, and social workers is preferred. Good-quality RCTs specifically recruiting people with DLB are few, and people with DLB are very sensitive to drug-related adverse effects. Hence, treating psychiatrists should adhere diligently to the general principles of geriatric psychopharmacology such as very low-dose initiation, slow titration, periodic monitoring, dose reduction at the earliest possible opportunity, and minimizing polypharmacy. Therapeutic decision-making is not easy when distressing psychotic symptoms and neuroleptic sensitivity coexist in DLB. It is tough for patients and their carers to make a choice between mobility and psychosis. Risks and benefits of all available treatment options should be discussed in such scenarios. **Table 43.2** presents a summary of available pharmacological management options for DLB.

Cognitive symptoms

Available evidence supports the use of acetylcholinesterase inhibitors in standard doses to treat cognitive symptoms in DLB. There have been two RCTs evaluating donepezil, and one RCT investigating the effects of rivastigmine in DLB [62]. Donepezil was significantly more effective in both RCTs, with a pooled mean difference of nearly 2 Mini-Mental State Examination (MMSE) points, and cognitive improvements were maintained for 52 weeks in both RCTs. Both RCTs have reported that people receiving donepezil were significantly more likely to have absence of deterioration on clinical global impression. People taking rivastigmine showed nearly 1-point improvement of their MMSE scores during the study period, but this effect was not statistically significant. An uncontrolled trial

investigating the efficacy of galantamine in DLB has reported improvements in cognitive fluctuations. There have been two RCTs investigating the effects of memantine in mixed DLB and PDD samples [63]. Subgroup analyses revealed small, but statistically significant, improvements among the participants with DLB. Moreover, meta-analyses have supported the use of anti-dementia drugs in DLB [64].

Neuropsychiatric symptoms

Evidence supporting the use of donepezil, rivastigmine, and memantine to treat neuropsychiatric symptoms in DLB is not robust. Some people with DLB may be on anti-parkinsonian medications. If they develop distressing visual hallucinations or other neuropsychiatric symptoms, the possibility of reducing anti-parkinsonian medications should be considered first. One RCT has provided evidence for the efficacy of donepezil to treat delusions, hallucinations, apathy, and depression in DLB, but a subsequent larger RCT has not confirmed this effect [62]. Another RCT has showed that rivastigmine could mitigate delusions, hallucinations, apathy, and depression in DLB, but the effects were not statistically significant. There have been two RCTs providing debatable evidence for and against the efficacy of memantine to treat neuropsychiatric symptoms in DLB. After considering a trial of an acetylcholinesterase inhibitor, the option of a low-dose dopamine antagonist may be considered. As already noted, dopamine antagonists are poorly tolerated by people with DLB, and there is insufficient evidence justifying their use. A small RCT has shown that risperidone was poorly tolerated, and it worsened cognition and neuropsychiatric symptoms in DLB [65]. People with DLB tolerate olanzapine poorly, but a small RCT has reported that olanzapine 5 mg/day could significantly reduce the severity of delusions and hallucinations [66]. A case series supported the use of quetiapine, but the only RCT investigating the effects of quetiapine in DLB was negative. There have not been any studies investigating the efficacy of clozapine to treat psychotic symptoms in DLB. However, extrapolating the evidence for its efficacy to treat psychotic symptoms in PDD suggests that low-dose clozapine (6.25–50 mg/day) may be the drug of choice in DLB also [57]. Similarly, pimavanserin, a selective serotonin 5-HT_{2A} inverse agonist, has not been evaluated in DLB, but level I evidence exists for its efficacy to reduce psychosis in PD. Future studies investigating its efficacy and safety in people with DLB are awaited with interest.

Drugs may be used to treat depression or anxiety symptoms in DLB, but the evidence supporting their use is weak. Citalopram is the only drug for depression that has been investigated by an RCT for its efficacy in DLB. The RCT did not show any benefit, and it showed that citalopram was poorly tolerated [65]. Drugs with anticholinergic adverse effects should be avoided. Other drugs for depression may be used in DLB after careful consideration of their adverse effect profiles and potential drug interactions. Besides, a case series each for zonisamide and ramelteon, as well as a very small RCT for the herbal medicine yokukansan, has provided weak evidence for their efficacy to lessen neuropsychiatric symptoms in DLB.

Other symptoms

Anti-parkinsonian medications are used in DLB to manage the extra-pyramidal symptoms, but they may worsen visual hallucinations and other neuropsychiatric symptoms. Moreover, levodopa response is variable in DLB. Assessing and managing the risk of

falls is essential for all people with DLB and mobility problems. Rivastigmine and memantine may reduce the frequency of RBD in DLB. Melatonin and low-dose clonazepam can be used to manage RBD. Gabapentin may be helpful in people with DLB presenting with restless legs syndrome. There is weak evidence to support the use of modafinil and armodafinil for managing excessive daytime sedation in DLB. Obstructive sleep apnoea is not uncommon in DLB, and its treatment may improve excessive daytime sedation in DLB. Fludrocortisone can be used to manage postural hypotension in DLB. Review of antihypertensive medications, salt supplementation, and compression stockings should be considered. Trosipium may help with urinary incontinence. Constipation in people with DLB can be managed by dietary changes, exercise, stool softeners, psyllium, or polyethylene glycol.

Non-pharmacological interventions

There have not been many systematic trials evaluating the efficacy of non-pharmacological interventions for managing various symptoms in DLB. Electroconvulsive therapy may be considered for people with DLB presenting with severe depression and psychosis, and a few case reports, as well as a small case series, support its efficacy and safety in DLB [67]. Repetitive transcranial magnetic stimulation may be helpful in DLB. A case study employing a novel structured intervention model—‘skill building through task-oriented motor practice’—has reported functional gains in a woman with DLB [68]. Physical exercise, social interactions, person-centred care, cognitive training, and cognitive behavioural therapy may help people with DLB, but further research is needed to investigate their efficacy.

Future research

A consensus should be reached on the definition of prodromal DLB. It will help future research for identifying novel biomarkers to help with early diagnosis and for developing potential neuroprotective therapies [69]. Large, robust RCTs are needed for addressing many unanswered questions regarding the efficacy of available pharmacological and non-pharmacological options for the symptomatic treatment of DLB. Genetics, transcriptomics, and epigenetics of DLB should be investigated further. Further research on extracellular α -synuclein and circulating exosomes may enhance our understanding of neurobiology of DLB and may reveal novel therapeutic avenues. Research on extracellular α -synuclein has already provided the impetus for developing immunotherapeutic approaches for DLB [70].

Dementia in Parkinson's disease

Michele Hu and Fahd Baig

Pathogenesis and pathophysiology

Neuropathology

The neurobiological basis for Parkinson's disease (PD) is the degeneration of nigrostriatal dopamine neurons and the pathological deposition of the protein, α -synuclein in intra-neuronal Lewy inclusions within vulnerable populations of neurons in the brain. Lewy bodies (LBs) (aggregations of proteins, including α -synuclein) and neurites (degenerating neurites with α -synuclein) have been considered to be pathological hallmarks of PD (see Chapter 43). Braak and colleagues have proposed a staging schema by which the distribution of Lewy pathology spreads through the brainstem in a prion-like fashion into the midbrain and subsequently throughout the cortex [1] (Table 44.1; Fig. 44.1). These pathological changes occur gradually and progressively over many years, with a significant period of clinically silent cell dysfunction and cell death or autonomic/sleep/mood symptoms before the onset of Parkinson's motor symptoms.

In the elderly, pathologies often occur on a background of age-related pathologies, which are extremely common in the over-75 age group. The pathologic substrate for Parkinson's disease dementia (PDD) and Parkinson's disease with mild cognitive impairment (PD-MCI) appears to be heterogenous and includes LBs, Alzheimer's disease (AD) pathology, cerebrovascular disease, and other findings, including cerebral amyloid angiopathy (Fig. 44.2) [2].

The most compelling evidence to date suggests that Lewy-related pathology is the most important factor in the development of cognitive impairment in PD. The distribution of synuclein pathology has been shown, to some extent, to map the clinical symptoms [3–5]. However, neuronal loss can be present in the absence of Lewy pathology [6], leading to the investigation of smaller α -synuclein aggregates [7]. Further uncertainty about the role of synuclein pathology is caused by the presence of LBs in the absence of Parkinsonian symptoms, termed incidental Lewy body disease. There also appears to be a synergistic relationship between α -synuclein, amyloid peptide, and tau proteins [8]. The additional presence of Alzheimer's pathology is associated with a shorter time to dementia and a higher burden of Lewy pathology in the cortex. There are also some data suggesting that chronological ageing may be an important driving factor in the onset of dementia in PD

patients [9], a factor also related to the prevalence of AD pathology in patients with dementia.

Neuropathologic studies have also linked tau deposition to Lewy body diseases, with the following observations. In both patients with DLB and those with PDD, the presence of tau pathologic changes, in combination with A β and α -synuclein, has been shown to potentiate dementia [10]. Furthermore, as in patients with AD [11], tau aggregates in those with PD have been found to correlate with the severity of cognitive impairment [12], and tau aggregates measured at autopsy late in the course of the disease are commonly observed in both patients with PDD and those with DLB. However, greater tau burden has been noted in the tissue of patients with DLB than in those with PDD [13], raising the possibility of a difference during life. The contribution of brain tau aggregates during life to the clinical manifestations and course of these diseases has only recently been delineated due to new imaging tracers (see Imaging under Biomarkers for PDD, p. 443, for imaging correlates).

In summary, it is very likely that there is a synergistic effect between α -synuclein pathology, age, and other pathologies, including AD and tau pathology, that is the main driver of cognitive decline in PD.

Neurotransmitter systems

Multiple neurotransmitter deficits have long been emphasized as of major importance in PD, and particularly in underlying the cognitive deficits. An understanding of these deficits has led to current management options for PDD, namely cholinesterase inhibitors and changes to dopamine medication use.

Dopamine and PDD

Dopaminergic neurons in the brain are found in three main mid-brain dopamine regions, projecting to the *basal ganglia* (nigrostriatal system), *limbic regions* (mesolimbic system), and *cortical regions* (mesocortical system; Fig. 44.3).

The largest group of dopaminergic neurons are found in the substantia nigra (SN), which project upwards to the striatum (largely the putamen) in an important feedback loop controlling actions and thoughts. The ventrolateral portion (red-VLa SN) of this loop degenerates early in PD before LB formation and dementia, leading to progressive motor deficits of bradykinesia, rigidity, and tremor helped by dopamine replacement. In PDD, there is greater

Table 44.1 Stages in the evolution of PD-related pathology

Area of pathology	Possible clinical correlate	Subregions affected
Stage 1: medulla oblongata	Constipation, hyposmia	Lesions in dorsal IX/X motor nucleus
Stage 2: medulla oblongata and pons	Sleep, depression, anxiety	Pathology of stage 1 plus lesions in raphe, reticular, and caeruleus–subcaeruleus nuclei
Stage 3: midbrain	Motor PD	Pathology of stage 2 plus midbrain lesions, especially substantia nigra
Stage 4: basal prosencephalon and mesocortex	PD-MCI	Pathology of stage 3 plus prosencephalic lesions, temporal mesocortex
Stage 5: neocortex	PD-MCI/PDD	Pathology of stage 4 plus higher-order sensory neocortical lesions
Stage 6: neocortex	PDD	Pathology of stage 5 plus first-order sensory association areas of neocortex

Source: data from *Neurology*, 64(8), Braak H, Rüb U, Jansen Steur ENH, et al., Cognitive status correlates with neuropathologic stage in Parkinson disease, pp.1404–10, Copyright (2005), American Academy of Neurology.

degeneration of the medial SN dopamine neurons [orange—medial SN and ventral tegmental area (VTA)], which project through the mesolimbic pathway and are involved in behavioural selection and impulsivity. Dopamine agonist use may enhance this pathway, contributing to impulse control disorders (ICDs) in PD. Degeneration of dopaminergic neurons in the VTA (yellow) may lead to a reduction in cortical dopamine through the mesocortical system, affecting cognitive function.

Other monoamine systems and PDD

Marked degeneration of noradrenergic neurons in the locus caeruleus projecting to the forebrain are well described in PDD. Degeneration of serotonergic neurons in the median raphe nucleus as the disease progresses, with reduced serotonin innervation, is described.

Acetylcholine and PDD

An approximate 40% loss of cholinergic pedunculopontine neurons, which project to the thalamus, is observed. However, degeneration is most marked in the nucleus basalis, leading to severe, widespread cortical reductions in choline acetyltransferase, which correlate with the extent of cognitive impairment and can be demonstrated with functional imaging studies. Anticholinergic medications accelerate

PD cognitive impairment, while cholinesterase inhibitors, such as donepezil and rivastigmine, benefit PDD.

Summary of neurotransmitter systems

In summary, the emergence of PDD occurs on a background of severe dopamine deficits and correlates with a marked loss of limbic and cortically projecting dopaminergic, noradrenergic, serotonergic, and acetylcholinergic neurons.

Epidemiology and risk factors

The heterogeneity of cognitive deficits found in PDD, coupled with a variability in cognitive tests and diagnostic criteria, cause significant problems when comparing published studies. Recent attempts to address this have included the publication of diagnostic standards, which have included the introduction of the concept of PD-MCI. This classification system is drawn from the study of AD as a means of classifying cognitive problems which do not meet the criteria for dementia.

Dementia is common in PD; while the point prevalence of PDD is estimated to be 31.3% (95% CI 29.2–33.6%) [14], the risk of developing dementia increases with time. While not all suffering

Reproduced from *Mov Disord.*, 29(5), Halliday GM, Leverenz JB, Schneider JS, *et al.*, The neurobiological basis of cognitive impairment in Parkinson's disease, pp. 634–50, Copyright (2014), with permission from John Wiley and Sons.

dementia, even in the earliest stages of the disease, up to half will have a degree of cognitive impairment. The onset of dementia itself is highly variable, with a mean onset of 6 years and up to half of patients developing dementia within 10 years from diagnosis in a community study followed up from diagnosis [15]. By 20 years, most (the long-term cumulative prevalence is up to 80%) will have developed dementia, although not all [16, 17].

While the cognitive decline is progressive, it is non-linear and heterogenous. The pattern of cognitive deficits (including visuo-spatial, executive, and memory domains early on) varies considerably between individuals, as does the rate of the evolution of the symptoms. Overall, however, allowing for this inter-individual variability, the rate of global decline (as measured by global cognitive tasks) is slower initially and increases with disease duration and the

onset of dementia [18]. This may be because the global cognition scores are not sensitive enough to pick up the subtle changes earlier in the disease course but has been a consistent finding. The decline is overall faster than reported in age-matched control groups.

Studies consistently agree that older age increases the risk of more rapid cognitive impairment [15, 19]. Other features, such as vascular risk factors [20], the presence of REM sleep behaviour disorder [21], motor impairment, poor fluency, and visuo-spatial dysfunction [15] may also predict an earlier dementia. The impact of PDD is substantial, with major consequences for functioning, institutionalization, psychiatric comorbidity, caregiver burden, and mortality [22]. Once dementia has developed, progression of physical and cognitive decline to death is similar across all groups, lasting on average 3 years (range 1–9).

Fig. 44.3 (see Colour Plate section) Dopamine pathways affected in PD and PDD. Red outline: SN, which contains both dopamine neurons in the pars compacta that give rise to the nigrostriatal projections, and GABA neurons in the pars reticulata, which innervate the thalamus. Dotted red line: ventrolateral (VL) SN, which is selectively damaged in patients with PD. Yellow outline: ventral tegmental area (VTA), which contains both dopamine and non-dopamine neurons that project to limbic and cortical regions. Dotted orange outline: medial SN and VTA, which give rise to mesolimbic projections affected in patients with PDD. cp, cerebral peduncle; N. acc, nucleus accumbens; R, red nucleus.

Genetic risk factors and PDD

Familial PD

Several mutations have been found to be associated with PD, and it is generally accepted that interplay of genetic and environmental factors in an ageing brain are influencing disease development and progression. However, despite clear evidence for monogenetic and susceptibility genes in PD, the role of genetic factors in the development of dementia in PD is less clear [23]. Dementia is more common in patients with PD with a strong family association of PD probably reflecting the influence of genetic factors in the development of dementia in PD [24]. Mutations in the α -synuclein gene (*SNCA*) can be found even in sporadic PD. Functional studies on brain tissue revealed that *SNCA* genomic copy number and gene expression are related, as an increasing number of *SNCA* copies leads to an increase in α -synuclein expression, as well as LB formation. Consistent with these findings, a relationship between *SNCA* dosage and clinical phenotype, including age at onset, progression, and development of dementia, has been reported.

Mutations in the leucine-rich repeat kinase 2 gene (*LRRK2*) and *parkin* are the two most common genetic causes of Parkinsonism. Patients displaying various mutations in *LRRK2* have a low rate of cognitive dysfunction and dementia. In *parkin* mutations, progression of the disease tends to be rather slow, and dementia is not a common feature. Much less is known regarding the association with dementia of two other mutations associated with PD—*Pink1* and

DJ-1. It should be noted, however, that these monogenic forms of PD are generally rare and will occur with an overall frequency of <5% in community-ascertained, unselected Caucasian PD cohorts.

Cognition and risk genes

Mutations in the genes transcribing microtubule-associated protein tau (*MAPT*), apolipoprotein E (*APOE*), glucocerebrosidase (*GBA*), and *SNCA* have all been associated with increased dementia risk in PD. *MAPT* helps assemble and stabilize microtubules throughout the central nervous system, predominantly found in the axons of neurons. The gene encoding *MAPT* is located on chromosome 17q21, part of a 900-kb fragment which is commonly inverted, causing two common haplotypes H1 and H2. Despite the fact that tau pathology is not a neuropathological feature of PD, the *MAPT* gene (H1/H1 *MAPT* haplotype) has been consistently identified as a risk gene for both PD and PDD [15, 25, 26]. Interestingly, a gene–gene interaction between *MAPT* and *SNCA* was also reported [27].

Mutations in the *GBA* gene have been found to increase both PD risk and the risk of PDD, with affected patients presenting at a younger age and developing dementia earlier. Visuo-spatial deficits specifically have been associated with this haplotype, even prior to the onset of dementia, with regionally specific changes in cortical activation [28–30]. The link between dementia risk and the *APOE* ϵ 4 genotype is strongly established, with the ϵ 4 allele associated with a higher risk and an earlier onset of AD. In PD, however, there is no association between the *APOE* ϵ 4 genotype and PD risk. However, this genotype

is an independent predictor of PDD, even when controlling for AD pathology severity [31]. The enzyme catechol-*O*-methyltransferase (COMT) is an important regulator of synaptic dopamine, particularly in the frontal and prefrontal cortices. A common functional polymorphism causing lower enzymatic activity is linked to poor attention and executive performance in early PD subjects; however, this genotype is not predictive of future dementia [32]. Lastly, a recent study characterized the *SNCA* gene locus in PDD and DLB, and found a PDD risk haplotype that was distinct from DLB, with association profiles in single-nucleotide polymorphisms across the *SNCA* gene for Parkinsonism and dementia [33].

Classification, clinical criteria, and controversies

Cognitive impairment in PD is heterogenous both in severity and pattern and is subject to influences both integral and external to the disease. Diagnostic criteria have been developed by the Movement Disorders Society that help to guide clinicians and researchers to an accurate diagnosis of PD-MCI [34] or PDD [35]. These criteria largely meet the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition criteria for dementia. In both PD-MCI and PDD, gradual cognitive decline within the context of established PD and objectively demonstrated cognitive deficits are core features (Table 44.2).

In PDD, cognitive deficits in more than one domain are required, whereas in PD-MCI, a single domain may be affected. In PDD, the deficits must be severe enough to impair activities of daily living, whereas in PD-MCI, they must not be sufficiently severe to interfere with functional independence (although minor difficulties may be present). To operationalize these criteria and to assess the pattern and severity of cognitive dysfunction, we need: (1) valid measures of cognitive abilities covering the major domains of cognition; (2) a method to determine whether or not the performance represents a decline from a person's previous level of functioning; and (3) an assessment of how the individual's cognitive abilities enable (or disable) function in day-to-day activities. These will be further discussed in Diagnosis and differential diagnosis, p. 441 later in this chapter.

Although cognitive impairment in PD exists on a continuum of severity, it is often divided into two categories—mild cognitive impairment and PDD, based on the extent to which the impairment interferes with activities of daily living (Table 44.2). This classification system risks oversimplifying a very complex entity but has been fundamental to clinical trials of therapies for cognitive dysfunction in PD, which have been largely devoted to the treatment of PDD. Currently, therefore, evidence-based treatment of cognitive impairment in PD is restricted to PDD and depends on making a diagnosis of this entity. Identifying mild cognitive impairment is also useful, however, because it has prognostic significance. Several longitudinal studies have demonstrated that PD-MCI is a risk factor for developing PDD. There is also evidence that the pattern of cognitive deficit is prognostically important (see [36] for review).

Controversies: the 1-year rule

With advances in knowledge, disease boundaries may change and require redefinition of the disease. In the case of PD, as diagnostic criteria currently stand, dementia developing before the second year of Parkinsonism is an exclusion criterion for PD; the diagnosis is DLB.

If dementia starts after 1 year, the diagnosis is PDD. Beyond the arbitrary nature of the 1-year rule, there is increasing controversy about whether the distinction itself is valid. PDD and DLB share many similarities in dementia presentation, neuropsychological findings, non-motor profile (olfactory loss, depression, sleep disorders, and autonomic dysfunction in both), imaging, genetics, and pathology (Fig. 44.4). However, broad differences do exist and are summarized in Fig. 44.3. Fig. 44.5 illustrates how the type of cortical pathology and clinical presentation of PDD and DLB might interact. A recent MDS task force proposed that the 1-year rule separating PDD and DLB be omitted [37]. The authors argued that rather, when a patient presents with motor signs and meets full clinical criteria for PD, the diagnosis of PD is applied, regardless of the presence or timing of dementia. In other words, dementia is no longer an exclusion criterion for PD. For those patients who already carry a DLB diagnosis (according to consensus criteria [38]), the authors argued that the diagnosis can optionally be qualified as 'PD (DLB subtype)'. Note that this proposal would not invalidate the diagnostic category

Table 44.2 Criteria for PDD

	Core features	Associated features	Exclusions
Probable PDD	1. PD diagnosis	1. Typical cognitive deficits in two of four domains (attention, executive function, visuo-spatial function, and free recall)	1. Vascular disease on imaging or other abnormality that may cause cognitive impairment, but not dementia 2. Unknown time interval between motor and cognitive symptoms
	2. Slowly progressive dementia syndrome	2. At least one behavioural symptom (apathy, depression/anxious mood, hallucinations, delusions, or excessive daytime sleepiness)	3. Acute confusion resulting from systemic diseases or abnormalities or drug intoxication 4. Features compatible with probable vascular dementia
Possible PDD	1. PD diagnosis	1. Atypical cognitive deficits in one or more domain (fluent aphasia or storage-failure amnesia) with preserved attention	1. Acute confusion resulting from systemic diseases or abnormalities or drug intoxication
	2. Slowly progressive dementia syndrome	Vascular disease on imaging or other abnormality that may cause cognitive impairment, but not dementia, and/or unknown time interval between motor and cognitive symptoms	2. Features compatible with probable vascular dementia

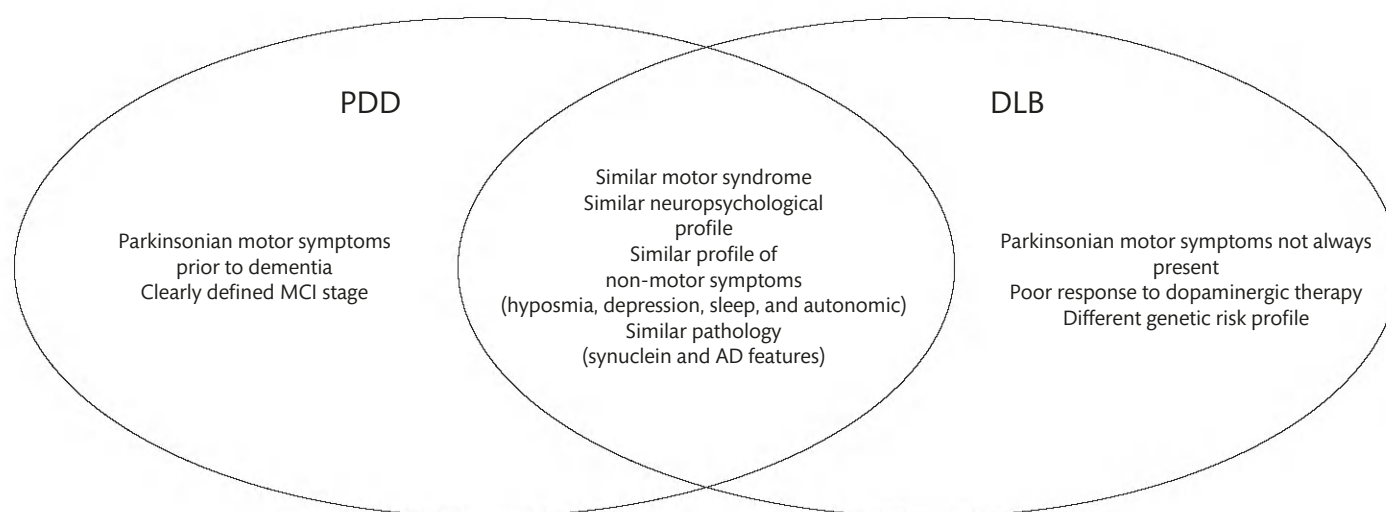

Fig. 44.4 Similarities and differences between PDD and DLB.

of DLB. In clinical communication with patients with the DLB subtype, the diagnostic term DLB could continue to be used [37].

Contrary to this, others have argued that the 1-year rule distinguishing PDD from DLB is worth maintaining because it serves an important purpose in clinical practice, clinical and basic science research and when helping the lay community understand the complexity of these different clinical phenotypes. Furthermore, opponents believed that adding an additional diagnostic label 'PD (dementia with Lewy bodies subtype)' will confuse, rather than clarify, the distinction between DLB and PD or PDD and will not improve management or expedite therapeutic development [39].

Clinical features

Cognitive syndrome

PD-MCI

The spectrum of impairment ranges broadly in phenotype, as well as in timing in the disease course. Cognitive deficits can occur in one or more domains, vary in severity, and present differently at various

stages of the disease. Studies of incident PD indicate that cognitive impairment is not just a late-stage problem but occurs in up to 50% of early cases, including untreated individuals, who manifest PD-MCI [40–43]. Executive function represents the most common cognitive domain affected in PD early on, as well as later, in the disease. Deficits can be detected on tests that are sensitive to frontal dysfunction (for example, tests of planning, spatial working memory, and attentional set shifting). However, impairments in attention, explicit memory, and visuo-spatial function also are demonstrable in early PD. Executive dysfunction may occur individually as a single-domain impairment or in combination with other cognitive deficits as multiple-domain impairments. Some, but not all, studies investigating clinical features and frequencies of cognitive impairment in PD patients without dementia revealed that non-memory (non-amnestic) single-domain deficits are the most frequent cognitive subtype.

PDD

The cognitive profile of PDD remains variable, although it often affects cognitive domains similar to those affected in PD-MCI, but with more severe deficits and with the disruption of multiple areas. The onset of PDD is insidious. In one prospective study, the mean

Fig. 44.5 Cortical pathology and clinical presentation of PDD and DLB. Dementia in DLB/PD is associated with two major pathologies: synucleinopathy (a-Syn, i.e. Parkinson pathology) and neuritic amyloidopathy (i.e. Alzheimer pathology). In PD patients who develop dementia very late in their illness, or not at all (far left), neuritic amyloid deposition is minimal (or absent), and cortical pathology is mainly that of a-Syn deposition. At the other extreme, DLB patients with predominant neuritic amyloid deposition and very minimal a-Syn deposition would usually be diagnosed as AD during life, developing clinical DLB hallmarks late (if at all). Between these two extremes of the spectrum lie the most patients with PD and DLB.

Reproduced from *Mov Disord.*, 29(4), Berg D, Postuma RB, Bloem B, *et al.*, Time to redefine PD? Introductory statement of the MDS Task Force on the definition of Parkinson's disease, pp. 454–62, Copyright (2014), John Wiley and Sons. Reproduced under the Creative Commons Attribution License (CC BY).

annual decline on the MMSE during 4 years was 1 point in the non-demented and 2.3 points in the PDD group, the latter figure being similar to the decline observed in patients with AD. A similar rate of decline was reported in another longitudinal study; the mean decline in MMSE over 2 years was 4.5 and was comparable to that seen in patients with DLB, with a mean decline of 3.9 points [35].

By definition, PDD includes impairment in at least two cognitive domains but, as per MDS criteria, does not require memory deficits. The predominant cognitive deficits in late PDD are similar to those in DLB, with marked visuo-spatial dysfunction and fluctuating attention. Impairments in executive function, working memory, and episodic memory are also common in PDD, although language, particularly as measured by object naming, tends to be relatively preserved (see [44] for review).

Longitudinal relationship between PD-MCI and PDD

The CamPaIGN study, a longitudinal population-based cohort of incident PD, recently reported 10-year follow-up data [15]. Analyses at multiple time points in this cohort ($n = 142$) indicated that, aside from age, the most significant baseline predictors of later dementia were impaired semantic fluency and pentagon copying (hazard ratios of 3.1 and 2.6, respectively, for dementia at 10 years from diagnosis). There was no association between 'fronto-striatal-based' executive dysfunction and later dementia and, in fact, there was no decline in executive function performance over this time.

Neurological findings

By definition, the PDD patient will have features of established motoric Parkinsonism, of which *bradykinesia* is key—characterized by a progressive *decrement* in the amplitude or velocity of movement (or both), rather than the generalized slowness seen with cerebellar or pyramidal disorders. Rigidity and tremor are common, and in general, motor Parkinsonism will be more severe than that seen in DLB or the mild extra-pyramidal features associated with AD. Parkinsonism is typically levodopa-responsive, with levodopa-induced dyskinesias common at this advanced stage and other features such as wearing-off periods. As the disease progresses, severe Parkinsonian symptoms with gait freezing are common, so that the patient frequently falls and becomes wheelchair-bound. The quality of the dementia resembles a subcortical pattern, with pronounced psychomotor slowing, not usually accompanied by severe aphasia, agnosia, or apraxia. Patients perform disproportionately poorly on timed tests and visuo-spatial tasks.

Psychiatric issues

A variety of neuropsychiatric symptoms, including depression, anxiety, hallucinations, apathy, psychosis, and ICDs, occur commonly in up to 90% of PDD patients [45]. Psychotic symptoms affect 60% of PD patients long term and include hallucinations and delusion. The occurrence of these symptoms are predictors of nursing home placement and mortality. Complex visual hallucinations, often of animals or people, are the most typical manifestation, occurring in 40–90% of PDD patients, but other visuoperceptual disturbances can occur, including illusionary experiences, sensations of movement in the periphery (passage hallucination), and a feeling of presence (extracampine hallucination). Auditory, tactile, and olfactory hallucinations are less common. Delusions manifest when insight is compromised, so they are

associated with a degree of cognitive impairment. Delusions in PD tend to be paranoid in nature, and other phenomena, including delusional misidentification (for example, Capgras and Fregoli syndromes), can occur in a minority.

Depression is one of the most common non-motor symptoms in PD, with clinically relevant symptoms occurring in 35% of PD patients. Rates are higher in PD-MCI, and there is a known association between depression and cognitive impairment. Generalized anxiety disorder (GAD) is the most commonly diagnosed anxiety condition in PD, followed by panic attacks and phobias. Anxiety is also strongly linked to depressive symptoms but appears to be less common in PDD than PD, and is also related to motor symptoms, particularly occurring in the off condition in patients with motor fluctuations. Apathy, defined as a decrease in goal-directed behaviour, verbalization, and mood, is common in a range of neurodegenerative diseases, including PD. It is usually accompanied by reduced self-awareness, so changes are noticed and brought to the attention of clinicians by caregivers. A common assumption is that the patient is depressed, although a lack of endorsement of sad mood suggests apathy instead. Apathy can occur independently of cognitive impairment in PD, but overlap is common. Some studies estimate the prevalence of apathy in PDD to be up to 50%.

ICDs (for example, compulsive gambling, buying, sexual behaviour, and eating) are increasingly recognized as common and clinically significant disorders in PD. Given that research suggests that the strongest risk factors for ICD development in PD are dopamine agonist treatment and younger age, and given that cognitively impaired patients are more likely to be older and less likely to be prescribed a dopamine agonist, it is not surprising that ICDs are not commonly reported in PDD patients. In one single-centre study of 805 PD patients, ICD symptoms were less common in PD patients with dementia (3.8%), compared with non-demented patients (9.6%) [46].

Diagnosis and differential diagnosis

As mentioned in Classification, clinical criteria, and controversies, p. 439, the clinical diagnosis of PDD requires: (1) valid measures of cognitive abilities covering the major domains of cognition; (2) a method to determine whether or not the performance represents a decline from a person's previous level of functioning; and (3) an assessment of how the individual's cognitive abilities enable (or disable) function in day-to-day activities. Core features are established PD (clinical diagnosis usually made by a physician) and objectively demonstrated cognitive deficit.

Clinical evaluation

The cornerstone in the evaluation of a patient with suspected PDD is detailed clinical and neurological history and examination, including interview with a close informant. Assessment of social functions and activities of daily living, as well as psychiatric and behavioural symptoms, is part of the basic evaluation.

Measuring cognitive function

Cognitive function in PD is generally measured in one of three settings: (1) in the course of an evaluation by a physician or an

occupational or speech therapist; (2) by a neuropsychologist performing a dedicated clinical cognitive evaluation; or (3) in a research study. These assessments require different tools; a physician or an occupational therapist usually requires a relatively short global cognitive scale with adequate sensitivity to screen for the presence of cognitive impairment or to follow changes over time (Table 44.3). A neuropsychologist uses multiple tests, each emphasizing a specific cognitive domain, to provide a detailed assessment of the pattern of cognitive dysfunction. Research studies require variable detail, depending on the goals of the study, but generally necessitate an instrument with good specificity for an accurate diagnosis and often responsiveness to change over time. Thus, methods for assessing cognitive function in PD need to be selected with careful thought to the goals of the assessment [36]. A useful summary of cognitive screening measures and their approximate administration time is given later in this chapter.

In terms of selecting a brief bedside screening tool, the author would generally favour the MoCA over the MMSE for assessing PD cognition, as it has greater sensitivity across a range of cognitive sub-domains, shows less ceiling effects, and is more sensitive than the MMSE in detecting longitudinal change over time [41].

Establishing cognitive decline

As described previously, to establish a diagnosis, it is critical to understand whether or not any impairment represents a decline from a premorbid level of cognitive functioning. Subjective reports of decline are often spontaneously reported during clinical and research contacts and can be elicited with general questions about concerns related to memory or thinking. A more formal method is to use a cognitive complaint interview. However, patients are not very insightful into their own difficulties, questioning the reliability of this approach. Work in AD has suggested that patients with earlier dementia, but not MCI, underreport cognitive difficulties, compared with caregivers, suggesting that incorporating caregiver report of cognitive complaints is important.

To the author's knowledge, this issue has not been evaluated in PD; however, the use of a caregiver-reported questionnaire—the short form of the Informant Questionnaire on Cognitive Decline in the Elderly (SHORT IQ-CODE) [47]—is currently being evaluated, to assess for cognitive decline in the Oxford Discovery PD

cohort. Lastly, cognitive decline can be established on the basis of serial performance on cognitive testing by a clinician or on the basis of results from neuropsychological test performance that is poorer than expected based on an estimate of a person's premorbid cognitive abilities. Estimating premorbid verbal IQ can be accomplished using a reading test such as the Wechsler Test of Adult Reading or the National Adult Reading Test, which are relatively resistant to change in the face of common neurodegenerative conditions.

Assessing function in relation to cognition

Impairment on the patient's ability to carry out instrumental activities of daily living (IADLs) is an essential feature for establishing the severity of cognitive impairment. This is especially relevant for non-demented PD subjects in whom some aspects of altered functioning in IADLs may appear unnoticeable before the diagnosis of dementia without a formal examination.

As described, the presence of significant functional deficiency due to cognitive impairment is embedded in the current criteria to support the diagnosis of PDD. Moreover, the major formal differentiation of PD-MCI from PDD has typically required cognitive deficits not to interfere significantly with the patient's ability to implement IADLs. Presently, judgement as to the PD patient's ability to adapt to the demands of the environment and execute IADLs is mostly derived from indirect methods (for example, cognitive testing), unstructured interviews with relatives or other caregivers, or the use of functional scales intended for other dementias.

Scales not specific for PD do not take into account the motor impact of the disease and can overestimate the extent to which cognitive dysfunction is contributing to problems carrying out IADLs. The lack of a recommendable instrument, capable of measuring the specific impact of cognitive decline in PD, minimizing the motor symptoms of the disease, has made it challenging to set a standard for what is meant by 'significantly' (that is, dementia) or 'subtly reduced' (that is, MCI) functional performance. Two new PD-specific instruments—the PD-Cognitive Function Rating Scale (PD-CFRS) [48] and the brief Penn Daily Activities Questionnaire (PDAQ) [49]—may help fill the need for assessments of IADLs that are sensitive to cognitive impairment in PD, while minimizing the motor aspects of the disease.

Table 44.3 Generic and non-Parkinson's disease specific cognitive screening measures

Scale name	Assessed cognitive domains	Approximate administration time
Mini-Mental State Examination (MMSE)	Orientation, verbal registration and recall, attention, naming and repetition, verbal comprehension, praxis, visuo-spatial	10 min
Montreal Cognitive Assessment (MoCA)	Orientation, attention, memory, naming, fluency, verbal repetition, visuo-spatial/executive	10 min
Addenbrooke Cognitive Examination (Revised)—ACE(R)	Attention/orientation, memory, fluency, language, visuo-spatial	20 min
Cambridge Cognitive Assessment (Revised)—CAMCOG(R)	Orientation, language, memory, attention, praxis, calculations, abstract reasoning, perception	25 min
Dementia Rating Scale (2nd edition)/Mattis Dementia Rating Scale—DRS (2)	Attention, initiation/perseveration, construction, conceptualization, memory	30 min
Repeatable Battery for the Assessment of Neuropsychological Status (RBANS)	Attention, language, visuo-spatial/construction, immediate memory, delayed memory	30 min
Alzheimer's Disease Assessment Scale—Cognition (ADAS-Cog)	Memory, language, praxis	30 min

Differential diagnosis

The differential diagnosis of PD is extensive; of particular note, those that are also degenerative are associated with dementia/MCI, including progressive supranuclear palsy (PSP), multiple system atrophy (MSA), DLB, and cortico-basal degeneration (CBD). Occasionally, frontal lobe disorders may be mistaken for Parkinsonian disorders, such as Pick's disease, and non-degenerative aetiologies such as frontal lobe meningiomas or drug-induced Parkinsonism. Other progressive, non-degenerative diseases that have some Parkinsonian features include multi-infarct dementia and normal pressure hydrocephalus, usually excluded on an MRI brain scan. Occasionally, Parkinsonian features occur in patients with AD.

Biomarkers for PDD

The point prevalence of dementia in patients with PD is 25%, and it rises to 80% in patients who live for >20 years with the disorder. Cognitive decline in PD worsens the patient's prognosis more than any other non-motor symptoms. A prognostic marker delineating the probability for those patients at risk for cognitive decline would be of utmost importance. While PD-MCI is a risk factor for PDD, it is a heterogeneous entity, and it is not known which types of PD-MCI confer a higher risk of progression to dementia. In this sense, useful biomarkers are needed that can predict future outcome or that are useful to longitudinally track the underlying disease pathology in an objective way. In this section, we summarize the current knowledge on cerebrospinal fluid (CSF) and blood proteins, imaging, and the impairment of gait/postural instability as risk markers for cognitive decline in PD. Genetic predictors of PDD have been discussed elsewhere.

Cerebrospinal fluid

The presence of LBs, amyloid plaques, and neurofibrillary tangles in the neocortex and limbic system is associated with dementia and MCI in PD. Hence, the levels of amyloid- β (A β), tau protein, and α -synuclein have been studied in the CSF of PD patients (see [50, 51] for review). In most studies, there was less A β in PDD than in healthy controls, and lower levels of A β were associated with progression to dementia in PD and cognitive measures. By contrast, data for total (t-tau) and phosphorylated tau (p-tau) are less consistent, with increased or unchanged levels in PDD patients. Although total α -synuclein was similar in PDD and controls in initial studies, technically more advanced analyses showed that PDD patients have more oligomeric forms of α -synuclein, and a higher total α -synuclein concentration was associated with a faster decline in cognitive performance in *de novo* patients. However, most studies have failed to find any association between total or oligomeric α -synuclein and cognition in PD patients.

Proteins involved in inflammatory processes, oxidative stress, and neuronal viability have also been investigated in the CSF, with elevated C-reactive protein, IL-6, and IL-1b in PD-MCI compared to PD normal-cognition patients or controls. Uric acid (UA), a scavenger of free radicals, and cystatin C, which has anti-amyloidogenic properties, were also reduced in PDD and DLB patients. Despite some variability, reduced A β in PDD patients and those who progress to PDD is consistent, and this suggests that the A β protein

might represent a useful biomarker to identify specific types of PD-MCI that might be at higher risk of suffering dementia.

Plasma/serum and urine

Plasma or serum levels of proteins involved in inflammation (C-reactive protein), oxidative stress (UA), or neuroprotection (vitamin D, transthyretin) were not different in PDD and cognitively normal PD patients [50, 51]. However, in PD patients with normal cognition, low UA concentrations were associated with a worse outcome in global cognition, attention, and memory; high vitamin D levels with better semantic fluency and memory; and high concentrations of IL-6, tumour necrosis factor- α , and interferon- γ -induced protein 10, with lower cognitive scores. Importantly, low levels of epidermal growth factor (EGF) and insulin-like growth factor (IGF) have certain predictive values for the development of dementia and cognitive decline, and IGF positively correlates with global cognition and executive function.

There is no consistent relationship between plasma homocysteine and dementia or worse cognitive outcome. Lipids have also been evaluated because abnormal lipid peroxidation may play a role in the pathogenesis of PD and other neurodegenerative diseases. Whereas plasma levels of phospholipids were higher in PD-MCI than in normal cognition PD subjects, prostaglandin isomers derived from free radical peroxidation of polyunsaturated fatty did not differ. In keeping with findings in plasma, low UA levels are associated with poor neuropsychological performance. These findings are consistent with recent data linking neurodegeneration and ageing with disturbances in lipid metabolism and neuroinflammation.

Imaging

(See [50] for a review of this topic.)

MRI grey matter changes

Although there are many studies in this field, the most valuable are those with larger cohorts and more advanced analytic approaches, especially the longitudinal studies. Accordingly, reduced cortical volume or thickness in several areas, and especially in the hippocampus, appears to be associated with progression to dementia and MCI. This is a promising avenue to be followed, in which well-designed prospective studies using modern analytical models might help to validate these findings or identify new patterns that could serve as potential biomarkers.

White matter microstructure

Diffusion tensor imaging

Reduced fractional anisotropy (FA) or increased mean diffusivity (MD) in diffusion tensor imaging studies can indicate alterations in the microstructure of white matter (WM) tracts. Both approaches show that dementia and MCI in PD are associated with extensive areas of modified WM microstructure, with reduced FA being widespread in PDD along the main tracts.

Functional MRI

Cerebral blood flow

Functional MRI (fMRI) in resting state or during the execution of tasks indirectly measures neural activity and is used to study regional activation of the brain and the association or dependency

between two or more anatomic locations, termed functional connectivity. One interesting approach is to study the default network that reflects the predominant activity at rest, which is dampened when switching to a cognitive task. In PDD patients, this network has weaker connectivity in the right inferior frontal gyrus and is less intensely deactivated than in controls when confronted with a complex visual task. Considering the data available, it can be speculated that there are two main functional networks in the resting state: one more anterior that seems to be related to executive dysfunction, and another more posterior one that might herald the evolution to dementia. This would also be consistent with observations derived from the longitudinal CamPAIGN cohort (see Longitudinal relationship between PD-MCI and PDD, p. 441).

PET and single-photon emission computed tomography (SPECT) imaging

Cholinergic ligands

Pathological studies and pharmacological trials with acetylcholinesterase inhibitors indicate that cholinergic dysfunction is relevant in dementia in PD. Studies using different radiotracers show that the cholinergic activity in PDD patients was weaker in the whole cortex and in the occipital, precentral, parietal, temporal, and posterior cingulate cortices than in healthy controls. PET studies indicate that assessing the cholinergic state might be useful as a biomarker of dementia in PD, but current accessibility limits their clinical and research use.

A β ligands

Fibrils of A β can be assessed *in vivo* by Pittsburgh compound B (PiB) PET imaging [52]. Studies showed that cortical A β deposition is common in individuals with PD and PDD, that high levels of A β are observed in most cases of DLB [53], and that greater deposition of A β is a risk factor for cognitive impairment in patients with PD, accelerating cognitive decline once established [54]. These findings were consistent with prior neuropathologic reports. In AD, disease progression occurs in the context of high A β levels and is associated with the spread of tau deposits from the medial temporal lobe to the basal temporal neocortex and then to other neocortical regions [55], in association with regional neuronal loss. From the few such studies undertaken in PD patients, the *in vivo* results of PiB-PET studies are rather variable, with low sensitivity and specificity in the diagnosis of dementia and MCI in PD patients.

Regional blood flow/glucose uptake ligands

Reduced regional cerebral blood flow and FDG-PET uptake in the posterior cortical areas seem to be useful biomarkers of dementia in PD, in line with fMRI data.

Tau ligands

In the last year, the radioligand fluorine 18-labelled AV-1451, also known as [18F]T807, has been used to image tau in patients with LB diseases because of its high affinity, selectivity, and favourable kinetics for imaging tau. Two recent studies have shown: (1) AD patients can be distinguished from DLB patients on the basis of significantly higher AV-1451 uptake, representing cortical tau, particularly in the medial temporal lobes [56]; and (2) patients with DLB and

PDD manifest a spectrum of tau pathology, with cortical tau aggregates associated with cognitive impairment [52].

Gait and cognition in PD

Gait disturbance in PD shares neurochemical, pathological, structural, and genetic relationships with cognitive risk factors [51, 57]. It is believed that gait disturbance associated with the postural instability gait disorder (PIGD) motor PD phenotype and dementia is underpinned by a common neurochemical deficit in cholinergic function. Brain imaging highlights shared structural correlates of gait and cognitive impairment. Combined with evidence in older adults that gait changes may precede cognitive decline, these findings add validity to the role of gait as a surrogate marker of cognitive impairment. Longitudinal follow-up is required to explore the temporal relationship between these risk factors and their sensitivity and specificity.

Treatment

In recent years, there have been important advances regarding clinical characterizations, definitions, associated biomarkers, and risk factors for both MCI in PD and PDD. However, there is a paucity of effective therapies for cognitive impairment in PD, whether for mild symptoms or for moderate to severe dementia [58]. At present, only rivastigmine is U.S. Food and Drug Administration-approved for PDD, an indication received nearly a decade ago. Given the frequency of PD cognitive impairment and its substantial impact on both patients and families, the lack of available and effective treatments represents a striking gap in the field, especially when compared to the large number of available therapies. Improved symptomatic therapies, as well as potential disease-modifying agents, for PD cognitive impairment are needed.

Treatments can be broadly divided into pharmacological and non-pharmacological and are summarized here. However, special considerations apply to the management of PDD. Firstly, dopaminergic therapy is more likely to cause hallucinations and delusions in Parkinsonian patients with dementia than in those with uncomplicated PD. Secondly, neuroleptic therapy is more likely to cause an exacerbation of Parkinsonian symptoms, hence should be avoided unless absolutely clinically necessary. Third, on-off motor fluctuations may commonly be accompanied by mild fluctuations in cognitive state as well.

Pharmacological treatments

Modest symptomatic effect of the cholinesterase inhibitor rivastigmine for PDD has been shown, in particular for patients with accompanying visual hallucinations [59]. Other cholinesterase inhibitors, such as donepezil, have been shown to produce similar modest improvements in cognition and behaviour in PDD and DLB [60]. A naturalistic study indicated that amantadine may increase the time from onset of PD to dementia [61]. Several studies have used memantine to show benefit in patients with both PDD and DLB combined [62]. PD psychosis can be difficult to treat; practically, however, removal of anti-parkinsonian medications may help ameliorate psychotic symptoms, particularly in the earlier stages of the disease, and a specific order of withdrawal has been suggested,

beginning with anticholinergic agents through to dopamine agonists/COMT inhibitors, and then finally, if required, levodopa [45]. However, reductions in dopamine therapies can be challenging, given the need to adequately treat motor symptoms.

Specific pharmacological interventions include the use of drugs for psychosis; however, as mentioned, these are more likely to cause an exacerbation in motor symptoms in PD patients. Dopamine antagonists, such as haloperidol, can provoke severe neuroleptic sensitivity reactions and therefore are contraindicated in this population. Similar reactions or worsening of parkinsonism can also be observed with most of the newer drugs such as risperidone, olanzapine, and aripiprazole [63], which should be avoided because of the risk. While there have been numerous RCTs of antipsychotics for PD psychosis, there is a paucity of data looking at the benefits of these agents in PD patients with cognitive impairment specifically. The exception is clozapine where one major study with a positive outcome included some PD patients with possible dementia (mean baseline MMSE: placebo group, 21.7; clozapine group, 23.8) [64]. However, subgroup data for PDD patients were not provided, and widespread use of clozapine is limited due to its potential to induce agranulocytosis and the necessity for regular blood monitoring. Quetiapine is used most frequently for PD psychosis, but there is no evidence from controlled studies for its efficacy in PDD [65]. Additionally, prolonged use of dopamine antagonists may have deleterious effects on cognition, and they significantly increase cerebrovascular events and mortality in older people with dementia in general (see [45] for review), so these agents should be used cautiously in PD patients with cognitive impairment until demonstrated not to increase morbidity and mortality in this population.

A promising new drug for PD psychosis is pimavanserin (selective 5-HT_{2A} inverse agonist). A recent controlled trial found a significant benefit of pimavanserin on all endpoints, including the Scale for Assessment of Positive Symptoms in Parkinson's Disease (SAPS-PD) score, with additional improvement in night-time sleep and daytime somnolence [66]. Overall pimavanserin was well tolerated and did not worsen motor symptoms.

Cholinesterase inhibitors, in particular rivastigmine, may be an alternative first-line treatment option, as these agents can improve cognition, function, and neuropsychiatric symptoms. Other drugs, such as memantine (NMDA antagonist) and ondansetron (5-HT₃ antagonist), have also been considered for the treatment of PD psychosis. Overall the therapeutic benefit of memantine remains inconclusive, and from a psychosis perspective, improvements in the neuropsychiatric inventory (NPI) in patients with PDD have not been observed, although there may be some benefit in DLB patients.

Non-pharmacological treatments

There are no systematic studies evaluating non-pharmacological interventions for PD psychosis, although a small study suggested benefit for ECT in patients refractory to dopamine antagonists [67]. As mentioned, removal of anti-parkinsonian medications can help ameliorate psychotic symptoms, but often at the cost of motor control. Phased reduction, followed by withdrawal, if necessary, of dopamine agonist medication, in particular, is critical to the management of ICDs. Abrupt withdrawal of dopamine agonist medication should be avoided, due to the risk of causing dopamine agonist withdrawal syndrome (DAWS), an unpleasant syndrome characterized by agitation, motor restlessness, worsening of symptoms,

dysphoria, and anxiety. Similarly, abrupt withdrawal of levodopa or any dopaminergic medication can cause neuroleptic malignant syndrome and should always be contemplated with the full support and involvement of a PD physician.

Non-pharmacological interventions for PDD include several ongoing studies of deep brain stimulation (DBS) surgery in PD, targeting the bilateral nucleus basalis of Meynert, a cholinergic-innervated basal forebrain site involved in attention, learning, and memory processes, which is impaired in dementia. Non-pharmacological strategies for treating PD cognitive impairment represent an area of growing interest and include cognitive training, physical exercise and physical therapy, music and art therapy, and non-invasive brain stimulation techniques (see [58] for review). To date, many studies are open-label pilot studies; though there are several small RCTs, 'double blinding' of study personnel and patients in these types of interventions can be challenging. There is great heterogeneity in study methodologies [for example, different types of cognitive tasks and means of assessments (computerized interventions, neuropsychological tests, and word games, along with the duration of study and practice), physical exercises and methods (aerobic, dance, strength, and so on), and cognitive targets (attention, executive function, memory, and so on)].

Studies in PD have generally focused on cognitively intact or non-demented, but mildly cognitively impaired, PD patients, rather than those with PDD. Cognitive therapies include cognitive training exercises, computerized brain training, and non-physical leisure activities which have the potential to improve cognitive outcomes and IADLs (see [58] for review). Physical exercise and activity have reported benefits on motor PD symptoms, while studies investigating their effects on cognition are growing. Beneficial effects of combined physical activity and cognitive training therapies may be potentially additive [68, 58].

Prognosis and future perspectives

The cumulative incidence of PDD from longitudinal studies of incident PD cohorts is remarkably consistent, suggesting that around half will develop dementia within 10 years from diagnosis. The onset of PDD is insidious, with a similar reported mean annual decline on the MMSE to that seen in AD and DLB [35]. However, disease progression varies considerably, with some patients declining rapidly, while others have a more benign course. The determinants underpinning this variability are poorly understood. Post-mortem studies showed that concurrent AD neuropathology is associated with a more rapid cognitive decline in LBD patients, shorter time between parkinsonism and dementia onset, and a worse prognosis. There also appears to be a synergistic relationship between tau, α -synuclein, and amyloid pathology (see earlier). However, it is still unclear whether *in vivo* surrogate biomarkers (amyloid/tau imaging, CSF protein quantification) can predict LBD endophenotype in terms of disease progression. Response to current symptomatic treatments is also variable in PD, and a better understanding of the mechanisms of response and non-response to these agents will be key in informing who to target with a new range of emerging symptomatic drugs.

There is major pharma investment into disease-modifying treatments in early AD targeting amyloid and tau, with recent data, excitingly, suggesting benefit. Aggregation of these brain proteins also occur in LBD and may have deleterious effects, as well as synergistically promote α -synuclein aggregation (the core aggregate in LB

disease). Developing relevant stratification of biomarkers could therefore mean that any effective near-future anti-amyloid/tau treatments could also be offered to selected PDD and DLB patients. Furthermore, anti- α -synuclein therapies, protein degradation enhancers, and mitochondrial stabilizers are all in development, and stratification in PDD would be highly apposite to de-risking trials of these agents.

Lastly, the earlier any intervention, the more effective it is likely to be. Therefore, intervention at the PD-MCI stage, to prevent the inexorable progression to PDD, must be a key focus of future treatments in PD if they are to be effective. Biomarkers, in particular, the emerging imaging biomarkers outlined, could be especially useful to identify those PD-MCI patients at high risk of developing dementia in the short to mid term.

Dementia due to Huntington's disease

Russell L. Margolis

Introduction

Huntington's disease (HD) was first described in 1872 by George Huntington, an American physician living on Long Island, New York. His father and grandfather practised medicine in the same community, so that he had access to case notes from several generations of families who lived there. This long period of record-keeping allowed him to document a hereditary form of chorea, similar to 'common (Sydenham's) chorea', but progressing over many years to death. Its sufferers had a tendency to insanity and suicide. Huntington's brief essay, which also included a clear description of autosomal dominant inheritance, remains one of the classic descriptions of a medical disorder [1].

Clinical features and course of illness

HD is an inherited neuropsychiatric disorder prominently affecting the striatum and its direct connections. It is characterized by a triad of clinical features that are common to diseases of this region: a non-aphasic *dementia*, *depression* and other disorders of affect, and a variety of *dyskinesias*, most typically chorea [2, 3]. Chorea, from the Greek word for 'dance', describes involuntary, non-stereotyped jerky movements. The illness, insidious in onset, may begin with all or any one of these three features. Patients who present initially to psychiatrists usually have dementia, personality changes (such as apathy, irritability, or loss of temper), or depression, often with suicidal thoughts or attempts. Symptoms may appear at any time from early childhood to old age, most frequently between 35 and 45 years of age. Once the illness begins, sufferers gradually deteriorate over many years in their cognitive and motor functioning and end in a persistent vegetative state, with almost complete loss of voluntary motor function. Death occurs after about 15–20 years and is usually caused by inanition or aspiration pneumonia. Some patients die earlier from suicide or from injuries such as subdural haematomas caused by a fall. Patients with early onset seem to progress more rapidly than those whose symptoms begin later in life.

Pathology and genetics

The earliest visible neuropathology is in the striosomes of the caudate/putamen [4], followed by a dorsal-to-ventral progressive

loss of almost all striatal output neurons. The deep layers of multiple cortical regions are also prominently affected, and there can also be milder neuronal loss in some brainstem nuclei. Protein aggregates, most easily detectable in neuronal nuclei, are prominent. Neuroimaging studies have shown that neuropathological changes typically begin before the onset of clinically detectable disease. In particular, the extent of striatal loss in pre-symptomatic individuals, as measured by MRI, correlates with the predicted time until disease onset [5]. Cortical thinning [6] and white matter loss and disorganization [7, 8] have also been detected in pre-symptomatic gene carriers. Subtle changes possibly related to abnormal brain development have also been reported.

The prevalence of HD ranges from about 6 to 14 cases per 100,000 population in North America, Western Europe, and Australia, with much lower prevalence in Asia [9]. HD is caused by the expansion of an unstable triplet repeat sequence (CAG) in the first exon of a gene near the telomere of chromosome 4p [10]. It is transmitted as an autosomal dominant trait; if one parent carries the mutation, each offspring (regardless of sex) has an independent 50% chance of inheriting the abnormal gene. Normal repeat lengths range from about 7 to 28 triplets. Individuals with 29–35 triplets will not develop HD (with possible rare exceptions) but may pass an expanded allele to an offspring, while individuals with 40 or more triplets will develop HD. Repeat lengths of 36–39 triplets may or may not cause disease. The rate of mutation from a normal-length allele to an expanded one is low, so that most patients have an affected parent. Family history, however, can be obscured by multiple factors, including misdiagnosis of the parent, death of the parent before disease onset, adoption, and incorrect assignment of paternity. The repeat length does not remain stable at meiosis. In HD, the number of CAG triplets is more likely to increase when the gene is transmitted by fathers. As the number of repeats increases, the age at onset is earlier. Thus, paternal transmission is often associated with 'anticipation', earlier onset in the subsequent generation; most individuals with childhood onset have affected fathers [11].

The pathogenesis of HD is not well understood but appears to be multi-faceted [12]. The gene *huntingtin*, with the expanded repeat, is expressed as the protein huntingtin. The CAG repeat expansion is translated as an expanded polyglutamine tract, which appears to have neurotoxic properties. The region of the huntingtin protein with the polyglutamine tract may be cleaved from the rest of the protein and adopt an abnormal configuration, or it may be abnormally

modified by post-translational processes such as phosphorylation. These changes, in turn, are thought to lead to disruption of cellular functions, including transcriptional machinery, protein degradation processes, metabolism, and cellular transport. Other proposed pathogenic mechanisms include toxicity derived from huntingtin RNA transcripts containing the expanded CAG repeat, atypical translation of the *huntingtin* gene leading to proteins with long stretches of other amino acids, and loss of the normal function of the huntingtin protein.

Diagnosis

The clinical diagnosis of HD remains dependent on a thorough psychiatric history, including a detailed family history and history of changes in social adjustment, mental state examination, cognitive examination, and neurological examination. The features vary, depending on how long the patient has been ill [13]. Once the disease is suspected on clinical grounds, genetic testing, available through many commercial laboratories, provides the definitive diagnosis. A number of large completed and ongoing longitudinal studies of HD, including PREDICT, PHAROS, COHORT, REGISTRY, and Enroll-HD, have greatly enhanced knowledge of the signs, symptoms, and course of HD.

Diagnosis of patients with early symptoms

Patients with HD who initially consult psychiatrists may present with a variety of psychiatric syndromes, including depression, bipolar disorder, obsessive-compulsive disorder, schizophrenia, or excessive anxiety. Irritability or apathy may be a manifestation of one of these syndromes or may appear separately. The psychiatric syndromes seen in HD are clinically indistinguishable from idiopathic disorders, and in perhaps 20% of cases, neurological signs may not be present. Suicide is a risk in this prodromal phase, even if the patient is unaware of their risk for HD [14]. Presenting symptoms and problems with functioning at work or at home must often be elicited from an informant; the patient may minimize them through embarrassment or fear, or even be unaware of them. Common changes include decline in work speed or accuracy, which may result in demotion or warnings from superiors, a tendency to become irritated or physically aggressive in response to annoying stimuli that would not have elicited such a response in the past, and a decreased interest in activities. Most of these symptoms and behaviours are common in psychiatric disorders, but cognitive inefficiency and irritability may seem disproportionately extreme relative to the patient's other symptoms. On cognitive examination, the patient may have difficulty recalling dates of important life events and more difficulty than expected with 'serial sevens'. Cognitive changes are often easier to notice after the psychiatric disorder is treated, which can usually be accomplished using standard medications. However, unlike the typical response to treatment of idiopathic disorders, cognitive inefficiency and difficulties at work, apathy (if present), and sometimes irritability remain, even after the HD patient's mood, energy, and sleep patterns have improved.

On neurological examination, motor restlessness is usually present but is easily misinterpreted as a manifestation of anxiety. Motor signs may be subtle: slightly slow saccadic eye movements [15],

writhing movements of the protruded tongue or of the fingertips when the arms are held at 90°, or mild dysdiadochokinesia.

Diagnosis can be further complicated by the apparent lack of a family history of HD. The family may not have been informed about the affected parent's diagnosis or may know only that a parent died in a psychiatric institution or committed suicide. In other cases, the paternity is uncertain. If the family history is actually negative (this is quite uncommon) or unobtainable (often the case for adopted individuals who frequently present in childhood), the diagnosis may be confirmed by testing for the HD gene expansion.

HD with onset in childhood or early adolescence [16] most often presents with cognitive and behavioural features, including speech and language problems, a decline in school performance, deterioration of handwriting, and loss of interest in school and social activities [17]. These non-motoric disturbances may be the only clinical features for several years before motor impairment begins. The motor impairment in a majority of juvenile-onset patients will include prominent parkinsonism, bradykinesia, very slow saccades, lead pipe or cogwheel rigidity, and dystonia, with chorea less prominent or even absent. However, many affected juveniles have motor signs similar to typical HD. Myoclonus and epilepsy are observed in as many as 50% of early-onset HD, and some children develop a coarse tremor.

Even though it can be difficult, it is important to make the diagnosis of HD as early as possible, particularly in employed persons. Poor function at work (or in schoolwork or household duties) occurs early, and patients can lose their jobs or support of their family, often on suspicion of drug or alcohol abuse or of indifference to the work or home environment. This is usually avoided if the diagnosis is made known to the family and employer, allowing modification of the work environment or retirement on the basis of disability and family education about the illness. Prompt diagnosis does not always mean that the patient needs to be immediately informed of the diagnosis. Occasionally, patients are too depressed to do this safely; others indicate that they do not wish to be told. Treatment can usually proceed despite the patient's reluctance to label the disorder.

Diagnosis of patients with well-established signs and symptoms

After a few years of illness, diagnosis is easier. The signs and symptoms will have worsened, and usually the motor disorder is obvious. A typical patient who has been ill for about 5–7 years is unable to work or manage finances but lives at home and is able to manage personal needs. Some patients remain active and energetic, continuing to participate as fully in life as their cognitive and motor disabilities allow; others are apathetic most of the time, but irritable when disturbed; still others may have a depressive syndrome, at times complicated by delusions, obsessions, or compulsions. Many patients are anxious and easily upset by changes of routine. An uncommon, but very troublesome, feature of HD is sexual abnormality. While most patients become impotent or uninterested in sex, a few are hypersexual and may develop paraphilias [18]. It is important to inquire about these specifically because neither the patient nor his or her spouse will likely mention problems.

Cognitively, patients complain of forgetfulness and distractibility. Thinking is slow; patients have difficulty following a conversation and cannot complete a multistaged task. On cognitive examination,

Mini-Mental State Examination scores [19] may still be above the cut-off score of 23 for dementia, but serial sevens will be very poor, and one or two items will be missed on recalling words after a distraction. On neuropsychological testing, the IQ will be lower than expected for education, and there will be difficulty learning word lists and performing tests that require changing sets.

Most patients will have obvious involuntary choreic movements, as well as difficulty with control of voluntary motor movements, as seen by clumsiness, slowness, dysarthria, and an unsteady gait. The involuntary movements will wax and wane with the level of arousal; it can be worsened by performing serial sevens or by fine motor tasks. Speech will have an irregular staccato, often laboured, quality. Saccadic eye movements will be slow or irregular, and the patient will be obviously clumsy on tests of dysidiadochokinesia and rapid movements such as finger–thumb tapping, although finger-to-nose testing is normal. Gait will be wide-based and irregular, with difficulty with tandem walking. Reflexes are usually brisk, and a history of falls can be elicited.

Diagnosis of patients with advanced disease

After 10 years of illness, dementia is more severe, with poor performance on all aspects of the cognitive examination, except naming. Speech is dysfluent, with long lapses between the examiner's question and the patient's reply, rather like Broca's (expressive) aphasia. Some patients will be almost unable to speak, although language comprehension is relatively preserved. Patients (if they are co-operative) can carry out simple commands and will recognize relatives and nursing staff. Patients may be irritable, particularly when their verbal requests cannot be understood or routines altered. Psychiatric syndromes are more difficult to discern, but most can be diagnosed by observing behaviour such as hoarding, sleeplessness, or diurnal variation in mood. Physical disabilities are much worse. Patients often need to be fed, toileted, and helped with most daily needs. They have difficulty walking and may fall, causing further disability through broken limbs or subdural haematomas. Chorea often stabilizes or subsides [13], but the ability to carry out voluntary movements becomes seriously disabling. If they survive long enough, patients become unable to initiate speech or to walk, swallow only with great difficulty, and have such severely rigid muscle tone that they may be nearly unable to move their bodies. Clonus and positive Babinski signs are present. Patients in this sort of 'persistent vegetative state' [20] are difficult to distinguish from individuals in the late stages of other movement disorders or dementias; as in early disease, diagnosis will depend on eliciting a family history or genetic testing.

Differential diagnosis

The differential diagnosis of HD is extensive [3], but only a few of the disorders for which it can be mistaken are common [2]. These include other dementias, other movement disorders, and other psychiatric disorders. The most common subcortical dementia is *Parkinson's disease* (PD), in which motor slowness resembles that of HD, but the characteristic pill-rolling tremor and festinating gait of PD are rare in HD. The dementia associated with *late-life depression* can look very similar to HD, including motor slowness. *Alzheimer's disease*

is easily distinguished by the lack of motor signs during the first several years of illness and more prominent difficulty with memory and language, as opposed to attention and calculation. Perhaps most difficult to distinguish clinically are the *fronto-temporal dementias*, which present with prominent behavioural disturbances and a positive family history. The clinical presentation may be insufficient to distinguish these various dementias in patients with advanced disease, since they may all progress to a persistent vegetative state. The family history and duration of illness (which is longer for HD than for Alzheimer's disease or fronto-temporal dementia) can be helpful. The C9orf72 expansion mutation, a common cause of amyotrophic lateral sclerosis and fronto-temporal dementia, can also lead to a HD-like phenotype.

Several *less common diseases classified as movement disorders* may closely resemble HD. They often have an autosomal dominant inheritance pattern, and some, like HD, are caused by expansion of unstable triplet repeat sequences. Examples include Fahr's syndrome (calcification of the striatum), some forms of spinocerebellar degeneration and benign familial chorea, neuroacanthocytosis, HD-like 2 (HDL2), and dentatorubropallidoluysian atrophy (DRPLA). These disorders, while much rarer than HD (except for DRPLA in Japan), can so closely resemble HD that they can only be distinguished by genetic testing.

The most common movement disorder that resembles HD is *tardive dyskinesia*. Patients with HD occasionally have several years of a schizophrenia syndrome before the movement disorder begins. If they have been treated with dopamine antagonist medicines, the subsequent onset of involuntary movements can be mistaken for tardive dyskinesia. On the other hand, the choreoathetotic involuntary movements of severe tardive dyskinesia, which may involve the trunk and extremities, as well as the face, may be mistaken for HD. Usually, it is possible to distinguish patients with tardive dyskinesia by their normal saccadic eye movements, normal tandem gait, and fluid and fluent speech [21]. However, genetic testing may be necessary in some cases. Wilson's disease also presents with the subcortical triad and should be considered when neither parent is affected. It is recessively inherited, so that the only affected relatives are siblings. Very late-onset HD may be diagnosed as 'senile chorea' because the family history appears to be negative. Family members will also present with symptoms only late in life and may have died before their manifestation.

The differential diagnosis of nearly all psychiatric disorders includes HD, as described.

Treatment and management

Currently, there is no treatment that influences the fundamental course of illness of HD, though much work is now directed in that direction (see Future of HD research and treatment, p. 452). However, it is possible to alleviate some of the symptoms of HD through judicious use of pharmacological interventions [22]. Chorea can be diminished with tetrabenazine, low doses of dopamine antagonist medicines (though probably with less effect in advanced disease), and occasionally benzodiazepines, though risks and benefits with all of these treatments must be carefully weighed. The recently available modified versions of tetrabenazine, deutetabenazine, and valbenazine may prove more convenient to administer or less of a risk for depression than tetrabenazine.

itself [23]. Given the potential side effects of haloperidol, particularly at doses of more than 5 mg, newer dopamine antagonist medicines are now increasingly recommended for chorea suppression if tetrabenazine or its derivatives are contraindicated or ineffective. Dystonia may be treated with botulinum toxin injections or benzodiazepines, and there is evidence that deep brain stimulation may prove helpful in some cases [24]. Muscle rigidity and consequent contractions occur in late HD, causing pain and difficulty in positioning the patient to avoid pressure sores. Amantadine (which also has a positive effect on mood) can somewhat decrease the rigidity; chairs and beds must be padded and tailored to each patient's specific needs. In the setting of falls or unexpected worsening of movement or cognition, clinicians need to consider the possibility of a subdural haematoma.

Psychiatric manifestations are present to some extent in a vast majority of HD patients and may become severe in more than one-third. Appropriate pharmacological and non-pharmacological treatment has the potential to significantly improve the quality of life for HD patients and their families, and may help decrease the high rate of suicide observed in HD. Clinical experience suggests that depression, anxiety, and obsessive-compulsive disorder associated with HD usually respond to pharmacological treatments used for the similar idiopathic disorders, though there have been few systematic treatment trials of psychiatric syndromes in HD [25]. Because some patients are unaware of their depressed mood (just as they can be unaware of their involuntary movements), an informant is often needed to elicit the symptoms and monitor response to treatment. It is also important to distinguish depression (from which the patient is miserable and sleepless) and apathy, which does not cause distress. Occasionally, mood and anxiety disorders are chronic and unresponsive to treatment. Severe, unresponsive depression can be treated successfully with electroconvulsive therapy [26]. Bipolar disorder in patients with HD may not respond to lithium but may improve with carbamazepine or valproic acid. In addition, lithium is difficult to administer because of the risk of lithium toxicity related to insufficient fluid intake. Valproic acid, serotonin-specific reuptake inhibitors, and low-dose dopamine antagonist agents may also be helpful in the treatment of irritability. In one case report, high doses of sertraline were effective for intractable aggression [27]. Schizophrenic-like syndromes, while not particularly common, can be difficult to treat but may respond to a standard dopamine antagonist medicine, with a preference towards newer agents with less D₂ receptor affinity. Clozapine remains an option in patients not responding to other drugs. Apathy, when not part of a depression syndrome, does not respond well to pharmacological interventions.

As with most dementias, psychopathology influences, and is influenced by, the patient's environment. Patients do best in a calm, highly predictable environment where cognitive expectations are not too complicated. When the environment is too taxing, patients become irritable, especially towards their family. HD seriously damages family relationships, which, in turn, affects the patient. The well spouse becomes responsible for supporting the family, caring for the children and the patient, and making family and financial decisions. Spouses' lives are further complicated by patients' unwillingness to relinquish financial and family decision-making; patients usually make poor decisions that can damage family relationships and finances. Some patients neglect their children or treat them badly. If the other parent cannot prevent this, it is wisest to remove the patient from the home. There is no research on the treatment of sexual

aggression, which occasionally occurs in males, but a few men have been successfully treated with depot anti-androgen agents. Supportive psychotherapy for the patient should focus on minimizing demoralization at lost abilities. Spouses can be helped with reorganizing family life to maximize predictability of the patient's environment, diplomatically decreasing the patient's domestic responsibilities, and assuring that the spouse has time away from the patient.

Helping persons at risk for HD

People at risk for HD vary in their abilities to deal with the burden of uncertainty, depending on their personal attributes and their experience with the illness in a relative. A few consult physicians for reassurance, but most avoid doctors until they become ill, and even then many resist medical attention, claiming against all evidence that they are perfectly well. Currently, a minority of asymptomatic persons at risk for HD decide to have genetic testing, but these individuals, skewed towards those whose anxiety is lessened by planning for the future, have usually handled the test results well, regardless of whether positive or negative [28]. As more clinical trials are launched for individuals with the HD mutation who are without detectable symptoms, the incentive for pre-symptomatic testing will likely increase, with a concomitant change in the nature of individuals seeking testing. Fetal and pre-implantation genetic testing is now available in some centres, each with its own set of potentially complicated ethical and practical issues that must be sorted out prior to testing.

Pre-symptomatic genetic testing [29] of any sort should always be preceded by genetic counselling, provided either by a genetic counsellor or by a clinician familiar with HD genetics and the potential practical and psychological consequences of both positive and negative test results. Counselling should include a discussion of the motivations for seeking testing, which may include decisions about childbearing, education, employment, finances, participation in clinical trials, or the potential at-risk status of offspring. Many individuals who come for testing have not seriously considered the possibility that they will test positive for the mutation, so that role-playing about various outcome scenarios is important. Occasionally, persons request testing who have learnt only recently that they are at risk for HD. Others apply who are depressed or under unusual stress for other reasons. Such persons should be encouraged to delay testing until their situation becomes more settled. Finally, some people who request testing already have symptoms of HD, yet do not wish to have a diagnosis. Considerable care is required to decide how best to support such individuals, and family members or close friends of the person should be consulted.

Future of HD research and treatment

While efforts to explore the course of HD and to improve symptomatic HD treatment continue, the focus of HD research is moving towards finding treatments that can stop, slow, or prevent the development and progression of the neuronal dysfunction and neurodegeneration that underlie the disease. New tools for modelling HD, including a variety of animal models and induced

pluripotent stem cells, should facilitate preclinical work [30]. HD investigators are also attempting to develop increasingly sensitive biomarkers, measurable correlates of disease progression that can facilitate the detection of efficacious therapies in individuals who do not have clinically manifest HD and that can lead to clinical study designs that require fewer subjects and a shorter duration of treatment [31, 32]. Recent studies have demonstrated that some agents thought to be of general neuroprotective value, such as co-enzyme Q10, likely lack significant clinical efficacy in HD [33], while other protective agents still under investigation, such as PBT2, may have benefit [34]. Attention and funding have increasingly emphasized the development of methods for suppressing the expression of the mutant HD allele [35], with antisense oligonucleotide strategies just reaching the stage of clinical trials. The potential power of such therapeutic approaches, or even more sophisticated methods such as gene editing to remove the mutation from the genome, has generated considerable optimism among HD investigators and HD families.

Vascular cognitive impairment

Joanne A. Byars and Ricardo E. Jorge

Introduction

Vascular cognitive impairment (VCI), known as vascular dementia (VasD) in its more severe form, is cognitive impairment due to pathology of blood vessels in the brain. This pathology encompasses both ischaemic and haemorrhagic disease; however, most literature focuses on ischaemic disease, as this is the far more prevalent form.

Various sets of diagnostic criteria for VCI and VasD exist, but all share some factors in common—the patient must have evidence of cognitive impairment, evidence of cerebrovascular disease, and evidence of an association between the two [1]. The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) outlines criteria for major and mild vascular neurocognitive disorder, the term DSM-5 uses for VCI [2] (Box 46.1).

Aggressive modification of vascular risk factors has a greater potential to modify the course of VCI than the progression of neurodegenerative disorders such as Alzheimer's disease (AD). This makes an early and accurate diagnosis of VCI critically important.

Epidemiology

VasD is the second leading cause of dementia in the United States, affecting 1.2–4.2% of people over the age of 65 years and representing 15–20% of dementia cases. The prevalence of VasD increases with age [1]. It is unclear whether the prevalence of VasD differs by sex [1]. Currently, there are no reliable statistics on the prevalence of VCI not rising to the level of dementia.

Encouragingly, the rate of VasD appears to be falling. Recent data from the Framingham Heart Study found that the overall incidence of dementia has declined over the past 40 years, falling by 20% every 10 years [3]. The rate of VasD has fallen faster than that of AD [3]. The risk of developing dementia after a stroke has also decreased, from nine times higher to less than twice higher than that in individuals without a stroke [3]. While some evidence suggests that improved control of vascular risk factors may have contributed to the decline in dementia, this does not account for all the reduction seen [3].

Individuals with stroke are at higher risk for VCI than the general population. Following a stroke, 6–32% of patients develop dementia of some type [4]. Even small strokes substantially increase the risk of

cognitive impairment. One study of patients with lacunar ischaemic CVA, without large-vessel strokes, found that 47% had mild cognitive impairment (MCI), making MCI more common than physical disability [5].

Subtypes of VCI

Most classifications divide VCI into three subtypes: multi-infarct VCI, strategic infarct VCI, and small-vessel VCI [4]. Some authors refer to small-vessel VCI as subcortical VCI or Binswanger disease [4].

Patients with multi-infarct VCI may show the classic 'stepwise decline' pattern, in which each stroke adds a new cognitive burden, with periods of relative cognitive stability in between strokes. However, the other forms of VCI typically follow a different course.

In strategic infarct VCI, a single stroke affects a region critical for cognitive functioning and produces VCI after the single event. Classic strategic infarct locations include the thalamus, mesial frontal lobe, caudate, mesial temporal lobe, left angular gyrus, and genu of the left internal capsule [1]. However, strokes in other locations can also produce strategic infarct VCI, and due to individual variations in brain anatomy and connectivity, clinical findings may not always correlate with classic syndromes.

Notably, patients can show progressive cognitive decline following a single stroke; this may be due to disruption of brain networks resulting in ongoing worsening, though this hypothesis still lacks definitive proof [4]. In any case, this finding indicates a complex relationship between stroke and cognitive decline, which goes beyond the impact of neuronal demise resulting from stroke. However, reducing rates of stroke likely constitutes a very effective way to reduce rates of VasD.

In small-vessel VCI, patients typically show gradually progressive cognitive decline. They may never experience a 'clinical' stroke that produces an obvious and immediate change in neurologic function. However, physical examination may reveal abnormal neurologic findings such as hyperreflexia, Parkinsonism, and gait disturbance [6]. Small-vessel VCI can occur due to lacunar strokes or ischaemic demyelination [7].

As individuals with cerebrovascular disease commonly have involvement of both small and large vessels, patients can have

Box 46.1 Diagnostic criteria for vascular neurocognitive disorder**A. Cognitive impairment**

- Major vascular neurocognitive disorder:
 - Significant decline in one or more cognitive domains, based on clinical history and/or impaired performance on cognitive testing
 - Impaired functioning in everyday activities
- Mild vascular neurocognitive disorder:
 - Modest decline in one or more cognitive domains, based on clinical history and/or impaired performance on cognitive testing
 - Independent functioning in everyday activities (though may require more effort than previously)

B. Evidence of cerebrovascular disease

- Supported by history, physical examination, and/or neuroimaging

C. Clinical features consistent with a vascular aetiology

- Onset of cognitive deficits is temporally related to a cerebrovascular event
- Or
- Pattern of cognitive deficits is consistent with a vascular aetiology (that is, decline in complex attention or frontal executive functions)

D. Symptoms not better explained by another disorder

- Criteria A, B, C, and D must be met for diagnosis

Source: data from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, DSM-5, Copyright (2013), American Psychiatric Association.

combinations of multi-infarct, strategic infarct, and small-vessel VCI. One study found that lacunar infarcts represent the most common type of stroke seen in VasD [8].

Some studies have found that 70% of individuals with VasD also have comorbid AD-type pathology, a condition referred to as mixed dementia [9]. Most VCI is sporadic, but familial forms, such as VCI due to cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), also exist [4].

Overlap between VCI and Alzheimer's disease

Although VCI can occur in isolation, cerebrovascular disease and AD can co-occur and synergistically worsen each other.

One large community-based study found that, among individuals with either VasD, AD, or both, 13% had only VasD, 54% had only AD, and 33% had both [9] (Fig. 46.1). Notably, 83% of these patients with VasD and/or mixed VasD-AD had no clinical history of stroke and likely would have received an incorrect diagnosis if MRI had not been performed, underscoring the critical importance of neuroimaging for the correct determination of the dementia type [9].

In post-mortem studies, many individuals with dementia show a mix of cerebrovascular and AD neuropathology. Amyloid plaques, neurofibrillary tangles, cerebral amyloid angiopathy (CAA), and white matter lesions are found in both disorders [8]. About 10% of individuals with pure VasD show evidence of CAA, and CAA could contribute to further damage of blood vessels and progression of cerebrovascular disease, large intracerebral hemorrhages, and microbleeds [1, 8]. In AD, amyloid- β builds up around blood vessels in the brain, causing impairment of vascular functioning [1].

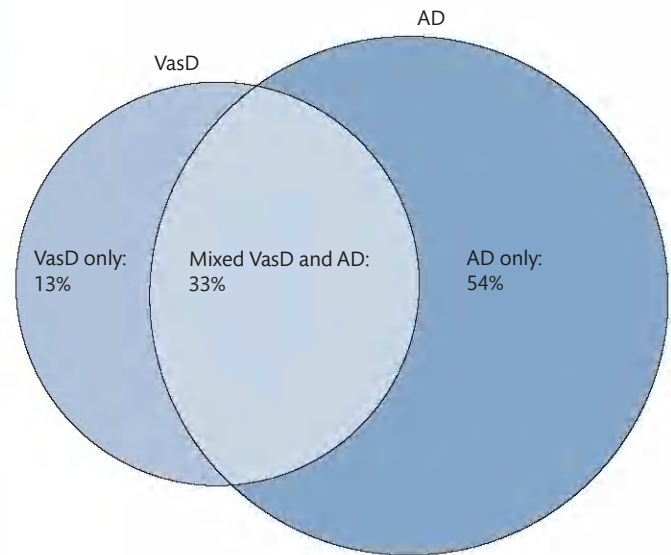

Fig. 46.1 Overlap between VasD and AD.

Almost 30% of individuals with VasD have hippocampal sclerosis, possibly related to hippocampal neurons being especially vulnerable to ischaemia [8]. Both vascular disease and AD-type pathology are associated with hippocampal atrophy [1].

Recent imaging advances—namely, the development of Pittsburgh compound B (PIB), a radiotracer used with PET—allow for the non-invasive assessment of amyloid- β burden. This technique permits a more accurate classification of pure VasD (VasD without evidence of amyloid- β burden) vs mixed VasD-AD (VasD with excessive amyloid- β burden) and has led to new insights into how these two subcategories of VasD resemble and diverge from each other.

Some studies have observed different patterns of MRI findings in individuals with VasD with and without concomitant amyloid- β burden. For instance, among patients with small-vessel VasD, those who are amyloid-positive may have smaller hippocampal volumes and those who are amyloid-negative may have more lacunar infarcts [10, 11]. One study found that individuals with small-vessel VasD, without evidence of amyloid burden, showed damage to the white matter throughout the entire cerebrum, as opposed to the regional pattern seen in AD without vascular disease [12].

Vascular risk factors not only increase the risk of VasD, but also the risk of AD. Hypertension, diabetes mellitus (DM), metabolic syndrome, coronary artery disease (CAD), smoking, atrial fibrillation, atherosclerosis, and obesity are all associated with an increased risk for AD, and having a stroke may double the risk for AD [4].

Vascular disease also worsens the severity of neurodegenerative dementia. One neuropathologic study found that, among individuals with AD or Parkinsonian neurodegenerative diseases, those who also had cerebrovascular disease required less primary neurodegenerative pathology (neurofibrillary tangles or Lewy bodies) to reach the same severity of clinical dementia as individuals with neurodegeneration only [13]. As cerebrovascular disease is common in individuals with neurodegenerative dementia, these findings suggest that tight control of vascular risk factors could potentially help in these conditions as well [13].

Conversely, neurodegenerative pathology can worsen VCI. One cross-sectional study of MCI due to subcortical vascular disease

found that individuals with excessive amyloid- β burden showed more cognitive impairment than those with only ischaemic vascular pathology [14]. Another prospective longitudinal study of small-vessel VasD found that patients positive for amyloid showed faster cognitive decline over a 3-year follow-up period [15].

Clinical features

In general, the pattern of cognitive impairment varies with the location of the vascular lesion or lesions. Although VCI has been classically associated with frontal executive dysfunction, other patterns of impairment also occur [1]. For example, while a patient with subcortical ischaemic white matter disease may show predominant impairment in frontal executive functions, a patient with a strategic infarct in the left middle cerebral artery (MCA) territory may show aphasia and/or apraxia. Memory impairment in VCI may occur due to stroke affecting the hippocampus or to the concomitant presence of AD-type pathology. Although lacunar strokes are often associated with impairments in frontal executive functions, one study found that episodic memory impairment was just as common in this stroke type [5].

Depending on the location of their strokes, individuals with VCI can also show deficits in elementary neurologic function such as hemiparesis, visual field cuts, urinary incontinence, and gait disturbance. They may also show other neurologic signs such as hyperreflexia and Parkinsonism.

Individuals with VCI also frequently experience neuropsychiatric symptoms. Up to 95% of patients with VCI may have at least one psychiatric or behaviour symptom [16]. Depression and apathy represent the most common symptoms, with depression present in 50–75% and apathy in one-third to two-thirds of individuals with VCI [16–18]. Apathy becomes more common with increasing severity of cognitive impairment [16, 17, 19]. Irritability, anxiety, and agitation each occur in about half of patients, disinhibition in about 10–30%, and psychotic symptoms in 20–30% [16, 17].

Individuals with VasD show poorer sleep than those with AD, and one cross-sectional study of subcortical VasD found that patients with more white matter hyperintensities (WMHs) experienced worse sleep [20].

Diagnosis

The diagnosis of VCI is based on history, neurological examination, cognitive testing, and neuroimaging. Neuroimaging can reveal evidence of cerebrovascular disease and ‘asymptomatic’ ischaemic or haemorrhagic damage, even in the absence of a clinical history of stroke.

Clinicians should be aware that patients who have never had a clinical stroke can still have VCI, as some forms of VCI (such as small-vessel VCI) do not necessarily cause any obvious abrupt neurologic changes.

Neuroimaging

In recognition of the variety of international practice settings, most criteria sets require *either* clinical (clinical history of stroke and/or findings of focal neurological deficits consistent with stroke on

neurological examination) *or* radiologic evidence of cerebrovascular disease.

However, in a country with ready availability of neuroimaging, clinicians should certainly obtain it to confirm evidence of cerebrovascular disease. Even if the history and examination are compatible with stroke, other aetiologies such as a tumour could, in some circumstances, produce a similar clinical picture but need drastically different treatment. Additionally, imaging distinguishes between ischaemic and haemorrhagic stroke—an important determination to make, as their secondary prevention strategies may differ significantly.

To diagnose VCI, MRI is preferable to CT, unless there is a contraindication, given its greater sensitivity. Specialized MRI sequences, such as susceptibility-weighted imaging (SWI) and gradient echo (GRE) sequences, detect the presence of blood with high sensitivity and specificity, including microbleeds related to amyloid angiopathy [21]. By evaluating the integrity of white matter tracts, diffusion tensor imaging (DTI) can identify white matter damage not seen on conventional MRI sequences such as T2 and fluid-attenuated inversion recovery (FLAIR) [12].

Common imaging findings in VCI include evidence of large-vessel ischaemic stroke(s), lacunar ischaemic stroke(s), extensive WMHs, white matter atrophy, and/or large or small haemorrhages. Microhaemorrhages are very common in ischaemic VasD—occurring in two-thirds to four-fifths of patients, a higher percentage than in other dementias such as AD [21]. Of note, individuals without VCI, cognitive impairment, cerebrovascular disease, or other structural brain disease can also show WMHs, for instance, patients with migraine or some individuals with healthy ageing [7]. When long tract signs, such as weakness or hyperreflexia, accompany WMHs, the WMHs more likely reflect genuine pathology [7]. However, there is no clear cut-off for the size or amount of vascular lesions required to cause VCI, as substantial inter-individual variability exists.

Dementia or cognitive impairment—of any type—cannot be diagnosed solely on an imaging basis. Some individuals have more cognitive reserve than others, so two people with the same imaging findings could have very different levels of cognitive functioning.

Cognitive evaluation

Cognitive evaluation should encompass both a thorough clinical history of cognitive and functional changes, and cognitive testing [20]. To diagnose VCI, there should be evidence that the patient has experienced a cognitive decline relative to his or her baseline functioning.

The clinical history provides key information about the patient’s prior functional level, the time course and nature of the cognitive changes, associated symptoms, and performance of activities of daily living and instrumental activities of daily living [22]. The clinical history does have limitations, however. The patient and/or other informants may dismiss worrisome events—such as getting lost while driving in a familiar area—as normal ageing, even though they are not. Sometimes, a similarly aged family member, such as a spouse, may also have cognitive impairment and thus not accurately perceive or remember the patient’s recent functioning.

In addition to a thorough history, appropriate cognitive testing—taking into account the patient’s age and educational, occupational,

and cultural background—is essential for diagnosing VCI. However, the test results must be interpreted in light of the overall clinical context, as no test is 100% sensitive or specific for cognitive impairment.

No cognitive test is entirely free of cultural and socio-economic bias. Typical cognitive batteries fail to capture important domains of cognition—such as social cognition, artistic creativity, and mechanical ability—and the clinical history may be more useful in uncovering decline in these areas. Patients functioning at a high occupational level may experience a decline in job performance as an early symptom of VCI; while this decline may have significant real-world importance, insufficiently challenging or occupationally specific cognitive tests may not detect any problems. For example, if a theoretical physicist comes to clinic complaining of recent difficulty solving problems in her field, very few physicians or neuropsychologists could determine if this was objectively true through office-based testing! Consultation with a professional colleague of the patient—with the patient's consent—may help establish whether there is an actual decline in functioning, even when cognitive test scores are in the normal range.

Some patients' premorbid functioning may have been higher or lower than predicted by standard test norms or by estimates of premorbid intellectual functioning, and thus isolated test results may mislead as to whether a decline from baseline has occurred. For instance, a patient may have limited formal education due to socio-economic circumstances but be self-taught, well read, and functioning at a high intellectual level prior to his or her current problems. Conversely, due to variation in educational quality, some individuals may have graduated from high school without achieving functional literacy. Additionally, no tests to estimate premorbid intellectual functioning have complete immunity to decline from the effects of an acquired cognitive disorder; the data do not support the idea that some areas of cognitive functioning are 'crystallized' and do not decline in dementia.

However, in most cases, the results of appropriately interpreted norm-based cognitive testing significantly help in clarifying the presence, severity, and nature of cognitive impairment.

Given the heterogeneity of cognitive deficits in VCI, testing should assess both overall cognitive function—using a test of general cognitive function such as the Folstein Mini-Mental Status Exam (MMSE) or the Montreal Cognitive Assessment (MoCA)—as well as multiple specific cognitive domains, including tests of frontal executive function, memory, attention and concentration, orientation, visuo-spatial function, and language, and assessment for neglect.

All tests have strengths and weaknesses. The MMSE depends heavily on the assessment of orientation, memory, and language and show less sensitivity for detecting impairment in patients whose primary problems may involve other domains; clinicians should supplement these tests with other instruments which better assess other cognitive functions. The MoCA may assess a broader variety of domains than the MMSE but may misclassify cognitively normal individuals with low educational attainment as having dementia.

One useful approach is to assess overall cognitive functioning with a general test such as the MMSE or the MoCA, and then use tests of specific domains to interrogate further into areas of possible impairment. **Box 46.2** lists several brief domain-specific assessments useful for administration at the bedside or in the clinic

Differential diagnosis

The differential diagnosis for VCI includes neurodegenerative dementias such as AD and fronto-temporal dementia; multiple sclerosis and other autoimmune neurologic conditions; chronic infections such as HIV or neurosyphilis; vitamin deficiencies; endocrinopathies; leukodystrophies; and toxic exposures such as medications which impair cognition, alcohol, opioids, heavy metals, and volatile substances. Of note, some of these disorders can cause white matter changes which may be difficult to distinguish from those of VCI without further investigation such as cerebrospinal fluid (CSF) analysis or enzyme testing.

When evaluating a patient for a cognitive disorder—whether suspected VCI or another condition—the most important task is to rule out potentially reversible or modifiable causes. If a patient with AD receives a misdiagnosis of VCI, that patient will not miss out on a disease-modifying treatment, as none currently exists for AD. However, if a patient with multiple sclerosis, severe B12 deficiency, or neurosyphilis is misdiagnosed with VCI, this could result in a lost opportunity to halt or reverse the progression of these treatable diseases.

Serum laboratory testing for reversible causes of cognitive impairment should include assessment of B12, thyroid function tests, complete blood count (CBC), comprehensive metabolic panel (CMP), ammonia, vitamin D, folate, thiamine, HIV, treponemal syphilis testing, erythrocyte sedimentation rate (ESR), and antinuclear antibody (ANA) [22, 23]. Depending on clinical circumstances (for example, a history of gastric bypass or other condition affecting nutrient absorption, or an occupational history of heavy metal exposure), additional testing may be needed to fully evaluate for potentially reversible causes.

Unfortunately, many older individuals use medications known to impair cognition and increase risk for dementia, such as anticholinergic medications (for example, allergy medications, over-the-counter sleeping aids, antispasmodic bladder medications, and certain drugs for depression, anxiety, and psychosis) and benzodiazepines. Alcohol and recreational drugs can also cause cognitive impairment. Fortunately, the cognitive harm done by these exogenous

factors is at least potentially reversible. Before diagnosing a cognitive disorder, clinicians should make all efforts to eliminate the use of these agents and then reassess cognition and functioning. Even if the patient does have VCI, these substances will likely worsen impairment and should be eliminated in any case.

Individuals with a history of stroke or ischaemic white matter disease show increased rates of depression, which can contribute to functional impairment and may resemble a neurocognitive disorder but which is reversible with appropriate treatment [1]. Clinicians assessing a patient for cognitive impairment should always evaluate for depression and treat it whenever present, regardless of whether or not it caused the cognitive problems—comorbid untreated depression can substantially worsen cognitive function. In addition to causing emotional suffering, post-stroke depression is associated with increased mortality, more disability, slower neurologic recovery, an increased risk of suicide, and worse quality of life [24]. The cognitive deficits most consistently associated with depression are impairment of attention/concentration, frontal executive function, working memory, and processing speed; depression would be very unlikely to cause other deficits such as aphasia or neglect [25].

Sometimes, it may not be possible to determine whether cerebrovascular disease or another condition such as AD is the primary determinant of cognitive impairment. However, in either case, uncontrolled vascular risk factors can cause worsening of functioning and cognition, so vascular risk factor modification should be undertaken regardless. Any patient with cerebrovascular disease needs vascular risk factor modification, regardless of cognitive status or type of cognitive disorder.

Mechanisms of VCI

Although strokes can produce cognitive impairment by direct damage to brain regions involved in cognition, additional mechanisms likely can also give rise to VCI.

Small-vessel VCI may disrupt the neurovascular unit, that is, the vascular endothelium, perivascular cells, glia, and neurons, which work together and influence each other to maintain cerebral homeostasis—via inflammation and damage to the blood–brain barrier, as shown in Fig. 46.2 [1, 7]. Injury to the neurovascular unit may play key role in the progression of white matter injury in small-vessel VCI and occurs more frequently in VCI than when white matter changes occur in the context of AD [6]. Neuropathologic findings in small-vessel VCI include abnormalities in and around small vessels, including endothelial dysfunction, vessel fibrosis, and inflammation [6]. These changes may cause cerebrovascular resistance and decreased cerebral blood flow, thereby potentially contributing to hypoperfusion and further vascular damage [4]. The CSF of individuals with small-vessel VCI shows elevations in albumin and matrix metalloproteinases, consistent with inflammation and blood–brain barrier disruption; specialized MRI also reveals evidence of damage to the blood–brain barrier [6, 26]. Damage to the neurovascular unit may impair perfusion during cognitive activities and thus further exacerbate neuronal dysfunction in vascular cognitive impairment [4].

In addition to the classic findings of ischaemia or haemorrhage, VCI may cause other brain changes which could adversely affect

cognition. VCI may cause changes in the corpus callosum, such as decreased white matter integrity and perhaps decreased size, potentially affecting interhemispheric transmission of information [27]. One study also found decreased white matter integrity in the corpus callosum in VasD [27]. One study found that strategic-infarct VCI from isolated left thalamic stroke was associated with decreased cerebral blood flow in both hemispheres, suggesting that even a single small stroke can have far-reaching consequences, perhaps by disrupting broader networks involved in cognition [28].

A cross-sectional study found that individuals with ‘asymptomatic’ subcortical lacunar infarcts showed more cortical and subcortical atrophy and more cognitive impairment than healthy controls [29].

Though classically associated with AD, cholinergic deficits may occur in VCI as well [1]. Neuropathologic case-control studies found impairment of cholinergic pathways in small-vessel VasD and CADASIL [30]. However, another neuropathologic case-control study found that individuals with ‘pure’ VasD, without any evidence of AD-type pathology, did not show evidence of temporal lobe cholinergic deficits, as compared to healthy controls; on the other hand, individuals with mixed VasD-AD did show cholinergic deficits comparable to those seen in ‘pure’ AD [31].

Outcomes and consequences of VCI

There is contradictory evidence on whether VasD progresses faster or more slowly than AD. Some studies have found that individuals with VasD survive for a mean of 5–6 years following diagnosis, a slightly shorter survival than in AD; however, these studies are over 20 years old and may not reflect changes in diagnosis (that is, increased detection sensitivity with more widespread use of MRI) and advances in vascular risk factor control, which could potentially improve survival in the current era [32]. One large cohort study of memory clinic patients seen found that individuals with VasD show slower progression of functional decline than those with AD [33]. However, only 2% of study participants had VasD, a far lower number than their proportion among dementia cases in the general population, raising questions about the generalizability of this finding.

VasD increases the risk of subsequent stroke and adversely affects stroke recovery. Individuals with VasD, but no prior history of clinical stroke or transient ischaemic attack (TIA), show a 2-fold higher risk for subsequent ischaemic stroke and TIA and a 4-fold higher risk for subsequent haemorrhagic stroke [34]. One study of patients hospitalized for acute stroke found that those with VasD have less functional recovery at 1 year follow-up than those with normal cognition; however, VCI not rising to the level of dementia did not worsen functional outcomes [35].

Individuals with VasD also show higher rates of other vascular diseases—namely, atherosclerosis, heart failure, and atrial fibrillation—as well as higher rates of non-vascular comorbidities such as sepsis, injuries, lung diseases including chronic obstructive pulmonary disease, and urinary diseases [36].

VasD increases the risk for delirium, which can worsen dementia outcomes [37]. One study of memory clinic outpatients found that one-third of patients with VasD had superimposed

Fig. 46.2 Schematic diagram of the pathophysiology of small-vessel VCI.

delirium at the time of their clinic visit [37]. Among individuals with neurodegenerative dementias such as AD, those with imaging evidence of comorbid cerebrovascular disease had higher rates of delirium than those without cerebrovascular disease [37]. Clinicians

treating patients with VasD should carefully monitor for delirium and educate family members and other caregivers about the symptoms and significance of delirium, so that they can seek treatment promptly if it occurs.

Risk factors

Stroke

Stroke, whether clinically apparent or silent, whether haemorrhagic or ischaemic, is a major risk factor for VCI. Having a clinical stroke doubles the risk for dementia [1]. Among people with stroke, 7% develop new-onset dementia within the first year after the stroke and nearly 50% develop dementia over the next 2 years [1]. Forty per cent of patients with first ever ischaemic or haemorrhagic stroke, who do not have severe aphasia, have VCI at 3-months' follow-up [38].

Individuals with silent ischaemic strokes, WMHs, and/or 'asymptomatic' cerebral microbleeds also show an increased risk for subsequently developing cognitive impairment [1, 8]. Among patients with MCI, those with more WMHs are more likely to convert to VasD [39].

All else being equal, patients with more brain territory affected by infarcts are more likely to have cognitive impairment than those with less affected territory. However, since other factors, such as stroke location, vary significantly between patients, overall there is no clear relationship between the number/volume of strokes and cognitive impairment [1]. For instance, even a small lacunar infarct in the thalamus could produce major cognitive consequences, while a larger infarct in the deep white matter could go largely unnoticed.

Other vascular risk factors

In addition to stroke itself, vascular risk factors associated with stroke also increase the risk for VCI. Even in the absence of stroke or dementia, individuals with more vascular risk factors show worse cognitive performance [4].

One large population-based prospective study of factors important for good vascular health—not smoking, maintaining a healthy body weight, engaging in regular physical activity, eating a healthy diet, and having blood pressure, cholesterol, and fasting glucose at goal—found that the more of these factors an individual had, the lower his or her risk for subsequent stroke, VasD, or cognitive decline [40]. Importantly, all of these factors are potentially modifiable, suggesting a strategy for preventing dementia.

Multiple longitudinal studies support an association between mid-life hypertension and subsequent development of VasD [1]. Hypertension appears to be a major risk factor for small-vessel VasD, found in a significant majority of patients [6]. However, one study in South Korea found that 25% of individuals with small-vessel VasD did not have any current or previous hypertension [41]. These individuals also had lower rates of other vascular risk factors such as DM, hyperlipidaemia, and obesity and lower rates of clinical stroke than other patients with subcortical VasD, and were not more likely to smoke [41]. Potentially, they have other novel risk factors predisposing them to small-vessel VasD [41]. One cross-sectional case-control study found that individuals with a history of hypertension had decreased cortical blood flow in the temporal and occipital lobes; this finding suggests an additional pathway by which hypertension could contribute to VCI, but the study did not actually measure cognition, making it impossible to draw a firm conclusion [42].

Most, but not all, studies have found that atrial fibrillation increases the risk for VasD; in the studies that did not find an increase risk, it is possible that participants were more effectively anticoagulated, thus attenuating their risk [1].

Diseases of other blood vessels—including CAD, peripheral arterial disease, carotid atherosclerosis, and carotid thickening or stiffening—are associated with an increased risk for VasD [1]. Some studies have found that increased carotid artery thickening and stiffness are associated with worse cognitive performance; although one study found that carotid artery stiffness predicted subsequent cognitive worsening, it is not known whether carotid artery changes cause or contribute to cognitive impairment or whether they are both related to some other factors [1].

Smoking is associated with a 1.4-times greater risk for subsequently developing VasD; however, former smokers who have quit do not have an elevated risk [43]. Similar relationships with smoking are seen for AD and all-cause dementia as well [43]. This pattern suggests that smoking increases the risk for developing VasD—as well as dementia in general—but that quitting smoking can eliminate this excess risk [43].

Type 2 DM (T2DM) increases the risk for subsequently developing VasD by 2.5 times; T2DM also increases the risk for AD, but not by as much [42]. Insulin resistance also increases the risk for VasD [8].

The role of hyperlipidaemia in VCI remains unclear [1].

Genetic risk factors

CADASIL is a Mendelian genetic disorder caused by mutations in the *NOTCH3* gene and markedly increases the risk for VCI [43]. CADASIL is the most common hereditary stroke syndrome, with a prevalence of up to 1 in 20,000 adults [43]. One epidemiologic study found that 48% of individuals with CADASIL had cognitive impairment [43].

Apolipoprotein E (APOE) is a protein involved in lipid metabolism, including CNS cholesterol transport, among other functions; it is well known that APOE 4 polymorphism increases the risk for AD [8]. The role of APOE polymorphisms in VasD risk is still unclear; a majority of studies have found that the APOE 4 allele does increase the risk for VasD, though the magnitude of increased risk is less than that for AD [8]. However, a significant minority of studies have found no relationship [8]. As the negative studies were conducted in areas where people may be more likely to eat a Mediterranean diet or a diet high in fish, diet could potentially moderate the relationship between APOE genotype and VasD, such that individuals with APOE 4 alleles who consume a heart-healthy diet do not face an increased risk, while those with APOE 4 alleles who eat more saturated fat and cholesterol do; however, no study has yet investigated this question [8].

Other risk factors

Individuals with depression late in life have a 2.5 times greater likelihood of subsequently developing VasD [46].

Inflammation and oxidative stress may also increase the risk for VCI. Increased blood levels of inflammatory proteins, such as α -1-chymotrypsin, C-reactive protein, and interleukin-6, are associated with an increased risk for subsequently developing VasD [1]. Chronic kidney disease—typically accompanied by inflammation, in addition to other adverse physiologic changes—is also associated with an increased risk for VasD [1]. One cross-sectional case-control study found that individuals with VasD showed a biomarker pattern consistent with increased oxidative stress, as compared to healthy controls, even after adjusting for other vascular risk factors [47]. Individuals with VasD may also show hyperhomocysteinaemia and hyperuricaemia [47].

One cross-sectional case-control study found lower serum levels of brain-derived neurotrophic factor (BDNF) in individuals with VasD than in healthy controls [46]. BDNF plays an important role in synaptic plasticity and neuronal survival, so loss of BDNF could plausibly contribute to dementia [46]. However, a prior study found that BDNF levels were not decreased in VasD; this may possibly reflect the different levels of VasD severity in the two studies [46].

Prevention and disease-modifying treatment

As VCI is caused by damage to the brain from vascular causes, that is, strokes and ischaemic demyelination—interventions to reduce the risk of stroke and improve vascular health can help prevent VCI and help arrest disease progression once VCI is present. Rates of VasD are falling, a hopeful finding which appears due, in part, to improvements in vascular risk factor modification [3].

Hypertension is the single most common modifiable stroke risk factor, and hypertension should be treated to reduce the risk for VasD [1]. One RCT in patients with a history of stroke found that reducing blood pressure with antihypertensives reduced the risk for developing dementia, and a prospective cohort study found an inverse relationship between VasD and antihypertensive drug use [1, 8]. White matter lesions increase when hypertension is not controlled, while treatment of hypertension reduces their progression [6].

Numerous observational studies of the Mediterranean diet, as well as one RCT of a Mediterranean diet supplemented with olive oil or nuts, have found that this diet reduces the risk of cognitive decline [49]. Although these studies did not specifically target individuals with VCI, other studies have found that a Mediterranean diet and olive oil can both reduce the risk of clinical stroke, WMHs, and silent stroke, making it very plausible that this diet could reduce the risk of VCI and even potentially slow disease progression in those who have it [49]. Theories for why a Mediterranean diet could benefit cognition and reduce vascular disease include its high levels of antioxidant and anti-inflammatory substances, including polyphenols and omega-3 fatty acids [49].

A meta-analysis of prospective longitudinal studies found that people who regularly exercise are less likely to get VasD [50]; however, these non-RCT studies do not permit a determination of causality. One cohort study of patients with white matter lesions found that increased physical activity was associated with lower rates of cognitive impairment [6].

RCTs of antioxidant and B vitamin supplementation—albeit not focusing on individuals with VCI—have, in general, found no effects on cognitive function, though some subgroup analyses suggest that some particular individuals (for example, those with poor dietary intake of vitamin B) may potentially experience some benefit [1].

Patients with VCI, a history of stroke or TIA, or imaging evidence of cerebrovascular disease should be worked up for modifiable risk factors—most importantly, hypertension, DM, and atrial fibrillation. Patients without these classic vascular risk factors—particularly young individuals—should undergo work-up for hypercoagulable states and other causes of cryptogenic stroke. All clinicians should encourage smoking cessation, as quitting smoking reduces the risk for subsequent VCI to the level of that seen in never-smokers [43]. Aggressive secondary stroke prevention measures—such

those delineated in the American Heart Association/American Stroke Association guidelines—should be undertaken to prevent worsening of cognitive impairment and disability and to lessen the risk for future stroke.

Symptomatic treatment

Although there are no FDA-approved treatments for VCI, there is reasonably good evidence to support the off-label use of medications approved for other conditions to ameliorate the symptoms of VCI.

Cognitive-enhancing drugs approved for AD—cholinesterase inhibitors and memantine—appear to show benefit in VCI as well. Donepezil has the best evidence base for use in VasD without concomitant AD [1]. Multiple double-blind, placebo-controlled RCTs have shown that donepezil improves cognition in VasD; however, different studies have differed on whether donepezil also improves functional outcomes [1]. In one study of donepezil, the 10 mg/day dose showed superiority to the 5 mg/day dose on the measure of dementia severity, but the doses did not differ on other measures [51].

Galantamine also has evidence supporting its use in VasD, with RCTs showing it improves cognition; however, the evidence is more robust for mixed AD-VasD than for pure VasD [1].

One large placebo-controlled trial found that oral rivastigmine improved cognitive outcomes, though not overall functional status, in individuals with VasD; however, a subgroup analysis found that the cognitive benefit was driven by participants aged 75 years old or above, who may have been more likely to have concomitant AD pathology [52]. Two small studies of rivastigmine in VCI did not find any benefits; however, it is possible they were underpowered, and in addition, one study used a smaller dose (6 mg/day) than the study which did find cognitive benefit (mean dose 9.4 mg/day) [53].

Overall, cholinesterase inhibitors appear to be safe and well tolerated in VasD, with rates and severity of adverse effects similar to those observed in AD [1].

Two double-blind, placebo-controlled RCTs examined the uncompetitive NDMA inhibitor memantine in VasD. Both found that memantine improved cognitive outcomes but did not affect functional status [54, 55]. Memantine was safe and well tolerated in these studies [54, 55].

In addition to their benefits in VasD, donepezil, galantamine, and memantine have RCT evidence that they are effective for post-stroke aphasia, again suggesting these agents can improve cognitive deficits due to cerebrovascular disease [56].

Some preliminary data suggest that SSRIs may improve cognition in VCI. A small randomized, open-label trial of fluoxetine in non-depressed patients with VasD found that participants in the fluoxetine group showed a small, but statistically significant, increase in cognitive function following 12 weeks of treatment [57]. Serum BDNF levels in the fluoxetine group also increased more and positively correlated with the degree of cognitive improvement, suggesting an SSRI-induced BDNF increase as one potential mechanism for the cognitive benefit [57]. A double-blind study of escitalopram in patients with stroke, but not necessarily VasD, and a retrospective open-label case series examining sertraline in VCI found similar cognitive improvement [57, 58]. Further studies are needed to help elucidate whether SSRIs may play a role in the treatment of cognitive impairment due to cerebrovascular disease, but these results suggest

SSRIs may represent one additional potential avenue of therapy. Fluoxetine has randomized, double-blind, placebo-controlled trial evidence that it can improve motor function following stroke, which suggests another way in which SSRIs could benefit individuals with VCI, many of whom also have motoric deficits [59].

One small double-blind, randomized, placebo-controlled trial for the treatment of aphasia in acute stroke found that dextroamphetamine improved language function in the subacute period [60]. It is unknown if stimulants could improve other post-stroke cognitive deficits.

Some individuals with dementia may develop severe behaviour problems and often receive dopamine antagonist drugs as treatment, though given their potential for adverse side effects, they should be reserved for situations in which non-pharmacologic means have failed. While dopamine antagonist drugs appear to improve behavioural disturbance in the short term in AD, there are no high-quality data on whether they are effective in VasD [61]. However, a retrospective cohort study of individuals with VasD, followed up for a mean of 2 years, found that patients who were prescribed risperidone, quetiapine, or olanzapine did not show an increased mortality risk; of note, the study did not examine the use of other dopamine antagonist drugs and did not evaluate adverse outcomes other than death [61].

Standard rehabilitation therapies for post-stroke cognitive deficits, for example speech therapy for aphasia, prism glasses for neglect, etc., may also be useful in patients with VCI who have these deficits, though they have not been specifically studied in the VCI population. Nonetheless, given the favourable benefit/risk ratio, if a patient with VCI has a cognitive deficit with a known post-stroke rehabilitation strategy, the patient should be offered the intervention.

Thus far, psychosocial interventions for VCI have received little study. One uncontrolled trial of recreation therapy—playing games, dancing, and playing music—improved cognitive function in patients with VasD, and the benefit increased with increasing number of sessions [62]. Given the potential for benefit and the very low risk of harm, it is reasonable to try psychosocial strategies with evidence for efficacy in dementia in general such as environmental enrichment, animal therapy, baby doll therapy, physical activity, social engagement, and provision of enjoyable activities [63].

Conclusions

VCI represents a leading cause of cognitive impairment, but vascular risk factor modification may reduce VCI risk and decrease disease progression. Individuals without a history of clinical stroke may still have VCI, so clinicians should consider this diagnosis in any patient with acquired cognitive impairment. Cholinesterase inhibitors and possibly memantine may improve cognitive functioning in individuals with VCI.

Traumatic brain injury

Christian Lepage, Inga K. Koerte, Vivian Schultz, Michael J. Coleman, and Martha E. Shenton

Introduction

Traumatic brain injury (TBI) is the result of blunt trauma, acceleration–deceleration forces, rotational forces, or blast exposure to the head. The injury involves a heterogeneous pattern of focal and/or diffuse damage to the brain. The severity of the injury covers the spectrum from mild to moderate to severe, with severe injury leading to possible coma and even death. In addition, the range of symptoms, the variability in treatment options, and the prognosis of TBI, as well as the psychosocial implications, make it a complex injury that often calls upon the services of neurosurgeons, neurologists, psychiatrists, psychologists, and rehabilitation specialists to help patients achieve the best outcome possible.

The aim of this chapter is to provide an overview of TBI that includes the classification, epidemiology, aetiology, and pathophysiology of TBI. This is followed by an overview of clinical symptoms and long-term outcome. We then review diagnostic implications and treatment options. This is followed by a review of other neuropsychiatric disorders that evince overlapping symptoms such as post-traumatic stress disorder (PTSD) and depression. We end with a summary that emphasizes evidence-based diagnosis and the need for more research focused on recovery over time.

Classification of mild, moderate, and severe TBI

TBIs are commonly classified into mild, moderate, and severe, using the Glasgow Coma Scale (GCS) score [1]. The GCS measures patient responsiveness along three dimensions: eye opening, verbal performance, and motor response. GCS scores range from 3 to 15, with higher scores reflecting greater functioning. GCS scores indicate TBI severity as follows: GCS scores of 13–15 are considered mild, 9–12 moderate, and 8 and below severe (Table 47.1). Further, duration of loss of consciousness, along with time span of post-traumatic amnesia (PTA), is also used to classify the degree of severity. The term ‘concussion’ is often used as a synonym for mild TBI (mTBI), both in general and in the field of sports-related brain injury. For a review of TBI classification approaches, see [2].

Epidemiology

TBI is a leading cause of disability and mortality [3] throughout the world. In the United States, an estimated 2% of the population lives with disability resulting from TBI. The annual incidence of TBI is approximately 1.7 million [4]. Fortunately, approximately 80% of these injuries are considered to be ‘mild’. The prevalence of mTBI is, however, likely greatly underestimated, as the extant statistics frequently exclude cases of TBI treated in non-hospital and military settings. Additionally, it is not known how many individuals do not seek medical care or whose diagnoses are missed altogether. Thus, the true prevalence is likely much higher for those with mTBI.

The annual direct costs associated with TBI are estimated to be \$13 billion, while the indirect costs, which include missing days of work, are estimated to be \$65 billion, making TBI one of the most costly health problems needing rehabilitation services [5]. Of further note, longterm disability is estimated to affect 43% of post-acute hospitalization cases [5]. Further, within 1 year of TBI, nearly a third of patients report difficulties with two or more activities of daily living, while about 40% require the assistance of another person due to cognitive and/or physical disability (mainly those with moderate or severe TBI). For example, a prospective study by Ponsford *et al.* [6] showed that, of patients employed prior to moderate or severe TBI, only 40% returned to work in some capacity (either to pre-injury or modified duties) when assessed at 2, 5, and 10 years post-injury. Thus, the outcome for those with more moderate and severe TBI is worse than for the majority of patients who are diagnosed with mTBI.

Aetiology

Sources of injury and mortality

The leading causes of TBI based on emergency department visits in the United States are falls (41%), a head strike by or against an object (19%), motor vehicle traffic accidents (15%), and assaults (11%) [7]. Falls associated with TBI are most common in children under 4 years of age and in adults 75 years and older, while TBI resulting

Table 47.1 Traumatic brain injury severity classification

Severity	GCS score	Alteration in consciousness	Loss of consciousness	Post-traumatic amnesia
Mild	13–15	≤24 hours	0–30 minutes	≤24 hours
Moderate	9–12	>24 hours	>30 minutes, <24 hours	>24 hours, <7 days
Severe	3–8	>24 hours	≥24 hours	≥7 days

GCS, Glasgow Coma Scale.

from motor vehicle accidents is most common between the ages of 15 and 34 years, and TBI resulting from assault is most common between the ages of 20 and 34 years [4]. Additionally, head impacts by or against an object are most common from childbirth to 19 years and peak again between the ages of 25 and 34 [4]. Finally, TBI-related mortality is most commonly caused by firearms (35%), motor vehicle accidents (31%), and falls (17%) [8].

Risk factors for TBI

The incidence of TBI is affected by a number of variables, including sex, age, socio-economic status, race and ethnicity, alcohol and other substance use, and experiencing a previous TBI. More specifically, across the sexes and over the lifespan, TBI is most common in children age 0 to 4, adolescents age 15 to 19, and adults over the age of 75 years [4]. Males have a higher incidence of TBI than females across all age groups [4, 9], with the exception of those who are aged 75 years or older where females have a higher incidence. The greater number of TBIs in males has been attributed to increased risk-taking behaviours and activities.

The incidence of TBI also varies by socio-economic status, with a higher incidence of TBI in families with lower income. The incidence of TBI is also increased in non-white ethnic groups in the United States [4, 8]. Moreover, African Americans, Native Americans, and Alaska Natives are reported to have the highest incidence of assault TBI [10]. The use of alcohol and other substances is also often associated with an increased risk for TBI [11]. It has also long been recognized that an initial TBI carries a greater risk than the general population for subsequent TBI(s) [12]. In fact, individuals who incur a first TBI are three times more likely to incur a second TBI, and those who incur a second TBI are 7.8 (males) to 9.3 (females) times at greater risk for a third TBI [13].

Pathophysiology

TBI may lead to shear deformation of the brain with stretching of axons and the surrounding myelin sheath. This stretching may result in changes in cell membrane permeability, which may, in turn, result in ionic shifts, including an influx of calcium. Calcium may then accumulate in the mitochondria where it leads to impaired oxidative metabolism, with subsequent energy failure of the cell, and eventually to the breakdown of microtubules. In addition, there may be other factors that contribute to brain injury such as sudden changes in cerebral blood flow and decreases in inhibitory neurotransmitters such as GABA and/or activation of NMDA receptors. [14, 15].

Brain injury following TBI is characterized by focal and/or diffuse neuropathologies that, depending upon their localization and severity, can lead to dysfunction at physiologic, cellular, and subcellular

levels. The initial effects of a head injury include scalp and skull lesions, cerebral contusions, haemorrhages, intracranial haematomas, and diffuse traumatic axonal injuries [16]. The primary injury may also initiate processes that lead to secondary damage, which can evolve over the course of recovery and may result in later effects of injury. Such secondary damage is more likely in moderate and severe TBI and may include ischaemia, elevated intracranial pressure, neuroinflammation, cell death, infection, and gliosis [16]. In mTBI, there are generally no visible brain alterations observed on CT scans or conventional MRI scans, although there is evidence of brain injury in post-mortem studies of those diagnosed with mTBI who died from other causes [17].

Clinical presentation

Moderate and severe TBI

TBI is associated with a range of neurologic, neuropsychiatric, cognitive, and behavioural disturbances where the degree of impairment typically reflects the severity of the injury. In the acute phase following injury, the symptoms observed often reflect the location and severity of damage to brain tissue and blood vessels, as well as the presence of concomitant injuries, e.g., skull fracture. Acute symptoms may include headache, nausea, dizziness, disorientation, and disturbances of consciousness or even coma [18]. In the subacute phase following injury, seizures are common and carry the added risk of a secondary injury to the brain [19]. In the chronic phase, moderate to severe TBI may result in alterations in consciousness, paresis, neuropathies, speech impairments, seizure disorders, attention, memory, and concentration problems, sleep disturbances, changes in personality, depression, irritability, impulsivity, fatigue, and other emotional and behavioural problems [20].

Mild TBI

Acute symptoms following mTBI may include nausea, headache, neck pain, blurred vision, insomnia, dizziness, postural instability, fatigue, memory, attention, concentration problems, and slowed processing speed, among other symptoms such as light and sound sensitivity [18]. These symptoms are typically most prominent in the acute stage of post-injury and, in most cases, resolve over days and weeks (Fig. 47.1). It is important to note, however, that not all symptoms are present in all patients who suffer from mTBI, and in the absence of radiological evidence from CT or MRI, the diagnosis is generally made based on the occurrence of a head trauma and self-reported symptoms.

In the event that there are radiological findings in mTBI, for example cerebral contusion or haematoma, such an injury is often referred to as ‘complicated mTBI’ [21]. Of note here, there appear to

Fig. 47.1 This is a schematic multistage disease model of possible short- and long-term sequelae, following single and repetitive brain trauma. There are three possible trajectories: an acute/subacute phase, a chronic/static phase, and a neurodegeneration phase. Subconcussive head impacts usually do not result in acute symptoms indicated by the horizontal dotted line in the acute/subacute stage. Some patients may experience chronic post-concussive symptoms that resolve over time (black line) or continue (light grey band). A small subgroup will develop a neurodegenerative disease (darker grey band).

be no differences in reported symptoms, neurocognitive measures, or long-term prognosis in those diagnosed with complicated mTBI vs mTBI. Notably however, as a group, those with complicated mTBI tend to take longer to return to work than those with mTBI without radiological findings [21]. Moreover, a recent study by Panenka and colleagues [22] reported that while there were no differences between mTBI and complicated mTBI with respect to reported symptoms, neurocognitive functioning, or clinical outcome, there were differences in DTI findings 6–8 weeks following injury. Thus, diffusion imaging measures may be a more sensitive measure of diffuse axonal injury, which is one of the most characteristic findings in mTBI.

Long-term outcome

Post-concussive syndrome

While most individuals recover completely from mTBI, there are up to 15–30% who continue to experience cognitive and behavioural symptoms that may persist for months or even years [23] (Fig. 47.1). These individuals have been referred to as the ‘miserable minority’ [24]. The term ‘post-concussion syndrome’ (PCS), or persistent post-concussive symptoms, has been used to describe these patients where there is often a combination of non-specific symptoms that persist beyond 3 months post-injury. Symptoms may include headache, fatigue, dizziness, blurred vision, nausea, irritability, sleep disturbances, hypersensitivity to light and noise, depression, and anxiety, in addition to deficits in attention, memory, concentration, executive function, and speed of processing (for example, [25]). PCS is presumed to result from a dysfunctional cognitive feedback loop [26] where acute TBI-related symptoms disrupt cognition and cause anxiety, which, in turn, results in further cognitive disruption. The literature suggests that there may also be premorbid risk factors that contribute to the development of PCS. These risk factors may include neurologic findings, psychological and personality

factors, psychosocial issues, and/or being a participant in litigation (for a review, see [27]). Cognitive biases and misattribution of symptoms, as well as excessive cognitive and physical rest, may also contribute to prolonged recovery from mTBI. The problem is further compounded by the fact that the symptoms in mTBI in general, and in PCS in particular, also overlap with other disorders such as depression and PTSD. Nonetheless, taken together, the possible explanations for PCS are many. It is also clear that radiological evidence that goes beyond conventional MRI and CT is needed because these more conventional measures lack sufficient sensitivity to detect diffuse axonal injuries, which, as noted previously, are the most common brain injury in mTBI [28].

Psychosocial issues

TBI-related alterations in cognition, behaviour, and emotion can also adversely affect psychosocial adjustment across multiple domains, including life satisfaction, social functioning, employment and school, independent living, and leisure activities (for reviews, see [29, 30]). For example, moderate to severe TBI is often associated with lower overall life satisfaction, both in the acute and long term post-injury phases. Changes in life roles (for example, work, hobbies, relationships) and depression are common following such TBI, and they are strong predictors of life satisfaction across the first 5 years post-injury [31], making these important targets for early intervention.

Several pre-injury variables are also noted to increase the risk for poor psychosocial outcome following TBI. Pre-injury psychiatric burden and a history of substance abuse are, for example, both associated with decreased employment and independent living status following moderate to severe TBI. Furthermore, both pre-injury functioning (including education and employment) and pre-injury condition (including psychiatric disorder, substance abuse, sensory dysfunction, and learning difficulties) are associated with less post-injury life satisfaction and function [32].

Families and caregivers are also an integral part of rehabilitation following TBI. Unfortunately rates of distress, including anxiety, depression, and poor social adjustment, are common in adult caregivers of individuals with TBI (for a review, see [33]). Such interpersonal challenges, initiated by TBI, may change family roles, and relationships may become strained. In mild to moderate TBI, better family functioning, including reduced caregiver distress, is associated with greater home and social integration [34]. In severe TBI, increased social support of the caregiver is associated with improved productivity and social integration in the patient [34]. Thus, support for TBI patients, as well as for their families and caregivers, is a critical part of any rehabilitation programme.

Neurodegenerative disorders

Neurodegenerative disorders have been associated with a *history* of TBI (Fig. 47.1). There is evidence to suggest that a history of TBI is associated with a greater risk for Parkinson's disease [35], amyotrophic lateral sclerosis [36], and Alzheimer's disease [37]. In general, a history of TBI is believed to increase the risk for later-life proteinopathies, which are the underlying pathophysiology of these three neurodegenerative disorders [36]. Another proteinopathy with a strong link to a history of repetitive TBI is chronic traumatic encephalopathy (CTE).

In post-mortem studies, CTE is characterized by a pathognomonic pattern of perivascular deposition of hyperphosphorylated tau (p-tau) in neurons and astrocytes. In early stages of the disease, more focal perivascular accumulations can be detected at the depths of the cortical sulci. As the disease progresses, widespread distribution is detected throughout the brain [38]. In later stages of the disease, brain atrophy may be extant [38]. At present, CTE is diagnosed post-mortem. Moreover, a history of exposure to repetitive head impacts is assumed to be a necessary, but not sufficient, cause for the development of CTE (for a review, see [39]).

CTE has most often been reported in athletes participating in contact sports involving repetitive head impacts (for example,

boxing, ice hockey, American football, and soccer) and in military service members who are exposed to blast and/or direct head impacts [38, 40]. The clinical presentation of CTE, however, is not well understood [38, 41, 42]. Via next-of-kin interviews and medical record review of neuropathologically confirmed CTE, a constellation of prodromal symptoms appears to herald the disease. These symptoms include disturbances in behaviour (e.g., increased impulsivity and aggression), mood (e.g., depression), and cognition (e.g., difficulties with memory and executive function, as well as eventual dementia) [42]. In addition, symptoms associated with CTE may begin years following exposure to repetitive head impacts. At this point, it is not known why some individuals experience symptoms earlier and in closer proximity to the repetitive head impacts. At present, knowledge regarding the course of neurodegenerative brain alterations that result from repetitive blows to the head is sparse.

Repetitive subconcussive head impacts

Subconcussive head impacts generally do not result in acute symptoms but may lead to structural and functional brain changes similar to those caused by mTBI [43]. Using diffusion MRI, a study by Koerte and colleagues detected microstructural brain alterations in active soccer players without a history of concussion or mTBI. However, professional soccer players experience a large number of repetitive head impacts while heading the ball [44] (Fig. 47.2).

Another study reports impaired brain function using task-based functional MRI in contact sports athletes without a history of concussion. Further studies also demonstrate cognitive, functional, and biochemical changes in athletes participating in contact sports, despite the absence of clinical symptoms associated with mTBI (for a review, see [45]). These findings may be due to cumulative effects of repetitive head impacts or they may reflect the beginning stages of a neurodegenerative disease, including CTE [46]. It is also not known if these observed brain changes are reversible, although one

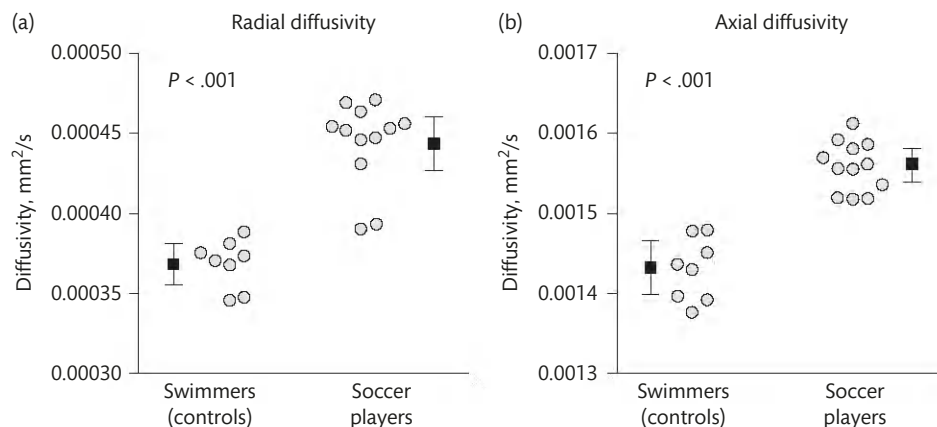

Fig. 47.2 Diffusion tensor imaging was used to compare professionally trained young adult soccer players with age- and gender-matched controls engaged in a non-contact sport (swimming). Increased radial diffusivity was observed in the white matter in soccer players, compared to swimmers, suggesting structural changes similar to those changes observed after mTBI.

Reproduced from JAMA, 308(18), Koerte IK, Ertl-Wagner B, Reiser M, *et al.*, White matter integrity in the brains of professional soccer players without a symptomatic concussion, pp. 1859–61, Copyright (2012), with permission from American Medical Association.

recent study of college football players suggests that following a rest period of 6 months, subtle microstructural changes reverted to baseline [47].

Diagnostic implications

Neuroimaging

In the acute setting, neuroimaging modalities such as CT and non-contrast MRI are often used to rule out complications in TBI, including fracture of the skull, haemorrhage in the intracranial compartments, and oedema. However, only 10% of CT scans and 30% of magnetic resonance scans reveal abnormalities in mTBI [28]. Moreover, CT and conventional MRI are not sensitive enough to detect subtle brain alterations, including traumatic axonal injury, which is commonly observed following mTBI [28]. Most importantly, information based on conventional CT and MRI is not associated with long-term prognosis following mTBI. There is thus a critical need to follow these individuals over time in future studies.

Indeed, radiological evidence for mTBI is needed using highly sensitive and objective measures to ensure early diagnosis and provide accurate prognosis. Currently there are advanced neuroimaging modalities being developed to understand better brain abnormalities following TBI, and especially mTBI and repetitive brain trauma (for a review, see [28, 45]). These imaging modalities include techniques to investigate brain structure

Fig. 47.3 (see Colour Plate section) Diffusion tensor imaging measures the preferred direction of diffusion of water molecules. High directionality of diffusion can be observed in well-organized regions of the brain such as in the corpus callosum, as depicted here (see arrows). Diffusion tensor imaging provides information about the microstructure of brain tissue and thus may provide useful information in patients with TBI where diffuse axonal injury that involves the white matter is common. Reproduced from Koerte IK, Hufschmidt J, Muehlmann M, *et al.*, *Advanced Neuroimaging of Mild Traumatic Brain Injury*. In: Laskowitz D, Grant G [Eds.], *Translational Research in Traumatic Brain Injury*, pp. 277–299, Copyright (2016), with permission from Taylor & Francis Group LLC.

(structural MRI) and tissue microstructure (DTI) (Fig. 47.3), as well as blood flow (arterial spin-labelling, single-photon emission tomography) and to detect micro-haemorrhages (susceptibility-weighted imaging). There are also techniques to measure indirectly brain function (fMRI) and brain metabolism (PET, MRS) (for reviews, see [28, 45]).

Neuropsychological evaluation

A neuropsychological assessment may also contribute to understanding cognitive functioning in TBI, including psychiatric and neurobehavioural sequelae. Such an evaluation typically includes the assessment of cognitive, emotional, and psychosocial domains. In the acute stage of recovery from TBI, comprehensive assessments are not typically carried out because in cases of moderate to severe TBI, patients often exhibit various symptoms, such as variable or absent responsiveness, disorientation and/or delirium, and disrupted comprehension, each of which can interfere with accurate neuropsychological assessment [48]. Instead, a brief evaluation at the bedside may help to determine the patient's level of consciousness, the magnitude of PTA and confusion, general cognitive functioning, language functioning, and the emotional state. Several such bedside evaluations may reveal changes in the patient's status and also inform early clinical care. These assessments may also help to provide feedback to the patient, family, and caregivers, as well to monitor treatment interventions (for example, medication) and decision-making capacity (for an in-depth review, see [49]).

The cognitive sequelae of TBI are also variable and are influenced by pre-, peri-, and post-injury factors [50, 51]. Thus, when indicated, comprehensive neuropsychological assessments may play an important role in characterizing specific cognitive deficits and strengths, as well as aid in educating both patients and families, establishing treatment goals, developing rehabilitation plans, and informing prognosis [52]. In moderate to severe TBI, such assessments are recommended once patients have recovered from states of confusion and/or at 3- and 6-month intervals [53]. In mTBI, cognitive disruption, if any, is generally resolved within days of post-injury [54, 55], which has led some to recommend that comprehensive neuropsychological assessments are indicated only after this time period [56]. In sports-related concussion, on the other hand, baseline neuropsychological data are increasingly collected, albeit from briefer assessment batteries such as the Immediate Post-Concussion Assessment and Cognitive Testing (ImPACT) [57]. Here, repeat testing informs concussion management, including return-to-play decisions. Concussed athletes are usually removed from both play and practice until they are asymptomatic and neuropsychological testing demonstrates baseline performances [52].

Electroencephalography

EEG is an important assessment tool for the clinical management of moderate and severe TBI in the acute phase of injury. More specifically, EEG is used to determine the depth of coma and to diagnose cerebral death [58]. Continuous EEG monitoring is recommended, particularly in the acute period following moderate to severe injury, in order to detect (subclinical) seizures which are common and carry the risk for secondary injuries to the brain [59]. Alterations in EEG in these patients also provide prognostic information regarding outcome. In subacute to chronic phases following moderate to severe

TBI, EEG is important for the diagnosis of post-traumatic epilepsy. The severity of TBI is, in fact, a strong risk factor for post-traumatic epilepsy [60]. Although the risk is highest within 6 months after injury, it is important to note that post-traumatic epilepsy can manifest even years after trauma [60, 61]. Finally, in subacute and chronic phases following moderate to severe injury, EEG biofeedback is sometimes used in the rehabilitation process [62].

In contrast to moderate and severe TBI, the application of EEG in mTBI has not been established for clinical use. Recent research suggests, however, that EEG may provide information on brain abnormalities associated with mTBI [63]. Alterations in EEG are more likely seen with a history of longer periods of loss of consciousness (LOC) or PTA and usually manifest as focal or generalized slowing, accompanied by a decrease in frequency of the posterior alpha [64]. In the subacute phase after mTBI, weeks to months after injury, a frequency increase of 1–2 Hz in the posterior alpha can be observed [64, 65]. This may reflect a return to baseline after the aforementioned slowing in frequency. Notably, most EEG abnormalities resolve within weeks to months post-injury [63]. In chronic phases of mTBI, 6 months or more following injury, EEG abnormalities can still be observed in a subgroup of patients. Of note, left temporal slowing may be associated with PCS [66]. It is, however, important to note that such EEG abnormalities may also occur in other psychiatric disorders such as PTSD, depression, and anxiety disorders and are therefore not specific to mTBI [67–69]. These abnormalities may also reflect comorbid illnesses with mTBI. Furthermore, and as noted previously, standardization for the use of EEG for mTBI in the clinic has not been established.

Treatment

Psychopharmacotherapy

TBI at all levels of severity can initiate a cascade of neurobiological processes responsible for neurotransmitter dysregulation that contributes to cognitive impairment and neuropsychiatric sequelae (for a review, see [70]). Accordingly, pharmacotherapy has long been part of the treatment and rehabilitation of TBI-related cognitive and neuropsychiatric dysfunction (for example, see [71]). Moreover, by alleviating neurocognitive symptoms, pharmacotherapy can increase the benefits from other non-pharmacological treatments (for example, cognitive rehabilitation). However, to date, there is a lack of RCTs that could form the basis for evidence-based clinical practice [72, 73]. Thus, although pharmacological interventions are common after TBI, there exists considerable variability among the specific agents administered between and within cognitive and neuropsychiatric domains [74, 75].

Despite a shortage of guidelines, comprehensive reviews of the literature offer the following recommendations [70, 72, 74, 76]. Specifically, methylphenidate and, to a lesser extent, cholinesterase inhibitors have shown efficacy in treating deficits in attention and information processing speed. Similarly, cholinesterase inhibitors and neurostimulants have demonstrated limited recovery of memory and executive function. With respect to neurobehavioural and psychiatric symptoms, β -blockers can improve agitation and aggression, while limited evidence suggests that sertraline can alleviate depression, particularly in the later phases of recovery. Beyond

these, clinicians may prescribe medications based on common practice for similar dysfunctions. However, this is based on limited evidence and mainly on subjective clinical impressions and expert opinion (see [75]). As a result, some authors have offered clinical practice directives for the delivery of pharmacotherapy—initial dosing should be lower than in non-brain-injured populations, and increased doses should occur at a more conservative pace (that is, start low, go slow). Also, reassessment of both direct and side effects should be frequent. Further, a partial response can be met by the introduction of a second agent with a separate mechanism of action, and if targeted symptoms worsen upon the introduction of the pharmacological agent, doses should be lowered, or ceased, if the symptoms intensify [76, 77].

Cognitive rehabilitation

As noted previously, TBI-related disturbances in neurocognitive and psychiatric functioning can interfere with psychosocial functioning, independent living, and vocational and educational pursuits. Cognitive rehabilitation (CR) includes interventions aimed at assisting patients, as well as their families, to cope with cognitive and behavioural deficits following TBI. The evidence of CR has burgeoned over the last 30 years, leading to many options for clinicians seeking to improve the cognitive and psychosocial functioning of TBI patients (for reviews, see [78–81]).

Clinician-directed CR interventions may also improve cognitive functioning across many domains, including memory, attention, and executive function [82]. Deficits in memory are best addressed using external memory aids, such as journals, notebooks, and planners, as well as electronic aids like smartphones and electronic calendars [83, 84]. Although generally thought of as distinct cognitive abilities, within the context of CR, attention and executive function have been thought of as a unitary construct [78]. Accordingly, cognitive abilities within the purview of attention and executive functions include goal setting, planning, organization, initiation, and maintenance of activities, as well as executive control of attention (that is, selective attention, alternating attention, and working memory) [78]. Attention and executive function interventions demonstrate efficacy when they include direct attention (that is, repetition, hierarchical strategy development) and metacognitive training [85, 86]. Thus, these components are recommended practice standards for the rehabilitation of attention and executive function [82].

Interventions for mild TBI

Although, as previously mentioned, mTBI is associated with a constellation of cognitive, affective, and neurologic symptoms, for most individuals, injury-related impairments tend to resolve within days to weeks, with a smaller number resolving in 3 months. Historically, rest has been considered the gold standard for clinical management. However, there is little consensus on the definition and duration of rest following mTBI, and the benefits of rest are not based on empirical evidence. Prolonged rest may, in fact, even increase the risk for post-concussion-like symptoms [87]. Silverberg and Iverson, for example, noted the possible deleterious effects of too much bed rest in their guidelines for the clinical management of mTBI. Their guidelines include: (1) bed rest for more than 3 days is not recommended; (2) pre-injury activities should resume gradually; (3) for the first 2 weeks following post-acute injury, there should be a reduction in

physical and cognitive demands; and (4) for patients symptomatic after 1 month, supervised exercise should be considered. Marshall and colleagues [88] provide similar guidelines for athletes who have suffered a sports-related concussion. These include: (1) players should be medically evaluated on site by a licensed health provider who will determine the appropriate disposition of the player; (2) in the absence of a health provider, the player should be removed from practice or play and a referral to a physician should be arranged; (3) after first aid, an objective assessment of concussion should be administered; (4) the player should be accompanied and monitored over the first few hours post-injury; and (5) diagnosed or suspected concussions should prohibit return to play or practice [88]. It is important to note, however, that while elite athletes may experience significant cognitive and psychological sequelae from concussions, they are more likely to minimize the short- and long-term consequences of head impacts. A clear example is an anonymous NFL nation survey conducted by ESPN. In this survey, 320 NFL players were asked if they would play in the Super Bowl 2014 with a concussion; 85% responded 'yes' [89].

Beyond rest in the acute stage (for example, 3 days post-injury), there is accumulating evidence to suggest that education and support, provided shortly after mTBI, can be helpful, especially for somatic and psychological complaints (for reviews, see [27, 90–92]). Education should be both verbal and in print, and should include information about the symptoms common to mTBI and the time course of convalescence. Moreover, the impact of educational interventions are optimal when delivered to patients and their families, friends, employers, insurers, and/or significant others [90]. Support may take the form of validation of the patient's complaints, normalization of the symptoms, and reassurance about expected positive recovery, along with techniques to manage stress [88].

For patients with significant and prolonged complaints (that is, PCS), education and reassurance have been efficacious in shortening the duration of post-concussive symptoms (for a review, see [27]). Marshall and colleagues [88] further recommended that, for patients with chronic post-concussive symptoms, primary care providers must consider the multi-factorial nature of these complaints and management strategies should be developed with all contributing factors in mind. Notably, there is little evidence that cognitive rehabilitation and cognitive behavioural therapy are effective interventions for patients with persistent post-concussive symptoms [92, 93]. Importantly, highly sensitive neuroimaging techniques have recently become available that might shed light on the nature of post-concussive symptoms.

Differential diagnoses

It is important to note that there is an overlap among the symptoms of mTBI and other disorders, including depression, anxiety, and PTSD. This overlap in symptoms creates diagnostic and treatment challenges for the clinician. Thus, an important first step towards differential diagnosis is to understand both the intersection and delineation of symptoms following TBI and common comorbidities. As mentioned previously, common causes of TBI include motor vehicle accidents, assaults, and combat. In addition to the increased risk for extracranial injury, such traumatic events can initiate pathological

anxiety and stress reactions, some of which may develop into PTSD, independent of TBI [94–96]. In addition, there is the issue of a differential diagnosis of depression and anxiety vs depression and anxiety being a consequence of TBI [97]. Here, we highlight important features of anxiety and depression, to aid in the differential diagnosis of mTBI (readers are referred to Chapters 74 to 92 for in-depth reviews of these topics).

Summary and future directions

The diagnosis of moderate and severe TBI is typically clear, as are the acute treatment interventions, e.g., neurosurgical intervention. Nonetheless, the prognosis is less clear, although there are guidelines regarding what to expect at different stages of progression or recovery. With mTBI, however, the picture becomes more complex, as even the diagnosis is not always clear. More studies are thus needed to understand better the neurobiological underpinnings of mTBI and to develop more sensitive methods to detect brain alterations associated with brain dysfunction. The previously mentioned advances in neuroimaging, including diffusion MRI and MRS, are among the most promising imaging modalities for providing sensitive measures of brain alterations following mTBI, which may become biomarkers for diagnosis and prognosis and for predicting treatment efficacy as new pharmacological treatments become available. Further, it is critical to characterize subject-specific injury profiles to move towards a more personalized medicine approach tailored to each patient. Moreover, it is important to identify risk factors for poor long-term outcome and to develop individualized interventions and potential preventative strategies. The development of reliable biomarkers for the diagnosis, prognosis, and monitoring of treatment efficacy is an important area for future research that will transform what we know about the underlying pathomechanisms, as well as what we know about the short- and long-term sequelae of TBI, and these developments will lead to more informed personalized medicine approaches to treatment by health care providers.

Substance use disorders and the mechanisms of drug addiction

Trevor W. Robbins and Barry J. Everitt

Introduction

Substance use disorders and the underlying problem of drug addiction have been affected by two major developments: firstly, the revolution in understanding provided by neuroscientific research, aided by arguably the most successful animal model of psychiatric disorder; and secondly, a recent significant change in the diagnostic criteria for 'substance use disorder' provided by DSM-5 ([Box 48.1](#)). Relevant to the present chapter, under DSM-IV, *substance dependence* was preferred to the term 'addiction', emphasizing the psychological and physiological concomitants of withdrawal phenomena. For opioid dependence, caused, for example, by abstinence in humans or by treatment with an opioid receptor antagonist, such as naloxone, in animal experimental studies, these withdrawal symptoms are classically manifest as a group of severe autonomic responses such as palpitations, sweating, and cramps, and in rats, by 'wet dog shakes' and piloerection, as well as by psychological dysphoria in humans and elevations of the reward threshold in rats [1]. This constellation of aversive symptoms can theoretically be considered as constituting *negative reinforcement*, an event increasing the probability of behaviour reducing its future occurrence (see Glossary of key terms, p. 488)—hence the drive to obtain more drug to avoid or escape from these withdrawal symptoms. This view of drug addiction thus accounts for the *maintenance* of drug-seeking and drug-taking behaviour, complementing the common sense view that the *initiation* of drug-taking is supported by positive subjective effects, before drug addiction sets in. These latter effects are thus described as positive reinforcement increasing the probability of behaviour producing them (see Glossary of key terms, p. 488). Such positive and negative effects are characteristic of all drugs of abuse, including stimulants such as cocaine and amphetamine, alcohol, nicotine, cannabis, ketamine, and benzodiazepines. However, the precise pattern of withdrawal effects varies considerably across compounds; the physical signs of withdrawal following cocaine are much less significant than the accompanying psychological dysphoria, for example. At this point, it is important to distinguish objective measures of behavioural and autonomic responses, from which much may be deduced about the underlying subjective motivational states, and

the subjective symptoms themselves, which are more difficult to measure ([Box 48.2](#)).

These positive and negative effects of drugs can be linked by opponent motivational theories, such as that by Solomon [2], as applied by Koob and Le Moal [3], to explain addiction ([Fig. 48.1](#)). These authors postulate that positive effects of drugs are counteracted by negative effects as the drugs wear off, and moreover that, with repetition, the positive effects become progressively smaller, perhaps, in part, caused by tolerance (that is, reduced efficacy of repeated drug treatments), whereas the negative effects become progressively greater, so that negative reinforcing events predominate. According to Koob and Le Moal [4], this process ultimately progresses to a state of 'allostasis', by which the drug abuser is unable to attain normal bodily and subjective 'homeostasis' by moderate drug-taking—leading to a vicious circle of drug bingeing and dependence, which is further exacerbated by its stressful sequelae.

This theory appears to be a compelling account of addiction and yet does not apparently explain why DSM-5 criteria of addiction have so radically moved away from substance dependence as its defining element. This is partly because it is evident from the study of other drug effects, such as those of caffeine, that a withdrawal syndrome per se is not necessary for the serious sequelae of drug addiction. Additionally, although withdrawal and tolerance are important potential symptoms of substance use disorder, they constitute only two of about 11 symptoms by which addiction is now defined ([Box 48.1](#)). From [Box 48.1](#), it can be noted that the other symptoms are mainly those associated with 'top-down' cognitive control, especially exemplified by the compulsive drug-seeking and drug-taking that occurs, for example, during relapse. These responses apparently occur almost reflexively to cues that have become associated with the drugs, including even people and places, and are exceedingly difficult to bring under conscious restraint [5]. The other quality of compulsive responses is the tendency for such behaviour to be performed despite evident aversive consequences. This pattern of behaviour has thus been associated with a rather different theory that emphasizes positive reinforcement and a progressive loss of top-down control from higher brain centres in addiction [6, 7].

Box 48.1 The new criteria for substance use disorders in DSM-5

- Taking the substance in larger amounts or for longer than you meant to
- Wanting to cut down or stop using the substance but not managing to
- Spending a lot of time getting, using, or recovering from use of the substance
- Not managing to do what you should at work, home or school, because of substance use
- Continuing to use, even when it causes problems in relationships
- Giving up important social, occupational or recreational activities because of substance use
- Using substances again and again, even when it puts you in danger
- Continuing to use, even when you know you have a physical or psychological problem that could have been caused or made worse by the substance
- Cravings and urges to use the substance (craving)
- Needing more of the substance to get the effect you want (tolerance)
- Development of withdrawal symptoms, which can be relieved by taking more of the substance (withdrawal).

>6 of these symptoms for a specific substance such as heroin or cocaine is sufficient for diagnosis as 'severe substance use disorder'. Note that the first 8 of these signs reflect failures of top-down cognitive control, or compulsive behaviour that persists despite detrimental consequences.

The positive reinforcement or reward-based theory of addiction

The idea that the positive subjective effects of drugs play a greater part in addiction gained much from the discovery of an apparent reward system in the brain. This was initially supported by the observation that rats would perform responses such as lever-pressing, leading to intracranial stimulation ('self-stimulation' behaviour), an obvious manifestation of positive reinforcement which was, however, limited to certain brain regions [8]. Eventually, it was realized that the regions coincided to a considerable degree, though not exclusively, with the location of dopamine (DA)-containing neurons in such areas as the ventral tegmental area (VTA) of the midbrain which innervate structures, including the nucleus accumbens (part of the ventral striatum), amygdala, and medial prefrontal cortex (Fig. 48.2). Focusing on stimulant drugs, such as d-amphetamine and cocaine, which were already known to be indirect agonists of the catecholamine neurotransmitter systems DA and noradrenaline (NA), Wise and others showed from pharmacological studies using DA and NA receptor antagonists that rodents appeared to regulate the amount of drug that could be self-administered intravenously via implanted jugular vein catheters to some sort of optimal level [9]. This regulation was selectively affected by DA receptor antagonists (such as haloperidol) [10]. Thus, a small dose of haloperidol would actually increase the rates of self-administration, presumably as the animal strives to overcome the effects of DA receptor blockade. This self-administration paradigm has subsequently become the gold standard for research studies of the reinforcing effects of drugs. Evidence of its validity comes from the fact that virtually all drugs of abuse in humans are self-administered by experimental

Box 48.2 Subjective feelings contributing to drug addiction

What is the underlying nature of positive and negative reinforcement? Positive reinforcers are defined according to Thorndike's Law of Effect which posits that they are events that increase the probability of responses that produced them. Early textbook theories of motivation, suggested that reinforcers have several functions including: (1) a reduction in drive or need reduction in relation to homeostatic regulation; (2) consolidation of learning or memory of associative or contingent relationships between environmental stimuli and responses or actions (leading, for example, to relatively automatic stimulus-response habits); (3) incentive-motivational effects leading to appropriate preparatory (appetitive) responses, such as approach behavior, or physiological adjustments in expectation of outcome or goal (such as eating food). Negative reinforcers are more difficult to characterize as they are defined as aversive events that increase the likelihood of their postponement or omission. Clearly both positive and negative reinforcement may play a role in drug abuse and addiction. But how do these aspects of reinforcement theory relate to the subjective effects of drugs that presumably play some part in addiction?

Incentive-motivational theories emphasize the hedonic properties of the reinforcer, especially when there is no obvious deficit or need state: for example, reinforcers such as intracranial electrical self-stimulation of the brain, cocaine, sex, sweet foods or novel objects. Thus reinforcers may have yet another function, to generate a subjective appraisal of their effects in terms of pleasure or aversion. This conceptualization has encouraged the use of terms such as 'reward' and 'liking' that connote hedonic subjective responses associated with positive reinforcers. Hedonic reactions are certainly important in early responses to drugs—for example, the subjective euphoria or 'high' initially associated with early experiences with the drug, which however may show a gradual reduction with repeated experience ('tolerance'). Moreover, it can be argued that behaviour governed by reinforcement is not always necessarily accompanied by conscious pleasure, as in the case, for example, of habits. Negative reinforcement may also be associated with subjective responses such as 'relief' (e.g. on avoiding an electric shock or escaping the pangs of withdrawal). Withdrawal itself is often accompanied by subjective craving for drug; however the precise causal, as distinct from correlative, role of such craving (also often called 'wanting') in motivating drug seeking behaviour remains unclear.

These issues are difficult to address because experimental animals, of course, do not have verbal responses to express any subjective feelings they may experience, whereas we can infer much about reinforcement processes from their overt behaviour. A causal analysis of the neural basis of subjective responses in humans is also only in a relatively early stage. Presumably, this must involve an attributional system which connects thoughts to actions and also may involve interactions with language based processing.

Indiscriminate substitution of the term 'reward' for 'reinforcement' therefore may therefore sometimes lead to mistaken assumptions about the neural nature of the human 'reward system'. This system undoubtedly includes those regions such as the nucleus accumbens, and its dopaminergic innervation, as determined from animal studies, but may well extend to other interactive cortical areas within a greater neural network. The orbitofrontal cortex is linked to sensory and value-based representations of reinforcers and the relative utility of different courses of action producing them, as well visual, auditory or olfactory cues which predict them through conditioning processes. Feelings of pleasure presumably arise from the visceral feedback provided from the autonomic nervous system which are integrated into emotional reactions by such structures as the insular cortex, and labelled as pleasant (or otherwise) according to the social and cognitive context in which they are experienced. This is in accordance with many studies of how environmental context may affect attributions of pleasure or aversion to what may be physiologically similar responses to drugs. Consequently, although it is important to take subjective responses into account, it is also a viable strategy to measure objectively how animal and human subjects actually behave in relation to repeated drug exposure.

Fig. 48.1 Opponent motivational processing. A theory of affective dynamics which suggests that the positive emotional State A arising from a stimulating (standard square wave) rewarding event undergoes several transitions, both after a few presentations and after many. The peak emotional impact of the event is experienced soon after its presentation and then exhibits sensory adaptation, declining over time while the stimulation is still ON. The hypothetical opponent negative or aversive experience (State B) comes after the event has been completed (that is, is OFF). This might relate to the effects of any reward (or, inversely speaking, of any punisher); in the case of a drug of abuse, it most obviously relates to the euphoric 'high', experienced soon after the drug takes effect (for example, almost immediately after intravenous self-administration), and the 'low' after the drug has worn off. Note that State B is always less marked than State A during the first few stimulations, so that the initial emotional state is positive. After many rewarding 'stimulations', the positive effects of State A have hypothetically markedly diminished, compared with their peak during the first few stimulations. In the case of drugs of abuse, this relates to the well-known *tolerance* (progressive diminution) of pharmacological effects with repeated experience. However, the aversive after-effects in State B have increased, and so the net impact is negative. For drugs of abuse, this stage hypothetically corresponds to the state of 'withdrawal' (see text) and motivates avoidance behaviour controlled by negative reinforcement.

animals [11]. (A notable exception is that of LSD; however, there are good grounds for believing that the psychomimetic use of this drug by humans is not typical of drug abuse.) More recently, drug self-administration has been incorporated into behavioural models of addiction that have some measure of face validity [1, 12, 13].

Further significant observations supporting a central dopaminergic mediation of the effects of stimulant drugs included findings that the depletion of DA in the so-called mesolimbic projections from the VTA to the nucleus accumbens reduced self-administration rates for cocaine [14]. Perhaps more dramatically, it was also shown that d-amphetamine was self-administered directly into the nucleus accumbens by rats through an implanted cannula [15], but not significantly into other brain regions (Fig. 48.2). Moreover, these effects were demonstrated to be DA-dependent, in that concurrent treatment with DA receptor antagonists again produced an upregulation of self-administration [16].

The implication of mesolimbic DA in the positive reinforcing effects of drugs was consistent with evidence that natural rewards, such as food and sex, also exerted their reinforcing effects via this pathway [11]. However, even more significant was that the positive reinforcing effects of other drugs of abuse whose primary mechanisms of actions were not dopaminergic could also potentially be indirectly mediated by this system because of their modulatory effects on other receptors present in the VTA or nucleus accumbens—for example, nicotine, opioids (Fig. 48.2), cannabinoids, and, via GABA and glutamate receptors, alcohol and benzodiazepines [11]. This hypothesis was supported by evidence obtained using *in vivo* microdialysis which showed that many of these drugs upregulated DA levels in the nucleus accumbens. The hypothesis that the DA system was a 'final common pathway' in mediating the positive reinforcing effects of drugs of abuse has been an attractive hypothesis, not least because

it provided a potential basis for understanding polydrug abuse, by which human drug abusers will readily switch between different combinations of drugs when the supply of one of them is cut off.

The implication of a positive reinforcement system focused on the VTA that mediated effects of opioidergic agents, such as morphine and heroin, was exploited by Bozarth and Wise to test the opponent motivational process account of opioid addiction described here. They showed that intracranial self-administration of morphine could be maintained into the VTA region, supporting the positive reinforcement hypothesis, but that the self-administering rats did not exhibit the symptoms of physical withdrawal when challenged with naloxone [17]. Therefore, the maintenance of self-administration could not be attributed simply to overcoming negative reinforcement. By contrast, administration of morphine to the periaqueductal grey in the hindbrain did lead to physical symptoms on challenge with naloxone [17]. Therefore, it appears that the positive reinforcing effects of morphine and heroin and their actions on autonomic centres can be dissociated; the fact that opioid receptors are involved in these different responses is coincidental and not inextricably related. Nevertheless, some form of the opponent theory can be supported, as a subsequent study showed that the antagonism of opioid receptors within the nucleus accumbens could produce conditioned aversion to the place where heroin was experienced, suggesting that the drug was producing aversive after-effects in this mesolimbic reward system [18]. The additional assumption that the positive effects were mediated by the DA reinforcement system was also contradicted by the fact that the self-administration of heroin was incompletely blocked by DA depletion from the nucleus accumbens, suggesting that at least some of its positive reinforcing action was DA-independent [19]. This picture is probably true for other drugs of abuse such as alcohol and nicotine; DA mechanisms

Fig. 48.2 (see Colour Plate section) (a) Intracerebral drug self-administration. By pressing a lever in an operant chamber, rats can deliver microlitre and microgram quantities of drugs, such as amphetamine, directly into the brain. A major neural locus that supports such drug self-administration is the nucleus accumbens. (b) A schematic sagittal section of the rat brain showing the mesolimbic dopamine system, comprising cell bodies in the ventral tegmental area (VTA), axons that run in the medial forebrain bundle in the lateral hypothalamus, and terminals in the nucleus accumbens (NAc), medial prefrontal cortex (PFC), and amygdala (AMG), among other forebrain structures. Nicotinic and opioid receptors are shown on both dopamine neuron cell bodies and terminals in the nucleus accumbens. Some major cortical afferents to the nucleus accumbens are also shown and include the amygdala, hippocampal formation, and prefrontal cortex. Opioidergic (beta-endorphin-containing) projections are shown originating in the hypothalamic arcuate nucleus (ARC) and innervating the midbrain periaqueductal grey matter (PAG). Small enkephalin-containing interneurons are represented in green. There is widespread agreement that all drugs of abuse, in addition to actions on their specific molecular targets, can increase activity in the mesolimbic dopamine system and dopamine release in the nucleus accumbens and is often therefore referred to as the common reward pathway. (See [90].)

may indeed play a role and be a part of a ‘final common pathway’ leading to rewarding effects, but these are not the only source of the positive reinforcing actions of these compounds.

The importance of conditioning and associative learning

One of the properties of reinforcers is that they support new learning, and there are many indications that drug addiction may represent aberrant associative learning. An implication of this hypothesis is that cues and contexts (places) associated with drugs may gain salience via association with drugs through Pavlovian conditioning and thus exert important control over behaviour. Such cues may be the sight of needles or drug-taking paraphernalia, which have been reported to produce euphoric ‘highs’ in their own right in some addicted individuals. Drugs, such as amphetamine and cocaine, can enhance the salience of stimuli paired with other rewards, such as food, water, and brain stimulation, and such stimuli can even act as reinforcers themselves after conditioning, when they are termed conditioned reinforcers [20]. The potentiation of rewarding properties of environmental stimuli has been shown to depend on an interaction between two major factors: the integrity of the basolateral amygdala (BLA), which enables the association between the conditioned stimulus (CS) (for example, a predictive noise or light) and the unconditioned stimulus (US) (for example, food, sex, or addictive drug) and the dopaminergic innervation of the nucleus accumbens (which is responsible for the behavioural activation produced by such stimuli in responding under the influence

of the stimulant drug) [21, 22]. These factors have been shown to influence drug-seeking behaviour to a considerable extent. Thus, in a schedule in which rats work to obtain intravenous infusions of drugs by their instrumental lever-pressing, drug-seeking behaviour can be maintained for long periods, even before drug delivery by the presentation of brief stimuli (for example, lights or noises) associated with the ultimate delivery of the drug [23–25]. The same phenomenon has been demonstrated in humans [26]. The use of the conditioned reinforcers to maintain behaviour in this way can be termed a second-order schedule of reinforcement, its special utility being that it is then feasible to measure the motivational effects of the drug in terms of the responding made during the drug-seeking period prior to drug self-infusion [23]. Subsequent to that first infusion, the motivational salience of the drug-paired cues presumably becomes even greater as a consequence of the actions of the drug itself. This schedule has been used in several ways: (1) to define the neural pathways responsible for drug-seeking behaviour; and (2) as a method for screening possible remedial drug therapies that reduce drug-seeking and may therefore be employed potentially to combat craving and relapse in human drug abusers [27].

Neural basis of drug-seeking behaviour

(See Fig. 48.3.)

Based on the previous findings implicating the BLA in CS–US association, it was perhaps not surprising to find that excitotoxic lesions of this structure significantly impaired the acquisition of cocaine-seeking dependent on drug CS to mediate delays to

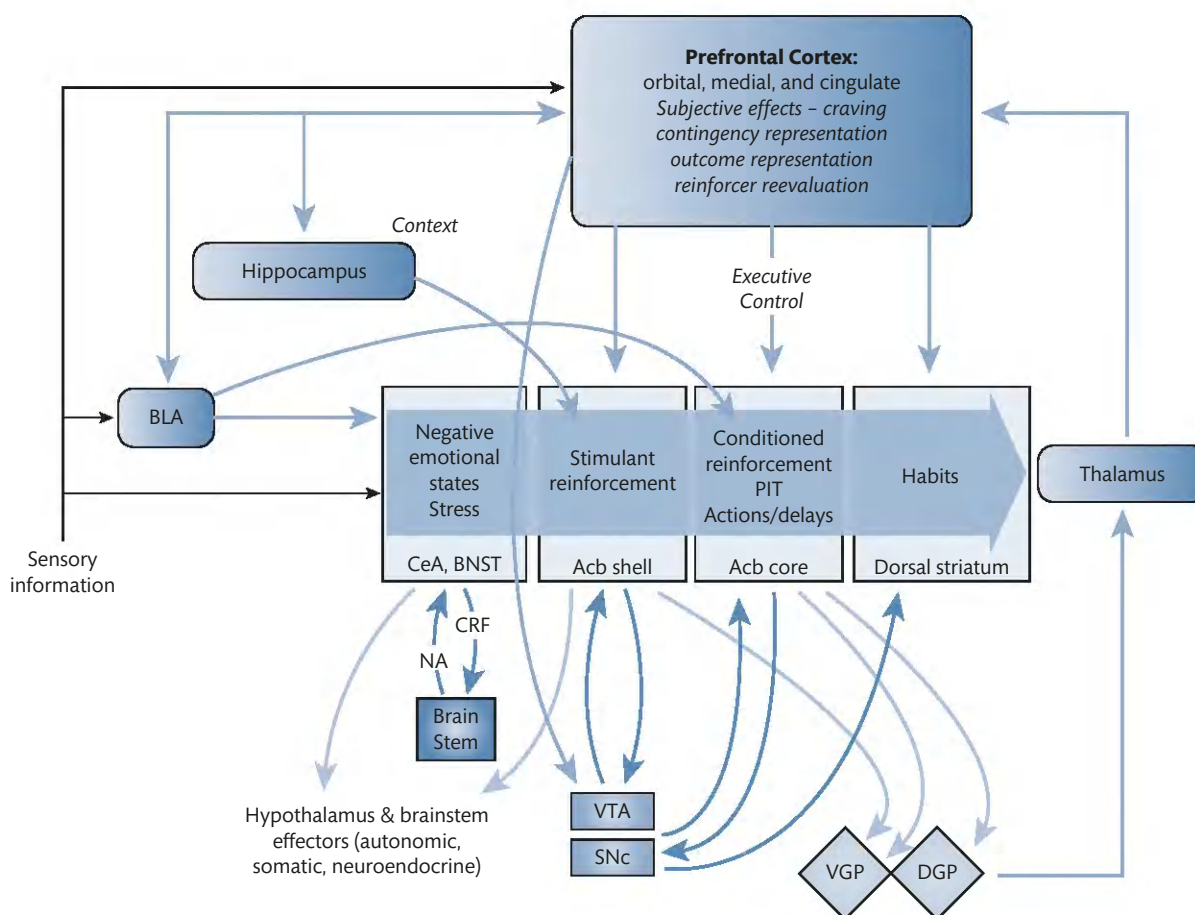

Fig. 48.3 (see Colour Plate section) Representation of key components of limbic cortico-striatal circuitry in which psychological and physiological processes important in drug addiction are indicated. These include: (1) the processing of conditioned reinforcement (and Pavlovian associations) between environmental stimuli and drugs in general) by the basolateral amygdala and of contextual information by the hippocampus; (2) goal-directed actions involve interactions between prefrontal cortical areas (orbitofrontal, ventromedial) and the dorsomedial striatum; (3) habits (stimulus–response associations) depend on interactions between the prefrontal cortex (sensorimotor) and dorsolateral striatum; (4) ‘executive control’ depends on the prefrontal cortex and includes representation of contingencies and outcomes and their value and subjective states (craving and feelings) associated with drugs; (5) in functional imaging studies, drug craving involves activation of the orbital, anterior cingulate, and insular cortices and temporal lobe structures, including the amygdala; (6) connections between dopaminergic neurons and the striatum, linking the ventral with the dorsal striatum via interactions organized in a striato-midbrain-striatal spiralling cascade of neuronal interconnections; (7) reinforcing effects of drugs may engage stimulant Pavlovian influences on behaviour such as Pavlovian-instrumental transfer, or conditioned motivation, and conditioned reinforcement processes in the nucleus accumbens shell and core and then engage stimulus–response habits that depend on the dorsal striatum; (8) the extended amygdala is composed of several basal forebrain structures, including the bed nucleus of the stria terminalis, the centromedial amygdala, and, more controversially, the medial portion (or shell) of the nucleus accumbens. A major transmitter in the extended amygdala is the corticotropin-releasing factor, which projects to the brainstem where noradrenergic neurons provide a major projection reciprocally to the extended amygdala. Activation of this system is closely associated with the negative affective state that occurs during withdrawal. Green/blue arrows, glutamatergic projections; orange arrows, dopaminergic projections; pink arrows, GABAergic projections. self-administration [28] (Fig. 48.2). Also thematic was the finding that similar lesions of the so-called core subregion of the nucleus accumbens produced similar effects, reflecting, in part, the innervation by the BLA of this structure [29], as later confirmed by disconnection of these two structures [30]. Intriguingly, lesions of the other major subregion of the nucleus accumbens—the shell—also affected performance, but mainly to reduce the rate of responding produced by the response-contingent conditioned reinforcers [29]. On the basis of these findings, it could be concluded that the acquisition of cocaine-seeking was controlled by an amygdala–accumbens

pathway. Whether this is also true for other drugs of abuse is not quite as clear, as second-order schedule performance maintained by heroin was shown to be less susceptible to BLA lesions [31]. There are several other afferent pathways to the nucleus accumbens, including from the hippocampus, insula, anterior cingulate, and prefrontal cortex, so it is possible that other pathways also contribute to the effects of conditioned stimuli in various contexts, including stress. There is indeed evidence from a specific model of relapse, termed reinstatement following extinction of drug-seeking, that these other structures participate in different forms of relapse [32].

The possible role of DA itself in drug-seeking has been determined by using *in vivo* microdialysis probes directed to various striatal sites, including the nucleus accumbens core and shell subregions. Of particular interest are not only the periods following self-administered infusions of cocaine, but also the initial period when only conditioned reinforcers are presented (Fig. 48.4). In the shell region (as well as other striatal domains), there were large increases following cocaine infusions, but no significant increases during the initial period. Presumably, this is one of the initial sites of the unconditioned reinforcing effects of stimulant drugs, consistent with the earlier evidence of effects of lesions described previously. In the core region, there was a similar picture, although the levels of DA were lower than in the shell, and some effects of the CS alone could be

discerned, but only if such stimuli were presented in a novel context (Fig. 48.4). Of greatest significance, however, was the finding that in the dorsal striatum (that is, the caudate–putamen of the rat), the release of DA in the periods producing the CS was approximately as great as for the drug itself (Fig. 48.4). This was one of the first pieces of evidence to suggest that the dorsal striatum also has a role to play in cocaine-seeking under the control of conditioned reinforcers, especially after a protracted period of training and increasing experience of the self-administered drug. However, other observations are consistent with this view. For example, autoradiographic evidence of changes in DA receptors in the striatum in rhesus monkeys chronically self-administering cocaine showed a gradual, all-encompassing involvement of the dorsal striatum [33].

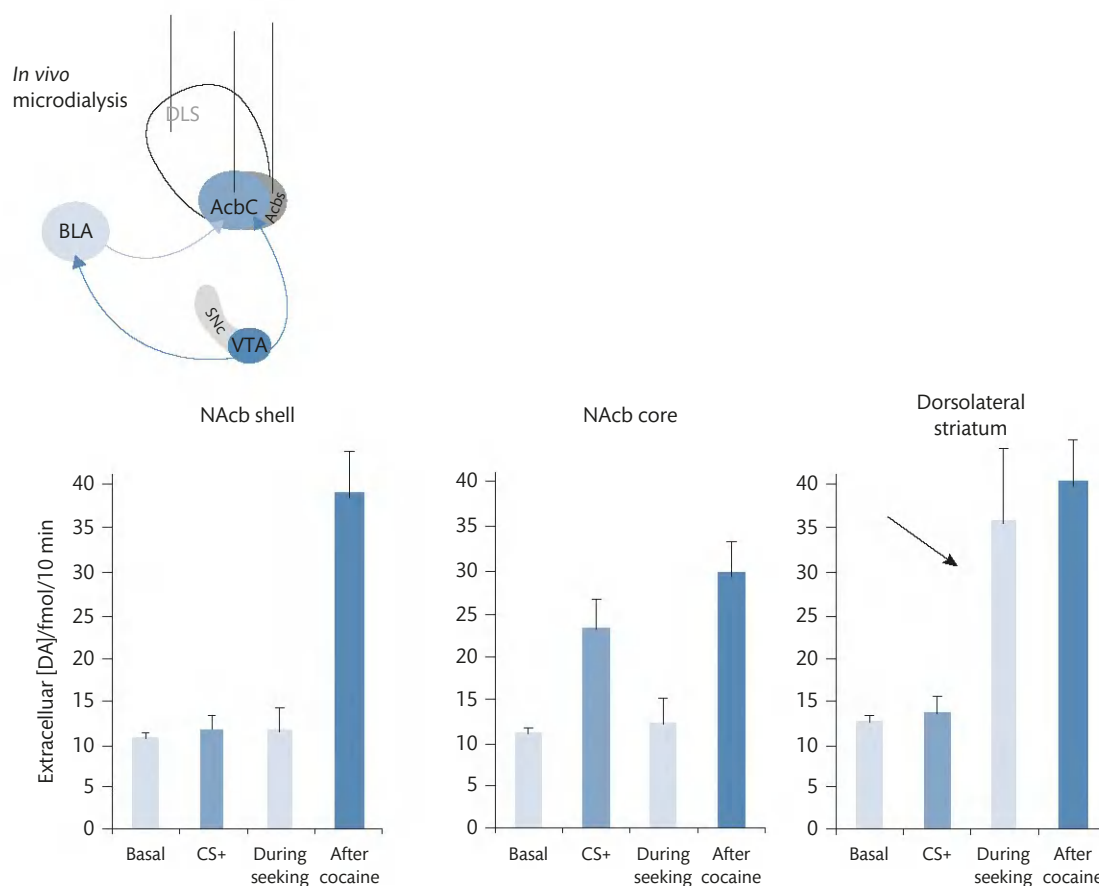

Fig. 48.4 In this study, rats were trained to respond for intravenous cocaine under a so-called second-order schedule of reinforcement, in which their drug-seeking behaviour depended on the response-contingent presentation of cocaine-associated conditioned stimuli (acting as conditioned reinforcers) during delays to reward. After a prolonged period of training, dopamine extracellular levels in three areas of the striatum were measured (at the end of 1-hour seeking sessions): the nucleus accumbens core, the shell, and the dorsolateral striatum. Following the infusion of cocaine, dopamine release was increased in all areas, indicating the effects of the drug on these richly dopamine-innervated striatal areas. However, there were no increases in dopamine in the nucleus accumbens core and shell following the prolonged bout of drug-seeking responding, but instead marked increases in the dorsolateral striatum. This area is strongly implicated in stimulus–response or habit behaviour, and this dopaminergic correlate of cocaine-seeking is a key part of the evidence in favour of the development of the habitual nature of drug-seeking after prolonged experience. Also of note is the increase in dopamine in the nucleus accumbens core when the cocaine-associated conditioned stimulus was presented surprisingly (that is, in a different context to previously), indicating that this component of the dopamine system is responsive to cues associated with drug reward but is less engaged by habitual drug-seeking behaviour. (See [92, 93].)

Neuropsychological theories of drug addiction

(See Fig. 48.5.)

The evidence of dorsal striatal involvement can be interpreted to suggest a devolution of control over behaviour, from the ventral to the dorsal striatum, with chronic drug exposure. In psychological terms, this might be construed as a shift in balance between two learning systems—a goal-directed system in which behaviour is controlled by its consequences (that is, rewarding drug effects), and a relatively unconscious stimulus–response habit-based learning system, which is more automatic and depends on stimuli that simply elicit responses without reference to the goal. Therefore, the hypothesis has been advanced [6, 7, 34] that drug-seeking behaviour eventually becomes less goal-directed and more habitual with drug experience—in other words, that habitual drug-seeking is at the basis

Fig. 48.5 Compulsive drug-seeking in an animal model of addictive behaviour. In this study, rats were trained on a task in which responding on one lever in an operant chamber gives access to a second lever, responding on which delivers an intravenous infusion of cocaine. These levers are therefore designated 'seeking lever' (on which responding is never reinforced) and 'taking lever' (on which responding is always reinforced), and the rats perform 'cycles' of seeking and taking. Then, either after a short or long drug-seeking-taking history, a cycle of seeking responses was unpredictably punished, rather than giving access to the taking lever and hence intravenous cocaine. Thus, in this procedure, rats must run the 'risk' of punishment in order to gain the opportunity to take cocaine; the analogy with humans foraging for cocaine is obvious. After a brief history of taking cocaine, all rats suppressed their seeking behaviour when punishment was introduced (they abstained). However, after a long history, the figure shows that although the majority of rats abstained, a subpopulation of about 20% of rats continued to seek cocaine in the face of punishment, that is, were compulsive (therefore meeting key DSM-5 criteria for 'addiction'). Rats with a behavioural trait of high impulsivity expressed before any cocaine experience are much more likely to become compulsive, that is, they are vulnerable to develop compulsive cocaine-seeking. (See [94].)

of compulsive drug-seeking symptoms, according to DSM-5 criteria (Box 48.1). However, such a theory requires some understanding of how habitual behaviour can become compulsive, despite adverse consequences, and this may require additional factors. One of these is the concept of loss of top-down control, especially by so-called executive mechanisms of the prefrontal cortex. There is considerable evidence that chronic drug-taking compromises prefrontal functioning in experimental animals and, as will be seen from evidence to be considered later, also in humans, and therefore, a mechanistic basis for habits to become compulsive [35–38]. A parallel, competing hypothesis is that compulsive behaviour arises from a gradual sensitization of the mesolimbic reward system by repeated drug exposure, leading to excessive motivation for drugs [39]. Although there is no doubt that effects of drugs can gradually augment over time and can be manifest in responses, such as enhanced locomotor activity, it is less clear how such augmentation can occur to enhance compulsive instrumental drug-seeking, leading to drug-taking. A further suggestion has been that stress can exacerbate the transition from goal-directed responding to habits [40] and may cross-sensitize with the effects of stimulant drugs. It should be noted that both drug-induced sensitization and stress have been shown directly to influence dorsal striatal mechanisms of habitual responding [40, 41].

How does one begin to distinguish among these various accounts of addiction to stimulant drugs? And to what extent does it apply to other drugs of abuse? These two issues, as well as the opponent motivational theory, are at the forefront of current research attempts to understand the theoretical basis of drug addiction. A possible reconciliation of habit with the opponent motivational theory would suggest that negatively reinforced behaviour is especially subject to habitual control [7].

Learning theory has advanced several methods for diagnosing the contribution of habits and goal-directed actions to behavioural output, with both playing a part (Fig. 48.5). Habits tend to emerge with extended training, and the nature of the reinforcement schedule is also important [42]. Habitual behaviour persists if: (1) goals are devalued, for example by satiety or counterconditioning with toxins, in the case of food reward; or (2) the contingent (that is, predictive) relationship between actions and goals is degraded in any way. Some of these tests have been used to probe the habitual nature of chronic drug self-administration for cocaine, alcohol, and nicotine in experimental animals, with, in every case, habitual control predominating (see [7, 43] for reviews). For example, it has been shown that overtraining of cocaine-seeking under a second-order schedule of reinforcement makes performance more vulnerable to suppression by DA receptor blockade of the dorsal striatum, compared with infusions into the ventral striatum [44]. This pattern contrasts markedly with that observed following the acquisition of drug-seeking behaviour, which, as we have seen, implicates especially the nucleus accumbens core (which mediates Pavlovian influences on instrumental behaviour [45]) and the dorsomedial striatum (which mediates action–outcome learning [46]). The nucleus accumbens core circuitry likely continues to play a part in the control of this behaviour, which can be assumed to be at least partly habitual in nature. A study that disconnected the nucleus accumbens core and the dorsolateral striatum by combining unilateral manipulations of each structure on opposite sides of the brain showed that a circuit functionally linking these two structures was implicated [47]. An obvious candidate for their interaction is the

cascading circuitry that links the ventral striatum to the dorsal striatum in a unidirectional manner, via backward and forward projections to and from successive sectors of the striatum, beginning in the accumbens shell and terminating in the putamen, a possible site of stimulus–response habit-based learning [48]. This circuitry provides the basis for the BLA, via its direct projections to the nucleus accumbens core, to influence the dorsolateral striatum, and hence stimulus–response habits—circuitry that has been demonstrated electrophysiologically [49].

Another way of measuring compulsive behaviour is to make it ‘risky’ by unpredictably punishing drug-seeking behaviour on one lever which, on other occasions, gives access to a second taking lever, responding on which results in drug self-administration. After a short cocaine history, all rats suppressed their drug-seeking. However, after a long history of cocaine exposure, a proportion of rats continued to respond (the majority suppressed their drug-seeking), despite these adverse consequences, and this therefore fulfils an operational definition of compulsive drug-seeking [12] (Fig. 48.5). Intriguingly, the proportion of rats showing such compulsive cocaine-seeking (about 15–20%) is rather similar to the proportion of human drug abusers thought to make the transition to cocaine addiction. Drug-seeking under punishment is associated with reduced forebrain levels of serotonin [37] and depends on the dorsolateral striatum [50], consistent with the view that compulsive drug-seeking reflects loss of control over habitual behaviour. Moreover, optogenetic stimulation of the medial prefrontal cortex (which is hypoactive in compulsive rats) restores sensitivity to punishment and reduces compulsive cocaine-seeking [38].

Impulsivity vs compulsivity

The issue of individual differences in the propensity for addiction has led to the search for biobehavioural markers of possible vulnerability. An early suggestion for stimulant drug susceptibility was that those rats exhibiting behavioural hyperactivity in a novel test environment would subsequently respond for lower doses of d-amphetamine, perhaps as a consequence of their risky ‘sensation-seeking’ which hypothetically promoted drug-seeking [51]. Another finding has been that rats consistently responding prematurely in an attentional task (in other words, responding prior to the presentation of visual targets needing detection for food rewards) also had an increased tendency to self-administer cocaine, when allowed binge access to the drug, although there were no obvious differences in acquisition of this behaviour [52]. They also exhibited compulsive drug-seeking in a procedure that measures addiction-like behavioural criteria (compulsivity, increased motivation, and persistent seeking in the signalled absence of the drug) [53]. Moreover, when behavioural hyperactivity was used to stratify the same population, there was no obvious effect in parallel with what had been shown earlier to affect the acquisition of drug-seeking; indeed ‘high responder’ rats were actually resistant to developing addiction-like behavioural criteria [53, 54]. Thus, it is possible that different phenotypes contribute to different aspects of drug addiction, for example to the tendencies to sample drug effects and for drug-seeking to become compulsive [7, 55]. Further analyses have been made of other predisposing factors that contribute to drug abuse in experimental animals, and other influences have been suggested to include the temporal discounting

of reward (that is, choosing small, immediate rewards in preference to larger, delayed ones), risky decision-making, individual differences in Pavlovian conditioning, novelty seeking, and anxiety [55]. Different predisposing influences may exist for different drugs or for different components of abusing the same drug. For example, the propensity for stimulant self-administration in male rhesus monkeys has been shown to depend on factors such as social dominance (submissive monkeys being more susceptible) [56]. Moreover, although high impulsivity has been shown to predict nicotine [57], as well as cocaine susceptibility, it does not predict vulnerability to self-administer heroin [58]. This is an area in which it is clearly important to explore possible parallels with humans, and one feature of research into addiction using experimental animals has been how well the principles so gained from appropriate behavioural models sometimes appear to apply also to human drug addiction.

Translation of experimental research on addiction in animals to humans

Striking parallels of research in experimental animals and humans addicted to drugs exist in both the behavioural and neural domains. Although much human research has revolved around relapse and its subjective correlates, which include the ‘craving’ or urge to take drugs, this has not handicapped application of the basic research findings to any great degree, as long as operational principles have been applied. An important example of how behavioural analysis is at least as important in humans as in experimental animals has been the observation of consistent drug preferences in drug-experienced humans for low doses of heroin that appear to occur without detecting any subjective drug effect [59]. It would appear that preference for certain drug effects may be occurring below the threshold for conscious detection of those effects, strongly implicating implicit factors at work, perhaps also involving brain regions not directly involved in conscious experience itself. Another intriguing connection is between the pharmacological studies described earlier, suggesting that drug-taking may begin as a form of self-medication by which rodents strive to attain an optimal level of functioning of the DA systems, and studies of the status of the central striatal DA function in healthy volunteers in relation to drug preference. Thus, volunteers without a history of drug abuse, but exhibiting low striatal D2/3 receptor binding, tended to find the effects of the psychomotor stimulant methylphenidate pleasurable, whereas those with high D2/3 striatal binding found them aversive [60, 61].

Research using experimental animals that has highlighted the role of the mesolimbic DA system and limbic–striatal mechanisms has stimulated parallel investigations in the human drug abuse literature. One of the main examples has been the work on DA receptors in human drug addicts by Volkow and colleagues. The authors were able to find, using a radioligand for DA D2/3 receptors with positron emission tomography (PET), that stimulant and heroin abusers, as well as alcoholics, all exhibited reductions in D2/3 DA receptor availability in the dorsal striatum [62], a striking endorsement of earlier animal work supporting a common role for DA in mediating the effects of a number of drugs of abuse. Important as these observations are, they entail a number of interpretative difficulties. These include whether the prime change is in D2 or D3 receptors (the radioligand in question being non-selective), whether it is pre- or post-synaptic

(while acknowledging the much higher concentration of post-synaptic D2 receptors in the human striatum), and consequently the precise status of DA function, given the opposite effects that inhibitory presynaptic receptors and post-synaptic receptors have on DA function. These issues can all be addressed, and a current consensus is that the reduced D2/3 receptor function may be correlated with reduced DA activity (at least in chronic drug abusers) [63]. An additional finding of interest is that the reductions in D2/3 DA receptors are correlated with hypometabolism in the orbitofrontal cortex [64], a prefrontal region of great importance for reward function and decision-making cognition in humans. Therefore, it is evident that the changes in striatal DA status are associated with impaired cortical function—and may represent one of the deficits leading to impaired top-down control of behaviour, in this case impaired goal-directed behaviour, and suggestive of an alteration in the balance between goal-directed and habitual behaviour, favouring the latter, in drug addiction [7, 43].

However, a yet more difficult consideration to resolve is whether the changes in D2/3 DA receptors are effects of excessive drug exposure or actually predisposing causes of drug abuse, a question evidently difficult to address in humans without the aid of a prospective longitudinal study. A behavioural issue posing an analogous cause-and-effect quandary is whether impulsive decision-making and compulsive drug use arise from possible 'neurotoxic' effects of excessive drug-taking or again whether it is a predisposing factor. The presence of such predisposing factors in experimental animals described here suggests the latter [53]. Equally, studies of D2/3 DA receptors using microPET in high-impulsive rats showed that they exhibit reduced D2/3 receptors in the ventral striatum, suggesting that this change may, in part, reflect a pre-existing state in the rats, perhaps caused by some combination of genetic or environmental

factors [52]. It is possible, of course, that both predisposing and drug-induced factors combine to drive down D2/3 receptor availability.

The study of human drug abusers using other state-of-the-art neuroimaging methods, including structural magnetic resonance imaging (MRI), functional MRI, and diffusion tensor imaging, combined with sensitive behavioural indicators, is beginning to unravel the causes and effects of drug abuse. For example, it has been shown that measures of response inhibitory control (in which subjects have to cancel or restrain an already initiated response) are impaired in individuals with DSM-IV-defined stimulant drug dependence. However, of even greater significance was the fact that their siblings who did not abuse drugs were similarly impaired, as compared to age- and IQ-matched controls and to recreational drug abusers not attaining DSM-IV criteria of drug dependence [65]. This strongly implies an intermediate phenotype or endophenotype of impulsivity predicting vulnerability to stimulant drug addiction, in parallel with the animal model described previously. The hypothesis of an impulsivity endophenotype has been further supported using questionnaires to measure impulsivity and sensation-seeking; whereas the former scores were elevated in both the stimulant-dependent individuals and their siblings, elevated sensation-seeking was confined to the stimulant-dependent and recreational groups only [66].

What factors then protect the siblings from becoming drug-addicted and thus confer resilience? A functional MRI study may provide some insight, as this shows reduced activity in a region of the prefrontal cortex implicated in inhibitory response control (in the region of the right inferior frontal cortex) in stimulant-dependent individuals, contrasting with enhanced activity in the same region in their siblings (Fig. 48.6) [67]. Hypothetically, the siblings may be attempting to exert enhanced restraint over predispositions to

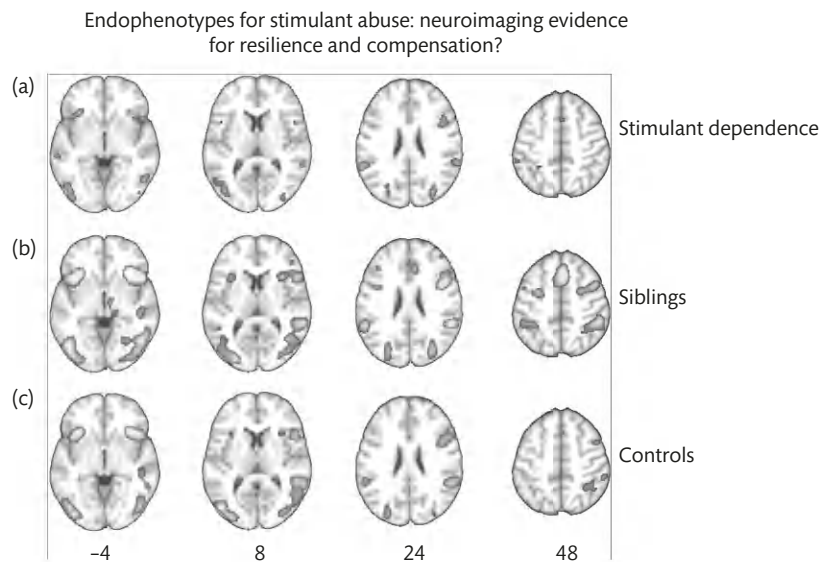

Fig. 48.6 (see Colour Plate section) Evidence of hypothetical resilience factors operating in siblings of stimulant-dependent individuals (bottom row scans) in terms of BOLD response overactivation of the right inferior frontal gyrus during functional magnetic resonance imaging study of the stop-signal reaction time task, as compared with healthy control volunteers (middle row scans) and stimulant-dependent individuals (top row)—the latter showing significant reductions, compared with controls. Significant brain activation maps were associated with stopping in each group ($P < 0.05$, family-wise error). Axial brain slices demonstrate main activation clusters per group at family-wise error, $P < 0.05$. The z-co-ordinate slices are: -4, 8, 24, and 48. The right side of each slice corresponds to the right side of the brain.

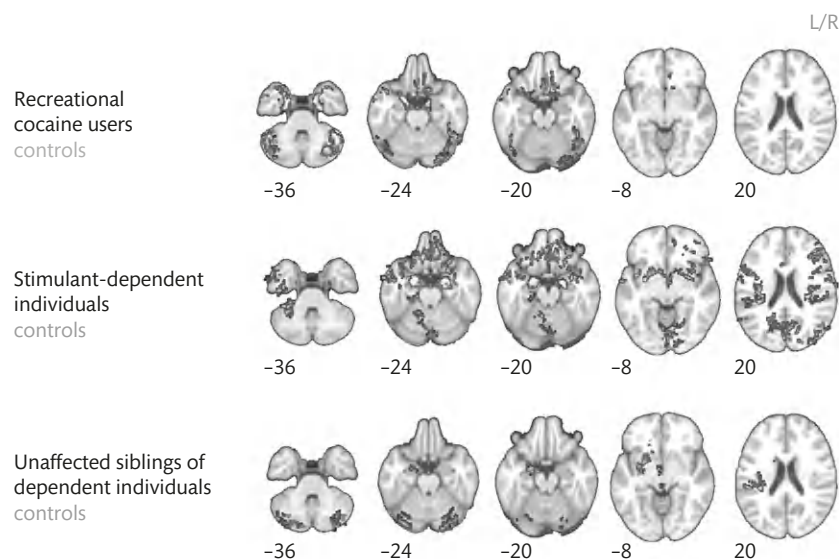

Fig. 48.7 (see Colour Plate section) Structural brain abnormalities associated with stimulant exposure and familial risk. Blue voxels indicate a decrease, and red voxels indicate an increase, in grey matter volume, compared with control volunteers. Both recreational and dependent stimulant users showed significant increases in the parahippocampal gyrus, compared with healthy control volunteers, but differed with regard to abnormalities in the orbitofrontal cortex. Recreational users did not show any of the changes in brain regions associated with familial risk such as increased volume of the amygdala and putamen and decreased volume in the posterior insula. Siblings of stimulant-dependent stimulant abusers showed larger grey matter volumes in the basal ganglia, particularly the putamen. Sections and horizontal numbers below each section of the image refer to its plane position (mm) relative to the origin in MNI stereotactic space. L, left; R, right.

Reproduced under the Creative Commons Attribution License (CC BY).

impulsive responding (although this may not always be successful). These attempts occur in the context of both the stimulant-dependent group as well as the siblings exhibiting reduced white matter innervation of the inferior frontal cortex via the arcuate fasciculus that correlates significantly with their performance on the inhibitory control task. There is, in fact, a burgeoning literature of failures in inhibitory control in drug abusers associated with cortical impairment (reviewed in [68]). Such factors could contribute to compulsive behaviour, in tandem with the hypothesized deficits in learning and conditioned drug responses observed in experimental animals.

There has been, by now, extensive confirmation that Pavlovian conditioned cues elicit disruptive craving responses and concomitant neural changes in activity in drug abusers in brain regions, consistent with what has been found in experimental animals. Thus, for example, Grant and Childress were among the first to demonstrate excessive activation of limbic regions, including the amygdala, in response to drug-related cues in drug abusers, compared with healthy volunteers [69, 70]. Consistent with stimulus–response habit-based dorsal striatal mediation of such effects, Volkow and colleagues found in functional MRI studies that drug cues associated with cocaine activated the dorsal, rather than the ventral, striatum [71]. Another study revealed similar findings for alcoholics, although, revealingly, recreational drinkers showed activation of the ventral striatum [72], clearly consistent in this cross-sectional study with a transition to dorsal striatal mechanisms in the drug-dependent individual.

Structural MRI has also shown that the amygdala and striatum tend to be larger in both stimulant-dependent individuals and their non-drug-abusing siblings, whereas the stimulant-dependent

individuals (though not recreational users) have reduced cortical grey matter in regions such as the orbitofrontal and temporal cortices [65] (Fig. 48.7). The extent of reductions in grey matter in the ventromedial prefrontal cortex has been shown to be related to the duration of stimulant drug use, suggesting that the drug has exerted a cumulative toxic effect, as well as to measures of compulsive drug use obtained using the Obsessive Compulsive Drug Use Scale (OCDUS). Indeed, a significant correlation between grey matter volume in the inferior frontal and rectal gyri and measures of compulsive cocaine-taking (OCDUS) has been demonstrated in a group of chronic cocaine users [73] (Fig. 48.8). These findings suggest that stimulant drug abuse does impair cortical functioning, although it is not known to what extent these changes are permanent and irreversible, for example, following abstinence. Other evidence can be cited in support of the shift in balance between systems of goal-directed control vs habit learning in stimulant drug abusers [74]. Comparable analyses exist of the sequelae of chronic alcoholism, as well as other drugs of abuse [72].

Behavioural studies of human stimulant drug addiction using the devaluation method and other computational paradigms are compatible with the hypothesis of habit-based learning in stimulant-dependent individuals. Thus, for example, stimulant abusers were slower to learn goal-directed responses that earned points leading to monetary reward but exhibited more robust appetitive habits than controls. They were also impaired in learning to avoid electric shocks, although their aversive habitual responding was normal [74]. These results suggest that there might be specific behavioural approaches to treatment.

Fig. 48.8 Significant association between grey matter volume and measures of compulsivity in a group of chronic cocaine users. Regions that correlated significantly with compulsive cocaine-taking (as assessed by OCDUS) are coloured in green. The scatter plot below the brain image shows the correlation between this measure and grey matter volume for each drug user in those regions. The probability threshold for significance was $P \sim 0.002$ for each analysis. The statistical results are overlaid on the FSL MNI152 standard T1 image, and the numbers above each section of the image refer to its plane position (mm) relative to the origin in MNI stereotactic space. L, left; R, right.

Treatment of drug addiction via translational studies

Despite the evident progress in understanding the behavioural and neural mechanisms underlying drug addiction, we are still some way from finding effective treatments for this heterogeneous and difficult patient group. This may arise, in part, from the habitual nature of addiction and its relapsing nature, which are antithetical to mainline cognitive behavioural therapy techniques, although motivational enhancement programmes may prove useful. Substitution

pharmacotherapy with the long-acting opioid methadone has long been a staple procedure for heroin abuse, although this can have several deleterious side effects, and there is certainly scope for promising alternative opioid treatments such as buprenorphine. For nicotine addiction, there is a variety of substitution therapies based on the nicotine patch, gum, and lozenges, and now nicotine vaping devices, as well as the partial nicotinic receptor agonist varenicline [75]. Nalmefene, an opioid receptor antagonist, has recently been introduced for the treatment of alcoholism through its ability to reduce volumes of alcohol drunk in a binge [76]. No such effective substitution treatments exist for stimulant drugs, although the atypical stimulant modafinil may offer some promise.

These are important and effective harm reduction strategies that might, though not necessarily, open the door to abstinence and the prevention of relapse, which are major goals in the treatment of addiction. However, it should be possible to develop such treatments and there are different targets in this regard, for example to reduce the impact of stress and anxiety associated with relapse to alcohol use or to medicate dysphoric and anhedonic states that can persist long into withdrawal from stimulants, nicotine, and opiates [77], or treatments that reduce the impact of drug-associated stimuli on craving and relapse [78]. Many treatment leads have been identified in a wide range of animal studies in the context of drug discovery programmes, well reviewed in the recent surveys by Koob and Mason [75] and Everitt [27]. Some have been licensed by the FDA, such as the opiate receptor antagonist naltrexone and acamprosate (a partial agonist at glutamate NMDA receptors/glutamate metabotropic receptor antagonist), for alcohol abuse. Experimental agents based on combating the effects of stress (corticotrophin-releasing factor receptor antagonist or dynorphin-kappa opioid receptor antagonists) or impulsivity (atomoxetine) or related anti-relapse actions by putative actions on top-down circuitry (gabapentin, *N*-acetylcysteine) have so far been shown to have limited effects in human trials but remain under experimental investigation. Despite a range of pharmacological agents having the ability to reduce drug cue-elicited cocaine-seeking and relapse in animal models, including a D3 dopamine receptor antagonist, a μ -opioid receptor antagonist, and drugs interfering with glutamate transmission, none has yet successfully made it to the clinic [27].

The evident overlap of neural circuitry controlling responses to emotional cues and memories with those implicated in addiction has led to the revisiting of extinction [79], as well as the application of memory reconsolidation methodologies [80] (Fig. 48.9), by which the associative links between drugs and associated cues that help to maintain drug-seeking behaviour can be disrupted in experimental animals by a combination of behavioural procedure and pharmacological intervention. While it has been shown that drug cue extinction can be achieved in a clinical setting, with consequent reductions in cue-elicited craving, it is clear that this provides, at best, a mildly effective relapse prevention treatment because of the context dependence of extinction (therapy in the clinic does not extend to real-life environments), such that spontaneous recovery, renewal, and reinstatement of the extinguished response are common [81, 82]. However, the recent demonstration of 'super-extinction' [83], achieved by combining a brief drug cue memory retrieval with a conventional CS extinction protocol followed after a brief delay (30 minutes), has re-awoken interest in extinction therapies, since, in this case, a more complete and long-term extinction of the CS is

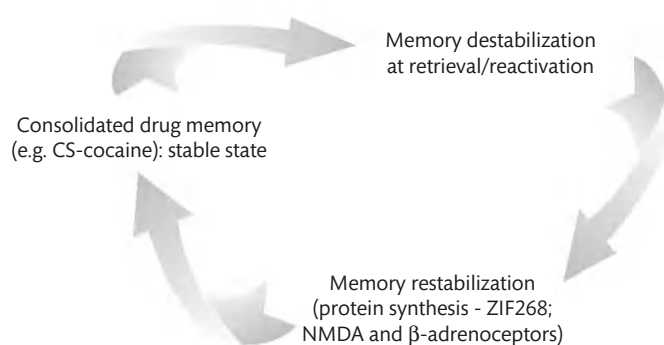

Fig. 48.9 Illustration of the concept of memory reconsolidation.

The consolidated drug memory, established by repeated Pavlovian association with an environmental stimulus (CS) and self-administered drug effect, is stored in a stable state. Brief presentations of the drug CS (called 'reactivation') can result in destabilization of the memory in the brain (in the case of a CS–drug memory, in the basolateral amygdala). The memory can persist in the brain if it is restabilized through *de novo* protein synthesis. The expression of the protein ZIF268 is a requirement of cued drug memory reconsolidation in the basolateral amygdala and is regulated by activation of NMDA receptors. Memory reconsolidation can be prevented by inhibiting protein synthesis in the amygdala or knocking down ZIF268 by infusing *zif268* antisense oligonucleotides or by blocking NMDA or β -adrenoceptors. Systemic NMDA or β -adrenoceptor blockade also prevents drug memory reconsolidation. The result is drug memory 'erasure', with the consequence that the drug-associated CS can no longer support drug-seeking, and this thereby reduces the propensity to relapse [27].

achieved. Although most often shown in conditioned fear studies, an impressive demonstration of the super-extinction of a CS–drug memory in animals self-administering cocaine or heroin, as well as, most remarkably, in a heroin-addicted inpatient population, with evidence of a decrement in craving and physiological responses to heroin cues 6 months later [84], suggests further detailed investigation is warranted. The neural basis of these effects remains unknown.

Targeting memory reconsolidation (Fig. 48.9) also holds translational promise [80, 85]. It is now widely accepted that under specific circumstances, memory retrieval (or, more appropriately, 'reactivation') that is too brief to engage extinction learning causes the memory trace to become labile in the brain, from which it must undergo protein synthesis-dependent restabilization if it is to persist [86]. Reconsolidation can be prevented by treatment with an amnesic agent, such as an NMDA receptor antagonist or a β -adrenergic receptor antagonist, given just once in conjunction with the brief memory reactivation [27, 87]. This results in amnesia and apparent erasure of the memory trace, or a great diminution of the strength of the memory, such that presenting the CS subsequently no longer elicits conditioned fear (in the case of aversive conditioning) or instrumental drug-seeking (in the case of animals seeking cocaine or alcohol) [27, 87, 88]. While the effects to reduce conditioned fear in animals has been successfully translated to the clinic in the successful treatment of phobias [89], to date, attempts to do so in the treatment of addiction have met with only limited, or sometimes no, success. It seems that a major obstacle to deploying reconsolidation strategies in the treatment of addiction is defining

precisely the conditions under which retrieval results in the destabilization of the memory. If the behavioural parameters can be defined precisely—a challenge when the conditioning history is so variable and of such long duration—then this approach to relapse prevention holds great promise.

GLOSSARY OF KEY TERMS

Positive reinforcer. An event which increases the probability of a response upon which it is contingent, for example, intravenous drug infusions maintaining lever pressing, alcohol ingestion maintaining licking or drinking.

Negative reinforcer. An event, the omission or termination of which increases the probability of the response upon which it is contingent, for example, withdrawal symptoms precipitated by scheduled administration of naloxone in morphine-dependent animals avoided by lever pressing which postpones the naloxone.

Incentive. A stimulus that elicits an approach behaviour (positive incentive) or a withdrawal behaviour (negative incentive). A conditioned incentive acquires such properties via Pavlovian conditioning. Incentives and conditioned incentives may also function as reinforcers and conditioned reinforcers, respectively, depending on environmental contingencies.

Pavlovian (or classical) conditioning. The process by which a conditioned stimulus (CS) elicits conditioned responses (CRs) that are normally elicited by an unconditioned stimulus (US) after a number of pairings. Such CRs are normally considered to be involuntary reflexes. The pairings require the onset of the CS to precede that of the US (temporal contiguity) and for there to be a positive temporal correlation (that is, predictive contingency) between the two events, for example, tolerance to a drug effect conditioned to a particular environmental CS.

Conditioned reinforcer. A stimulus which acquires its reinforcing properties (positive or negative) by pairings with other, generally primary, reinforcers such as food, drugs, sex, or electric shock. A stimulus can function as a conditioned reinforcer or as a discriminative stimulus in the same situation.

Contingency. A consistent temporal relationship between two (or more) events that reduces the uncertainty of the subsequent event, for example, between particular stimuli and particular responses.

Action–outcome learning. When instrumental actions are goal-directed, the actions (for example, lever-pressing) are made with the intention of obtaining the goal. The actions are sensitive to the devaluation of the goal; for example, an animal that has learnt to lever-press for food will respond much less or not at all for that food if it is devalued either by making it ill after ingesting the food or by pre-feeding to satiety with the same food. This is called **reinforcer devaluation**. It is very easy to devalue ingestive reinforcers, but not intravenously self-administered drugs such as cocaine.

Stimulus–response or 'habit' learning. In habit learning, instrumental performance is acquired through the association of responses with stimuli present during training. It therefore reflects the formation of stimulus–response associations, and reinforcers primarily serve the function of strengthening the stimulus–response association, but they do not become encoded as a goal. Therefore, devaluing the reinforcer does not affect instrumental responding.

Drug-taking. A term used to describe drug self-administration when the drug is readily available, for example, following each instrumental response on a lever or the simple drinking of alcohol

(so-called continuous reinforcement). The subject does not need to forage or to work for the drug nor mediate delays in acquiring, that is, does not actively need to 'seek' the drug.

Drug-seeking. This is instrumental or foraging behaviour performed to give access to the opportunity to take a drug, as measured under second-order schedules of reinforcement, in seeking-taking, and extinction–reinstatement tasks in animal models.

Compulsive drug-seeking. This is instrumental behaviour that persists in the face of adverse consequences such as punishment or the risk of punishment.

Genetics of substance use disorders

Yann Le Strat, Nicolas Ramoz, and Philip Gorwood

Genetics of substance use disorders: a historical perspective

The currently accepted claim that ‘addiction is a brain disease with a genetic component’ would sound familiar to a nineteenth-century alienist. While Esquirol had already mentioned the importance of heredity in the physiopathology of mental disorders, it was in 1860 that Morel gave heredity a central place within nosography by coining the term ‘degeneration theory’. Morel separated psychiatric disorders into two categories, depending on whether they are hereditary or not. Magnan and other French psychiatrists retained this nomenclature. If the scientific rationale is sometimes surprising, or even fanciful, some questions remain relevant in the twenty-first century. Thus, Bouchereau discusses the impact of placental transfer of alcohol as a possible confounding factor in the heritability of alcohol use disorder (AUD), and Morel evokes the possible inheritance of a diathesis, that is, a predisposition to the disease close to the modern concept of endophenotype. Finally, the ‘law of double fertilization’ of the same author attributes an identical importance to the ‘moral elements and organic conditions’ in the development of a mental disorder such as AUD, which could be compared to the gene \times environment interactions at the forefront of our current thinking.

Heritability of substance use disorders

It has been over 50 years since Kaij *et al.*’s first twin study on AUD, which suggested substance use disorders to be, at least in part, due to genetic variance. Subsequent twin and family studies have continued to support a genetic component to substance use disorders (SUD). Having a first-degree relative with SUD confers a greater risk than any individual environmental factor.

Heritability is defined as the proportion of the phenotypic variance attributed to additive genetic factors. Several methods have been used to calculate heritability. The data from twin studies are most often presented as pair and proband concordance in monozygotic (MZ) and dizygotic (DZ) twins. Pair concordance represents the percentage of all twin pairs within the sample who are concordant for disease.

Twin studies remain key to estimates of heritability in SUD, and their basis can be simply stated. Falconer’s equation of heritability

states that $h^2 = 2(r_{MZ} - r_{DZ})$, with h^2 = heritability, r_{MZ} = intraclass correlation of MZ twins, and r_{DZ} = intraclass correlation of DZ twins.

This equation assumes that:

1. The presence or absence of the disease is determined by genetic and normally distributed environmental factors.
2. All genetic influences are additive.
3. MZ twins share 100% of segregating genes.
4. DZ twins share, on average, 50% of segregating genes.
5. MZ and DZ twin pairs have a similar shared environment.
6. Genetic and environmental variations act independently of each other.

These assumptions are likely to be an oversimplification of the real genetic and environmental actions, and the estimations of heritability using this model are generally considered to be too narrowed, given that they include neither gene \times gene nor gene \times environment interactions.

Twin studies also assume random mating. However, a predisposition for SUD may be more frequently observed than expected in the parents of twins, and therefore, the genetic correlation between DZ twins is increased as a function of such assortive mating, biasing the estimation of heritability.

The estimations of heritability for alcohol, nicotine, cannabis, and illicit SUD across selected samples of twins are reported in [Table 49.1](#) [1–3].

The recent twin literature suggests that this heritability of the completed stage of addiction (that is, the genetic influence on the diagnosis of SUD) lumps together genetic factors involved at different stages of an addiction. Firstly, some genetic factors increase the risk that individuals are exposed to a substance and experiment with it. Secondly, other genetic factors are involved in the reinforcing effect of the substance. Thirdly, genetic variants might also modify the risk for developing an SUD after regular use. Fourthly, individual variation in the metabolism or pharmacological action of the substance may modulate the risk for addiction. Heritability will be a complex composite of the genetic factors operating early and late in the exposure to the substance of interest.

Heritability of addictions is specific to the population and varies by gender, is influenced by the cultural environment, and will also

Table 49.1 Heritability of alcohol use disorder, nicotine dependence, cannabis use disorder, and illicit substance use disorder among twin cohorts

Sample	Alcohol use disorder	Nicotine dependence	Cannabis use disorder	Illicit substance use disorder
VATSPUD	52%	52%		60–80%
Vietnam era twins	0–65%	60%	33%	34%
National Swedish register	22–57%	48–62%	70%	
Meta-analysis of twin studies	43–53% [1]	37% [2]	51–59% [3]	

be modified by exposure to the substance. If a trait or behaviour has no variability, even if it is strongly supported by genetic factors, its heritability cannot be estimated. For example, in the western adult population, it is not meaningful to examine the heritability of lifetime alcohol use, since most adults are likely to report at least one drink in their lifetime. Similarly, the heritability of nicotine dependence has ‘increased’ in women from zero in those born at the beginning of the twentieth century to levels comparable to those seen in men for those born after 1940, because of the greater opportunity for tobacco use in women in the second part of the twentieth century. The expression of the involved susceptibility genes could not be estimated when women had very limited access to tobacco [4].

Endophenotypes

SUD constitute a broad category of heterogeneous phenotypes, with patients exhibiting a large range of biomarkers and symptom severity, which has further complicated efforts to identify genetic variants. Employing more specific definitions of phenotypes may be more important than using larger sample sizes for detecting true genetic associations. The use of endophenotypes or objective measures of specific neurobiological functions may be particularly helpful in reducing clinical heterogeneity.

Neurobehavioural phenotypes associated with SUD include impulsivity and novelty seeking, stress reactivity, behavioural disinhibition, trait anxiety, and attention allocation, among many others. The expression of these traits varies through the lifespan and during the addiction's stages. For example, impulsivity is higher during adolescence, a period associated with enhanced experimentation with psychoactive substances. Moreover, drug use increases impulsivity, which may, in turn, promote continuous use of the substance. Delay discounting (DD), a decline in the subjective value of reward with increasing delay until its receipt, is an established model to determine one's location on the continuum from impulsive decision-making to self-control, and constitutes a promising endophenotype in the study of SUD [5]. Patients with SUD exhibit a greater DD (a tendency to choose lower, but quicker, rewards rather than higher, but delayed, ones) than controls. A positive relationship between DD and subsequent initiation or increased use of tobacco has been described. DD is also improved in substance users in response to therapeutic interventions. Given that the heritability of DD varies between 46% and 56% [6], it provides an avenue of future research as a candidate behavioural marker of SUD.

Subjective responses to initial substance use have also been considered as a plausible endophenotype. Individuals vary widely in their subjective experience of a psychoactive substance, and this

may play a role in the development of an SUD. Such subjective response represents a heritable endophenotype. Among the most important findings, the literature consistently shows that individuals who demonstrated low response to alcohol in an alcohol challenge test are more likely to develop an AUD at 8-year follow-up [7]. Low sensitivity might be unique to this drug, because it leads to higher consumption. Other studies have confirmed that positive experiences in early use of other substances are important risk factors for later SUD [8, 9].

Candidate genes

The candidate gene approach was the first strategy to investigate the genetic factors involved in SUD. This approach means searching for mutations, or screening for polymorphic markers, in one or more genes selected for their potential role in SUD. Such strategy requires recruiting patients with and without SUD, as: (1) a case-control study (to see if the studied allele is more frequent in the affected population, compared to the healthy control group); or (2) a trio approach (including affected patients and their fathers and mothers, in order to check if the vulnerability allele is more transmitted from the heterogeneous parent(s) to the affected proband); or (3) siblings (where affected sibs should have the vulnerability allele more frequently in common than expected by chances only); or (4) multiplex families (calculating if the vulnerability allele is more frequently transmitted to affected cases, and not transmitted to healthy relatives). Several national and international cohorts have been implemented, following at least one of these strategies. Some examples are the Collaborative Studies on Genetics of Alcoholism (COGA) from the National Institute on Alcohol Abuse and Alcoholism (NIAAA), the Family Study of Cocaine Dependence (FSCD), and the Collaborative Genetic Study of Nicotine Dependence (COGEND).

Current research suggests that a major gene effect on SUD vulnerability is unlikely [9], but some plausible positive findings have been obtained. The candidate genes involved in the reward pathway, especially dopamine receptors, have been widely investigated in SUD. Several studies reported that the Taq1A variant (corresponding to rs1800497) of the gene encoding the dopamine D2 receptor (the *DRD2* gene) is associated with alcohol dependence. Interestingly, this genetic variant changes an amino acid in a novel gene *ANKK1*, which encodes an X-kinase that regulates the presence of the dopamine D2 receptor at the cellular membrane [10]. Some genetic variants of the enzymes involved in the metabolism of ethanol, namely the alcohol dehydrogenase (*ADH*) and acetaldehyde dehydrogenase (*ALDH*) genes, have also been associated with a lower risk for developing AUD, mainly in South Eastern Asian populations [11].

Genome-wide association studies

The first genome-wide association studies (GWAS) were published in 2006. SNPs are used as markers of a genomic region, with the majority of them having minimal or no impact on the biological system. A minority can have functional consequences, by causing amino acid changes, altering mRNA transcript stability, or improving transcription factor binding affinity. SNPs are the most frequent form of genetic variation in the genome. The paradigm underlying GWAS is that complex disorders, including SUD, are polygenic, driven by multiple common genetic polymorphisms, and follow a non-Mendelian pattern of inheritance (Fig. 49.1).

In the GWAS approach, it is assumed that common disorders are likely to be influenced by genetic variation that is also common in the general population. The discovery of several susceptibility variants for common diseases with high minor allele frequency (including the *APOE* gene for Alzheimer’s disease [12, 13] or the *PPARG* gene for type 2 diabetes) led to the development of what is now called the ‘common disease/common variant hypothesis’ [14].

Contrasting with the candidate gene approach, GWAS do not require any assumption on the genomic location of the causal variants and use the strengths of association studies, even in the absence of convincing literature on the location of involved genes. The first GWAS strategy was published in 2014 [15].

The first GWAS of AUD was initially published in 2006 [16] in a sample of 1024 cases and 996 controls, using more than 500,000 SNPs (Fig. 49.2). Complete analysis reported that no associations were genome-wide significant [17]. The largest independent GWAS published to date involved more than 16,000 participants, providing information on about a million autosomal SNPs [18]. This study added to the evidence for the association of variants in the *ADH* gene coding for an alcohol-metabolizing enzyme and provided insight on the role of new loci mapping to the *ADH* gene cluster [18].

As for other similar analyses in psychiatry, a recent review of 12 published AUD GWAS [19] concluded that larger samples will be required to detect loci, in addition to those encoding the genes already mentioned.

A first GWAS on heroin published in 2019 and performed on 325 methadone stabilized, former severe heroin addicts and 250 controls showed an association with the the cytosolic dual-specificity phosphatase 27 encoded by the *DUSP27* gene [20]. Three GWAS reported genome-wide significant SNP association with opioid use disorder. These results included SNPs that mapped to *KCNQ2*, which encodes a potassium voltage-gated ion channel [21], and *CNIH3*, which encodes a glutamate receptor-associated regulatory protein [21]. A recent genome-wide study on cannabis dependence has been performed on three large independent cohorts including 15,000 subjects and detected interesting associations in novel genes, including a novel antisense transcript RP11-206M11.7, the solute carrier family 35 member G1, the *SLC35G1* gene, and the *CUB* and *Sushi* multiple domains 1 gene *CSMD1* [21]. The first GWAS on cocaine use disorder detected a significant role of the *FAM53B* gene, the product of which is involved in the regulation of cell proliferation, but with an unclear biological role in the development of cocaine dependence [21].

The most compelling evidence has come from GWAS and GWAS meta-analyses on nicotine use disorder, showing an association between the nicotinic acetylcholine receptor gene cluster *CHRNA5-A3-B4* on chromosome 15 (15q25) and both nicotine dependence and smoking cumulative quantity [22]. This is highly relevant, given that while there are thousands of compounds in cigarette smoke, nicotine is the principal component responsible for nicotine dependence and exerts its action in the brain through neuronal nicotinic acetylcholine receptors, which are widely distributed in both the central and the peripheral nervous systems [22]. Two associations between nicotine dependence and genetic variants was published in 2007, one in a candidate gene study [23] and one GWAS

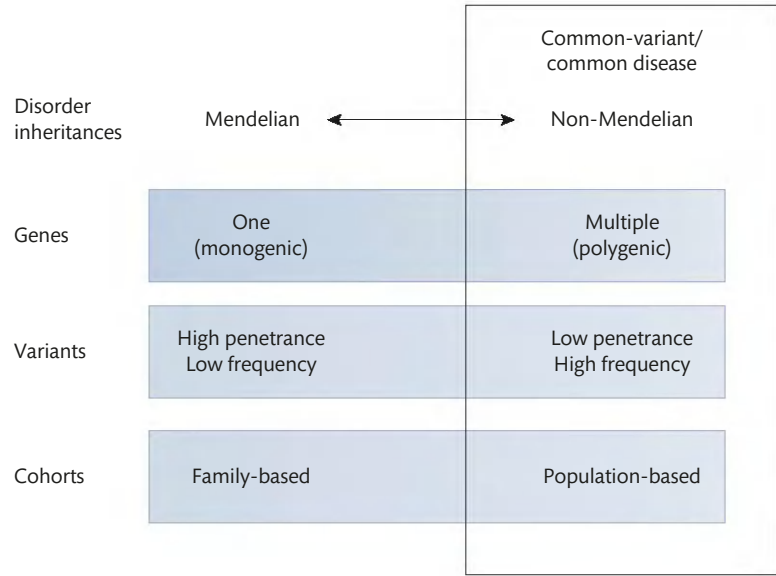

Fig. 49.1 Schematic representation of the hypotheses of genes and variants involved in disorder inheritance according to their Mendelian and non-Mendelian status. The paradigm is that Mendelian-inherited disorders should involve genetic variants with a high penetrance and a low frequency in one gene, while non-Mendelian-inherited disorders should involve variants with a low penetrance but a high frequency in different genes. Thus, Mendelian disorders could be studied with family-based cohorts, while non-Mendelian disorders could be studied with population-based cohorts.

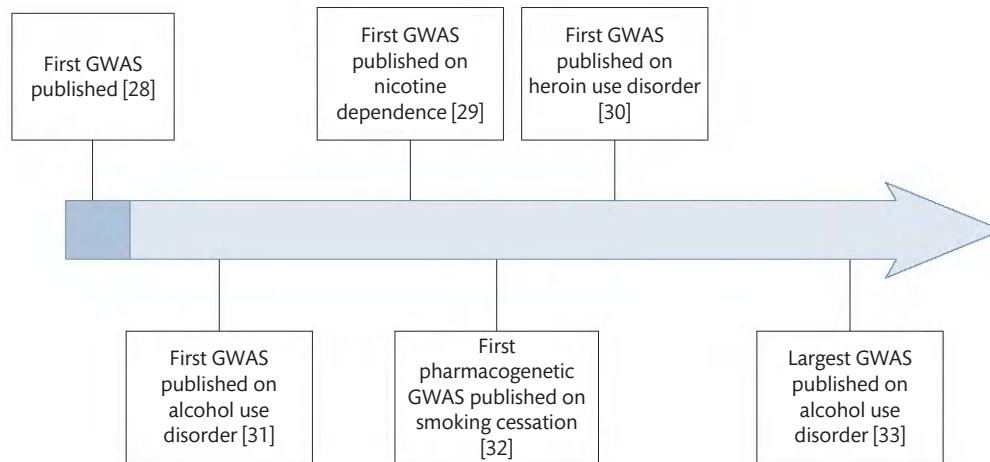

Fig. 49.2 Historical GWAS discoveries on substance use disorders.

on nicotine [24]. In this preliminary study, examining 3713 SNPs in more than 300 candidate genes and involving 879 light smokers and 1050 heavy smokers, multiple SNPs within the *CHRNA5-A3-B4* were associated with nicotine dependence [23]. In the GWAS study, 1050 dependent smokers and 879 non-dependent smokers as controls allowed to associated *CHRNA5* gene [24]. In 2008, two GWAS, considering smoking quantity, but also smoking-related disease (lung cancer and peripheral arterial disease), confirmed the association of variants within this locus and smoking-related phenotypes [25]. Further studies demonstrated the impact of a non-synonymous SNP in the $\alpha 5$ -nicotinic acetylcholine receptor gene (*CHRNA5*) on behaviours associated with the risk of developing tobacco dependence, including a decrease in the aversive effect of nicotine [26]. This genetic assessment for nicotine abstinence could be helpful to use as a biomarker of pharmacogenetics in smoking cessation [27].

Pharmacogenetics of substance use disorders

Recent interventions emphasize the importance of early and intensive treatment for SUD. These studies also demonstrate additional factors that influence outcome such as psychiatric comorbidity (including post-traumatic stress disorder or schizophrenia, among many others) or medical conditions associated with substance use. This has called for treatment elements, such as the choice of psychotherapy and medication, and the goal (abstinence vs controlled use, among many others) to be individualized, so that optimal patient outcomes can be met. It is also tempting to hope that recent genetic findings can help to develop an individualized approach in the clinical management of patients with SUD.

Pharmacogenetic studies may provide the first examples for innovation. In AUD, there appears to be important moderating effects of variation in *OPRM1* on the response to the opioid antagonist naltrexone [28]. The Asp40 allele of Asn40Asp, encoded by the A118G SNP, predicts a significantly lower rate of relapse in four RCTs, while the others were not significant. A meta-analysis confirmed that naltrexone-treated patients carrying the ASP40 allele of the A118G SNP had lower rates of relapse [29]. Human laboratory studies also suggested that the A118G SNP moderates the effects of alcohol, including a differential reduction of the alcohol euphoric effect or craving. Other dopaminergic, serotonergic, GABAergic, and

glutamatergic genes have been studied, but no other specific candidate polymorphism has to date yielded replicable findings [28].

A number of studies have examined the association of genetic variants on features of opioid use disorder and treatment outcome. Methadone and buprenorphine are two common and effective maintenance medications for opioid use disorder. The *DRD2* gene, coding for the D2 dopaminergic receptor and located on chromosome 11 (region 11q23), displays a polymorphism known as Taq1A and has been the subject of over 300 studies [30, 31]. Meta-analyses confirmed a modest, but significant, higher prevalence of the A1 allele in patients with opiate use disorder [30]. Taq1A has also been associated with greater heroin craving. In predicting the outcome of an opioid maintenance treatment, the results have been less conclusive so far. Indeed, in four studies including 404 participants with a maintenance medication, three failed to find an association of this variant with a significant difference in outcome. Similarly, several variants within the *OPRM1* gene (including the A118G SNP) and the *OPRD1* gene have provided inconclusive results so far in pharmacogenetic trials.

Conclusions and perspectives

National and international consortia, recruiting large samples of controls and affected patients, have been successfully used in the genetics of SUD. GWAS have demonstrated the role of variants of nicotinic receptor genes in tobacco dependence and confirmed the involvement of genes encoding enzymes in charge of the metabolism of ethanol in AUD. Furthermore, genes involved in the dopamine pathway have been found associated with several SUDs, although how they increase the vulnerability to SUDs is not entirely deciphered.

The development of new tools to investigate the genome, such as next-generation sequencing (NGS), now make it possible to sequence all exons of the 25,000 genes of the human genome. This technique will identify genetic variations within exons, including rare *de novo* mutations (detected in patients while absent in their parents), which was almost impossible with previous approaches. Analysis of the exome, or genome-wide exome sequencing (GWES), has indeed been a diagnostic tool in common pathologies, but not yet in SUDs. However, GWES is only sequencing about 1.5% of the entire human genome, and other variants, for example those located

in the regulatory regions of genes, may impact the risk of the disorder. Furthermore, genetic studies can now be combined with other analyses to investigate the epigenetics of SUD. Epigenetics relate to the modification of DNA chemistry (but not the DNA sequence), which leads to modifications of gene expression in response to different environmental factors. Early life trauma has been found, for example to increase the level of methylation in specific parts (called CpG islands) of the *GR1* gene, in patients who committed suicide and were abused during childhood [32].

Epigenetics could be the missing link between high heritability and the important role of purely environmental factors, that is, explaining, in part, the 'missing heritability', a concept focusing on the gap between high heritability and the weak role of any individual associated gene.

Future directions should therefore combine the study of developmental and environmental factors with genetic and epigenetic factors. Since the substratum of methylation sites (epigenetic regulation) is purely genetic, the impact of different trauma may vary according to individual genetic polymorphisms. This approach also places clinical evidence at the forefront when studying the genetic vulnerability of SUD.

Alcohol use disorder

Wim van den Brink and Falk Kiefer

Introduction

Alcohol is the most frequently used addictive substance in the world, with large regional variations in the amount of alcohol that is consumed and related variations in damage due to excessive use and alcohol use disorders. About half of the global adult population (48%) has never consumed alcohol, whereas 14% was drinking in the past but has ceased alcohol consumption and 'only' 38% is currently drinking [1]. There are, however, large regional differences, with 80–90% of lifetime abstainers in Islamic countries and only 20% of lifetime abstainers and 60–70% of current drinkers in North America and Europe. Worldwide, mean alcohol consumption among people aged 15 years and older is about 6.2 L of pure alcohol per person per year, which translates into about 13.5 g of pure alcohol per person per day, which is clearly within the WHO range for low-risk alcohol drinking (1–20 g/day for women and 1–40 g/day for men). However, there are large inter-personal and regional differences in the level of alcohol consumption. People in the Eastern Mediterranean region (for example, Jordan: mean 0.7 L) and the South East Asian region (for example, Pakistan: mean 0.1 L) generally drink much less, whereas people in North America (mean 9.5 L) and Europe (mean 10.9 L) drink much more than the worldwide average, with the highest drinking levels in Central and Eastern European countries (for example, Russian Federation: mean 16.1 L).[1]

There is no officially defined safe drinking level, and the amount and type of damage due to alcohol are mainly dependent on the volume of alcohol consumed, the drinking pattern, and the quality of the alcohol that is used. For example, alcohol consumption has been identified as a component cause for more than 200 diseases, injuries, and other health conditions, and for most of these diseases and injuries, there is a clear dose–response relationship [2]. Also the pattern of drinking affects the risks [3]; for example, drinking while eating is associated with less harm from chronic diseases than the same pattern of drinking at other times [4], whereas heavy episodic or binge drinking is linked to unintentional injuries (accidents), intentional injuries (suicides) [5], and ischaemic heart disease and ischaemic stroke [6]. Finally, the quality of alcoholic beverages may impact on health and mortality; for example, home-made or illegally produced alcoholic beverages can be contaminated with methanol or other toxic substances. However, there is no evidence

that consumption of illegally produced alcohol is markedly linked at a population level to morbidity or mortality over and above the effects of the level of ethanol use [7].

Worldwide, there are 3.3 million deaths every year resulting from the harmful use of alcohol representing 5.9% of all deaths, including 33% of cardiovascular diseases and diabetes, 17% of unintentional injuries, 16% of gastrointestinal diseases, 13% of cancers, and 21% of other diseases. These deaths occur early in life, and in the age group of 20–39 years, approximately 25% of total deaths are alcohol-attributable. Therefore, it comes as no surprise that 5.1% of the global burden of disease and injury in terms of disability-adjusted life years (DALYs) is attributable to alcohol [1]. Finally, the harmful use of alcohol brings significant social and economic losses to individuals and society at large.

It is important to realize that about two-thirds of all alcohol-related deaths are caused by 4–7% of drinkers, that is, drinkers with an alcohol use disorder and often with chronic, excessive alcohol consumption [8]. Like the level of alcohol consumption in the population, the 12-month prevalence of alcohol use disorders (harmful use/abuse and dependence) shows considerable regional variation, with low rates in the Eastern Mediterranean region (0.3%) and the South East Asian region (2.2%) and much higher rates in the Americas (6.0%) and Europe (7.5%) [1]. In this chapter, we focus on these people with an alcohol use disorder.

Classification and diagnosis of alcohol use disorders

The concept of addiction, later called dependence and now substance use disorder, is long, complex, and full of controversies. Alcohol use and alcohol use problems are already known from ancient biblical, Egyptian, and Babylonian sources. In the seventeenth and early eighteenth centuries, regular alcohol use was very common in Europe since alcohol represented a cheap and useful combination of clean water and calories. With the change from a mainly agricultural society to an industrial society in the middle of the eighteenth century, regular intoxication became problematic and 'habitual drunkards' were seen as morally weak and in need of re-education in a correctional centre that generally took the shape of a prison (*moral model*). This view changed in the beginning of the nineteenth century

with the start of the temperance movement. Habitual drunkards were no longer seen as morally weak, but as victims of the highly addictive substance alcohol, and regulation, or even prohibition, of the production, trade, and consumption of alcohol was seen as the best solution for the problem of excessive alcohol use (*pharmacological model*). The term ‘alcoholism’ was first used in 1849 by the Swedish physician Magnus Huss to describe the detrimental effects of alcohol. In the early twentieth century, psychoanalytic theorists proposed that alcoholism was not a separate problem, but just a symptom of a character neurosis/personality disorder (*symptomatic model*). Successful treatment of the underlying personality disorder (in a therapeutic community) would also resolve the alcohol problem. Between 1946 and 1960, E. Morton Jellinek performed a series of studies among AA members, and based on the results of these studies, he coined the term ‘disease of alcoholism’ with five different subtypes (*biological or disease model*). It was only in the 1970s that psychologists and sociologists developed theoretical and treatment models for problematic alcohol use, with psychologists proposing that alcoholism was a form of maladapted learnt behaviour that could be redressed during psychological interventions (*psychological or learning model*) and sociologists stating that alcoholism is a normal response to abnormal circumstances and that normalization of these circumstances would solve the problem (*social model*). In 1975, a WHO steering group discussed the latest developments, and based on this discussion, Edwards and Gross proposed a new model integrating biological, psychological, and social aspects [9]—the alcohol dependence syndrome with the following symptoms: narrowing of drinking repertoire; salience of drink-seeking behaviour; increased tolerance; repeated withdrawal; repeated relief/avoidance of withdrawal by drinking; subjective awareness of compulsion to drink (craving); and reinstatement of the syndrome after abstinence (*biopsychosocial model*). In 1997, Alan Leshner, then the director of the National Institute of Drug Abuse (NIDA), made a final contribution to the history of the concept of addiction when he wrote a paper with the challenging title ‘Addiction is a brain disease, and it matters’ (*brain disease model*) [10]. The brain disease model states that addiction is a chronic, relapsing disease that results from biological vulnerabilities and the prolonged effects of drugs on the brain. However, as with many other brain diseases, addiction has embedded behavioural and social context aspects that are important parts of the disorder itself. Therefore, effective treatments should include biological, behavioural, and social context components.

The history of the classification of alcohol use problems runs partly parallel with the history of the concept of alcoholism. In the first two editions of the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association (DSM-I, 1952; DSM-II, 1968), alcoholism was classified as a subcategory of the sociopathic personality disorder, and thus reminiscent of the moral or symptomatic model [11, 12]. In DSM-III (1980), the term ‘alcoholism’ was dropped in favour of two distinct, but loosely defined, categories labelled ‘alcohol abuse’ and ‘alcohol dependence’ and these new disorders were placed in a separate category ‘Substance use disorders’, rather than as subsets of personality disorders [13]. DSM was revised again in 1987 (DSM-III-R) [14]. This time, the alcohol dependence syndrome [9] was used as a starting point and explicit diagnostic criteria were provided. As a consequence, the category of dependence (≥ 3 out of nine criteria) was expanded to include some criteria that, in DSM-III, were considered symptoms

of abuse, and the category ‘Abuse’ (≥ 1 out of 2 criteria) became a residual category for diagnosing those who never met criteria for dependence but who drank despite alcohol-related physical, social, psychological, or occupational problems or who repeatedly drank in dangerous situations such as in conjunction with driving. In 1994, the fourth edition of DSM (DSM-IV) was published, with some minor changes in the criteria sets for dependence (≥ 3 out of seven criteria) and abuse (≥ 2 out of four criteria) [15]. The latest revision of DSM (DSM-5) was introduced in 2013 and contained important changes with regard to the classification of alcohol-related problems [16]. In DSM-5, the dependence criterion ‘legal problems’ was eliminated and replaced by ‘craving’ as a new criterion. In addition, alcohol abuse and alcohol dependence were integrated into a single disorder called ‘alcohol use disorder’ (AUD) with 11 criteria (ten old criteria and one new criterion—craving) and three levels of disorder severity, based on the number of criteria present in the last 12 months: mild AUD (2–3 out of 11 criteria), moderate AUD (4–5 out of 11 criteria), and severe AUD (≥ 6 out of 11 criteria). [Table 50.1](#) presents a summary of the criteria for the DSM-5 classification of an AUD [16] (also discussed in relation to mechanisms of addiction in Chapter 48).

Similar to DSM, there were also substantial and largely parallel changes in the definition of alcohol use problems in the International Classification of Diseases (ICD) of the WHO. Early definitions of alcoholism in ICD-7 (1958) and ICD-8 (1968) stressed the sociological, rather than the physical, aspects of dependence [17, 18]. However, in ICD-9 (1978), the term alcoholism was dropped in favour of alcohol dependence syndrome [19]. Similar to DSM-IV (1994), ICD-10 (1992) defined two mutually exclusive alcohol diagnoses: harmful use and dependence [20]. However, in contrast to DSM-IV where abuse was defined by alcohol-induced social impairments, inter-personal problems, legal problems, and/or hazardous use, in ICD-10, harmful use was determined by alcohol-induced psychological or physical harm. ICD-10 dependence (≥ 3 out of six criteria) was very similar to DSM-IV dependence but ICD-10 already included craving as one of the criteria. In the draft version of the latest version of ICD (ICD-11), the two mutually exclusive categories of harmful use and dependence are retained, but harmful use will now include the criterion ‘family harmed by substance use’, whereas the six dependence criteria of ICD-10 will be reduced to only three criteria: physical dependence (tolerance or withdrawal), priority of use (much time or reduced activities, or psychological/physical harm), and impaired control (quit/cut or larger/longer or craving) [21]. Symptoms from at least two of the three proposed ICD-11 dependence criteria are needed for a diagnosis of alcohol dependence ([Table 50.1](#)).

There are some early findings comparing DSM-IV to DSM-5 and ICD-11 (draft) to DSM-5. These findings show that the prevalence of AUD in the general population according to DSM-5 is somewhat higher than according to DSM-IV (abuse and dependence), but that very similar prevalence rates are obtained in clinical settings [22]. Furthermore, the threshold for DSM-IV alcohol dependence (≥ 3 out of seven criteria) seems to be very similar to the threshold for DSM-5 moderate alcohol use disorder (≥ 4 out of 11 criteria) [23]. In a general population study from Australia, the prevalence of alcohol dependence according to ICD-10, ICD-11, and DSM-IV was very similar, but the prevalence of DSM-5 moderate/severe AUD was substantially higher [24]. Finally, a study among American

Table 50.1 Classification of alcohol use disorders in DSM-IV, DSM-5, ICD-10, and ICD-11

	DSM-IV Alcohol dependence (≥3/7)	DSM-5 Alcohol use disorder (≥2/11) (mild 2–3/11; moderate 4–5/11; severe ≥6/11)	ICD-10 Alcohol dependence (≥3/6)	ICD-11 Alcohol dependence (≥2/3)
1		Craving	Craving	1. Impaired control over substance use often accompanied by craving
2	Persistent desire or unsuccessful attempts to reduce or stop alcohol use	Persistent desire or unsuccessful attempts to reduce or stop		
3	Alcohol use more or longer than intended	Alcohol use more or longer than intended	Alcohol use more or longer than intended	
4	Reduced social, occupational, and recreational activities due to alcohol use	Failure to fulfil role obligations due to alcohol use	Neglect of other pleasures and responsibilities due to time needed to obtain and recover from alcohol use	2. Substance becomes increasing priority in life and relegates other areas of life to periphery; continued alcohol use despite problems
5	Lots of time spent to obtain, use, or recover from the effects of alcohol	Lots of time spent to obtain, use, or recover from the effects of alcohol	(Subsumed in above criterion)	
6	Continued alcohol use despite recurrent or persistent physical or psychological problems due to alcohol use	Continued alcohol use despite recurrent or persistent physical or psychological problems due to alcohol use	Continued alcohol use despite harmful consequences	
7a	Tolerance indicated by increased use to obtain same effect or reduced effect with the same amount	Tolerance indicated by increased use to obtain same effect or reduced effect with the same amount	Tolerance indicated by increased use to obtain same effect	3. Physiological features, including tolerance, withdrawal, and/or alcohol use to prevent or alleviate withdrawal symptoms (not just hangover)
7b	Withdrawal manifested by specific withdrawal syndrome or alcohol use to relieve or avoid withdrawal symptoms	Withdrawal manifested by specific withdrawal syndrome or alcohol use to relieve or avoid withdrawal symptoms	Withdrawal manifested by specific withdrawal syndrome or alcohol use to relieve or avoid withdrawal symptoms	
	Alcohol abuse (≥1/4)		Harmful alcohol use (≥1/2)	
8	Continued alcohol use despite recurrent or persistent social or inter-personal problems due to alcohol use	Continued alcohol use despite recurrent or persistent social or inter-personal problems due to alcohol use	Continued alcohol use despite recurrent or persistent social or inter-personal problems due to alcohol use	(Partly in criterion 2)
9	Hazardous drinking (for example, while driving)	Hazardous drinking (for example, while driving)		
10	Failure to fulfil major role obligations due to drinking	Failure to fulfil major role obligations due to drinking		(Partly in criterion 2)
11	Recurrent alcohol-related legal problems			
12			Continued alcohol use despite recurrent or persistent physical or psychological problems due to alcohol use (see also criterion 6)

adolescents admitted for intensive outpatient addiction treatment showed that ICD-11 produced a lower prevalence of AUD, but a much higher prevalence of alcohol dependence than DSM-IV alcohol dependence and DSM-5 moderate/severe AUD, with very low levels of intersystem diagnostic agreement [25]. These findings show that the final word about the classification of alcohol use-related problems is still not spoken and that further studies are needed.

Mechanism of action of alcohol and neurobiology of alcohol use disorders

Alcohol modulates neural activity directly via ethanol-binding sites on several membrane receptors, including the *N*-methyl-*D*-aspartate

(NMDA) receptor, the gamma-aminobutyric acid A (GABA-A) receptor, the 5-hydroxytryptamine-3 (5-HT₃) receptor, and ion channels [26]. In addition to these primary targets, indirect effects on neurochemical and neuroendocrine systems trigger reinforcing and stress-related effects. The main indirect targets are the dopamine system, the opioid system, and the hypothalamus–pituitary–adrenocortical (HPA) axis [27–30].

Following chronic administration of alcohol, several neurobiological adaptations (for example, changes in gene expression, molecular alterations, synaptic and cellular changes) take place that may result eventually in long-lasting alterations in neuronal network activity [31]. These alterations persist during abstinence. Corresponding behavioural effects become evident when the recently abstinent subject is exposed to alcohol-related stimuli or stress. Thus, even after

successful detoxification and abstinence treatment, somebody with an AUD remains at risk for relapse. Animal models have assisted in identifying the molecular mechanisms that are primarily involved in alcohol reward and compulsive alcohol intake behaviour [32]. For example, a sensitization process within the dopaminergic reward system, especially in response to alcohol-related cues, drives relapse behaviour, even after protracted abstinence [33]. It is suggested that in the non-addicted, but vulnerable, brain, a phasic dopamine signal within the ventral striatum/nucleus accumbens (VS/NcAcc) leads to incentive salience and acts as a form of stimulus–reward learning, in which incentive salience is assigned to alcohol-related reward cues [34]. In the transition to addictive behaviour, VS/NcAcc-driven incentive salience to reward transforms into repetitive, automatized stimulus–reaction schemata that are mainly mediated by the recruitment of the dopaminergic dorsal striatum (DS), a change that is here referred to as the ‘ventral–dorsal striatal shift’ [10–37]. In addition, preclinical studies suggest a critical involvement of prefrontal cortical–striatal connectivity with glutamate–dopamine interactions in the transition from recreational to compulsive alcohol-seeking behaviour [38, 39]. The loss of type 2 metabotropic glutamate receptors (mGluR2) in the cortico-accumbal neurocircuitry due to chronic alcohol use is important for the increased propensity to relapse [40]. Loss of these auto-receptors is accompanied by a loss of neuronal plasticity, that is, the mGluR2-mediated long-term depression (LTD) is abolished in the addicted brain, resulting in reduced prefrontal cognitive control over the hyperactive reward system [41]. Due to this reduced prefrontal control and the progressive recruitment of a striatal dopaminergic mechanism (‘VS-DS shift’), automatized behaviour and repetitive and compulsive uncontrolled alcohol use are facilitated [36, 42]. Human neuroimaging studies are supporting the importance of prefrontal regions in the alcohol-addicted brain [43, 44]. Further detail on animal models and human experimental studies underlying this formulation is given in Chapter 48.

At the psychological level, relapse can be understood using the negative reinforcement theory. Thus, avoidance of an aversive state during withdrawal—which is characterized by depressed mood and elevated anxiety—triggers a relapse to alcohol use [45]. In most patients, these symptoms abate over 3–6 weeks of abstinence, while relapse risk persists long beyond this period. However, more subtle changes, such as increased behavioural sensitivity to stress, support the clinical relevance of negative emotionality for protracted abstinence and relapse [46]. Modelling this process of alcohol-induced negative emotionality in laboratory animals has led to the discovery of augmented corticotropin-releasing hormone (CRH) signalling in the amygdala as a pathological mechanism that drives negative emotionality, and thereby relief drinking. It has been postulated that CRH signalling via its CRH1 receptor is a key element of the neuroadaptive changes driving relapse behaviour [47]. Pathological engagement of CRH signalling in the amygdala leads to negative emotionality during protracted abstinence and subsequently to relief drinking. Another mechanism that leads to relief drinking is an upregulation of the dynorphin/kappa opioid receptor (KOR) system in the brain [48–50]. It is important to note that activation of the dynorphin/KOR system, especially in the NcAcc [51], induces a dysphoric state [52], which may also drive relief drinking.

These findings are important to better understand the nature of substance use disorders and the problems that patients with these disorders experience and to guide the development of new treatments.

Psychological treatments can be directed at increased motivation to reduce or stop the use of alcohol (for example, motivational interviewing), while pharmacological treatments can be directed at reducing the rewarding effects of alcohol (for example, opioid receptor antagonists). Psychological and pharmacological treatments can also be used to reduce negative emotions related to substance use (CBT, α -adrenergic antagonists), to reduce craving (for example, cue-exposure treatment, glutamate antagonists), to improve cognitive control (for example, CBT, stimulants), and finally to replace alcohol with less toxic substitutes (for example, high-dose baclofen). In the following paragraphs, these approaches will be discussed in greater detail.

Psychological treatments for patients with an alcohol use disorder

A crucial step in the treatment of patients with an alcohol use disorder is motivation for treatment. Many people with an alcohol use disorder are not aware of the fact that their alcohol use is causing problems (*precontemplation stage*), or they do recognize that alcohol is causing problems but they feel that there is still a reasonable balance between the short-term gains and the long-term problems (*contemplation stage*). In both cases, there is no perceived need to change one’s behaviour. At a certain time or after appropriate motivational stimulation, people with an alcohol problem may realize that the balance between pros and cons begins to tip in the direction of change (*preparation stage*), which may actually result in concrete changes in behaviour and in changes of the environment (*action stage*). However, even after a period of reduced drinking or abstinence, relapse is still very likely to occur if no measures are taken to prevent this (*maintenance stage*).

Until the 1980s, the common way to deal with ‘unmotivated’ patients was a harsh and confrontational strategy to overcome ‘pathological denial’. Since then, a more effective approach has been developed—motivational interviewing. It combines a supportive and empathic counselling style with a directive method for resolving the perceived ambivalence in the direction of change, that is, reduced drinking or total abstinence [53]. In the latest version of motivational enhancement therapy (MET), the intervention mainly tries to evoke ‘change talk’ and to prevent ‘counterchange talk’ [54]. In a recent fMRI study, it was shown that in patients with an alcohol use disorder, listening to their own change talk significantly reduced activation of the cingulate cortex and the insula during a priming dose of alcohol and that this reduction in brain activation was associated with a reduction in subjective craving [55]. MET is currently accepted as an evidence-based treatment for patients with an alcohol use disorder, with similar effects in patients in different stages of motivation.

In addition to MET, there are several other evidence-based psychological treatments for patients with an alcohol use disorder, including cognitive behavioural therapy (CBT), often with a strong emphasis on social skills training, although without clear support that improved coping skills mediate the benefit [56]; cue-exposure treatment (CET; often as part of CBT); 12-step facilitation (TSF), a professional intervention intended to make patients join a self-help group, for example Alcohol Anonymous (AA) meetings; contingency management (CM) with rewards for negative alcohol breath

tests or attendance of therapy sessions (often as part of a community reinforcement approach); community reinforcement approach (CRA), generally including an amalgam of different techniques, for example social skills training, medication compliance support, medication, vocational training, marital therapy, and/or CM; and behavioural couple therapy [57]. It should be noted, however, that behavioural couple therapy is probably not more effective than individual CBT [58].

There are also several interventions with no proven effectiveness or with proven non-effectiveness, including psychodynamic psychotherapy, experientially oriented therapies, and system-theoretically based approaches [57].

Finally, there are some new treatments with some empirical support, but without conclusive evidence of their effectiveness. The most promising of these are: mindfulness-based relapse prevention [59]; acceptance and commitment therapy [60]; approach bias re-training [61]; and counterconditioning [62].

According to most authors, MET and CBT should be available to all patients with an alcohol use disorder as the standard treatment, with other treatments being available for special patients or as an additional treatment for those who do not or insufficiently respond to MET or CBT. However, other authors claim that CRA, as a more comprehensive treatment, should be the standard with a different set of treatment modules for different patients. Unfortunately, there are very few studies directly comparing these different approaches.

With regard to MET/CBT, it is important to notice that group and individual CBT are equally effective [64] and that MET/CBT offered as an online self-help intervention is also effective, although an online self-help intervention blended with chat sessions with a professional is more effective and more cost-effective than online self-help-only intervention [65]. These findings show that MET and CBT can be effectively and cost-effectively offered in different treatment settings and even to people who are not (yet) ready to seek contact with an official addiction treatment service.

An unresolved question is the effectiveness and cost-effectiveness of treatment according to the time-honoured Minnesota model, that is, a comprehensive inpatient 12-step treatment followed by long-term AA attendance. In a review for the Netherlands' National Health Care Institute, it was concluded that the evidence for the efficacy of inpatient and day care treatments according to this model was weak at best (only two RCTs), that these treatments are probably not (much) more effective than standard outpatient treatments (for example, MET, CBT), and that these treatments are almost certainly less cost-effective than standard outpatient treatments [63].

Pharmacological treatments for patients with an alcohol use disorder

The first medication for the treatment of alcohol use disorder was disulfiram. Disulfiram and similar compounds were originally used for the industrial vulcanization of rubber. Some workers noticed that exposure to disulfiram, in combination with alcohol, made them feel sick. In 1948, Danish researchers made the connection and proposed disulfiram for the treatment of patients with an alcohol use disorder. Normally, alcohol is broken down in the liver by the enzyme alcohol dehydrogenase (ADH) to acetaldehyde, which is then converted by the enzyme acetaldehyde dehydrogenase (ALDH) to

harmless acetate. Disulfiram (125–250 mg/day) blocks ALDH, and after alcohol intake, the concentration of acetaldehyde in the blood may become 5–10 times higher than during metabolism of the same amount of alcohol alone. As a consequence, patients using alcohol while under the influence of disulfiram will experience a set of very unpleasant symptoms, including flushing of the skin, accelerated heart rate, shortness of breath, nausea, vomiting, throbbing headache, and sometimes even visual disturbances, mental confusion, postural syncope, and circulatory collapse.

In a recent meta-analysis, disulfiram was more effective than placebo in open-label, non-blinded studies (effect size $g = 0.70$), but not in blinded studies ($g = 0.01$), suggesting that the effect of disulfiram depends directly on the patient's anxious anticipation of its adverse effects [66]. Therefore, disulfiram seems to be a form of assisted psychotherapy, rather than pharmacotherapy per se. In the same meta-analysis, supervised disulfiram was more effective than acamprosate and naltrexone in establishing abstinence and to prevent relapse. However, it does not reduce alcohol craving, and (thus) there is poor compliance and the medication seems to be effective only when taken under supervision [67]. Moreover, disulfiram has many contraindications, including brain damage, heart failure, liver cirrhosis, and psychosis—conditions that are relatively frequent in patients with an alcohol use disorder.

From the introduction of disulfiram, it took about 40 years before new medications for the treatment of alcohol dependence entered the market in the early 1990s: acamprosate first in Europe and—much later—in America, and naltrexone first in America and—somewhat later—in Europe. Acamprosate changes the balance between the GABA and glutamate systems probably by its action on the NMDA receptor. It reduces withdrawal and craving, and it promotes long-term abstinence in compliant patients. It has to be taken at 333 mg three times a day, and the main contraindication is severe kidney impairment. Naltrexone is a non-selective opioid receptor antagonist that reduces alcohol reward and craving and results in reduced drinking with less heavy drinking days, and in some patients, it also promotes abstinence. Naltrexone is taken once a day (50 mg), and the main contraindications are the use of (prescribed or illicit) opioids, acute hepatitis, and liver failure. However, with the dose that is used, interference with liver function is rare, and if alcohol intake is reduced, liver function may actually improve. In a recent meta-analysis [67], acamprosate and naltrexone were equally effective, with no significant differences in drinking outcomes in studies where the two medications were directly compared. In placebo-controlled trials, acamprosate was mainly effective in the prevention of any drinking [number needed to treat (NNT) = 12], whereas naltrexone was mainly effective in the prevention of heavy drinking (NNT = 12) and much less so for the prevention of any drinking (NNT = 20).

Recently, a fourth medication—nalmefene—was registered in Europe for the treatment of alcohol dependence. Nalmefene is a mu (MOR) and delta opioid receptor (DOR) antagonist and a kappa opioid receptor (KOR) partial agonist. Since in alcohol-dependent patients, the KOR is already overstimulated, nalmefene is functionally a KOR antagonist. Nalmefene reduces alcohol reward (MOR antagonist), and it may reduce dysphoria (KOR partial agonist) in chronic alcohol-dependent patients [68]. In the recommended dose, nalmefene is quickly absorbed, with a maximum plasma concentration reached within 1 hour, occupation of almost all MORs

within less than 3 hours, and full receptor occupancy remaining for at least 26 hours [69]. In contrast to the other registered medications, nalmefene is used ‘as needed’ (that is, only when the patient experiences the risk of relapse); the goal is reduction of (heavy) alcohol use, rather than total abstinence, and the medication should only be prescribed to heavy-drinking patients. The strategy to take the medication ‘as needed’ puts the responsibility for the treatment clearly on the patient. As such, it synergizes with strategies that try to empower patients. Moreover, the goal of reduced drinking allows patients who are not ready or not willing to stop drinking completely to enter treatment. In a meta-analysis [68], nalmefene was shown to be effective in the reduction of the number of heavy drinking days, with a small effect in alcohol-dependent patients ($g = 0.20$) and a somewhat larger effect in alcohol-dependent patients with (very) heavy drinking risk levels ($g = 0.33$).

There are also other medications, often with different molecular targets, that have been tested for the treatment of alcohol dependence. Since none of these compounds have relevant marketing authorization, their prescription for alcohol dependence is off-label. The most promising so far is topiramate (150–300 mg/day), an atypical anti-epileptic drug that probably blocks voltage-gated sodium channels and high-voltage-activated calcium channels, strongly stimulates specific GABA-A receptor isoforms, and somewhat inhibits glutamatergic AMPA/kainate receptors. In a meta-analysis of seven RCTs [70], topiramate was effective in both the prevention of any drinking ($g = 0.47$) and the reduction of the number of heavy drinking days ($g = 0.41$). Topiramate has many frequently occurring side effects (for example, weight loss, paraesthesia, fatigue, dizziness, sleepiness, depression), and titration can take up to 8 weeks, making it less suitable for weakly motivated and/or impulsive patients.

Other promising medications include [71, 72] gabapentin (GABAergic medication registered for epilepsy, neuropathic pain, and restless legs), sodium oxybate (GABAergic medication registered for narcolepsy), varenicline [nicotinic acetylcholine receptor (partial) agonist registered for nicotine dependence], doxazosine ($\alpha 1$ -adrenergic antagonist registered for hypertension and urinary retention due to benign prostate hyperplasia), modafinil (a wakefulness-promoting dopamine reuptake inhibitor registered for narcolepsy), and baclofen (a GABA-B agonist registered for spasticity). In France, more than 200,000 patients with an alcohol use disorder have already been treated with baclofen at low (up to 60 mg/day) or (very) high doses (up to 330 mg/day), despite a paucity of evidence for efficacy at low doses and for efficacy and safety at (very) high doses. This is a very promising medication, but further studies are needed to learn more about the most adequate dose, the most suited patient profile, and the long-term safety [73].

Improving treatment outcomes

In the previous paragraphs, it has been shown that there many proven effective treatments available for patients with an alcohol use disorder. However, effect sizes are small to moderate ($g = 0.20$ – 0.50 ; NNT 10–20), and many patients do not respond to these treatments.

One of the main determinants of outcome is the stage of the illness when patients enter treatment. Most patients are in a relatively late stage, and thus a rather advanced state of the disease with more

complex neural consequences of their chronic and excessive alcohol use (for example, VS-DS shift) and with serious physical, psychological, and social consequences, including liver impairment, depression, homelessness, etc. Their response to treatment is generally less good than in patients with a short illness history. This situation can only be improved by interventions directed at destigmatization [74] and increased availability of (anonymous) online self-help and online blended interventions [75].

Other strategies to improve the effect of treatments for alcohol use disorders are: improving treatment compliance, combining psychotherapy and pharmacotherapy, combining medications with a different mechanism of action (polypharmacy), and personalized medicine, that is, matching specific patients to specific treatments [71].

For improved compliance, attempts have been made to produce long-acting medications, including subcutaneous disulfiram implants and intramuscular naltrexone injections. However, so far no positive results have been reported.

In the combination of psychotherapy and pharmacotherapy, it is clear that pharmacotherapy adds to the effect of psychotherapy (all pharmacotherapy registration trials used the medication/placebo as an add-on to some form of psychotherapy or psychosocial support), whereas psychotherapy does not seem to add substantially to the effect of pharmacotherapy, neither in terms of compliance nor in terms of alcohol use outcomes [76, 77].

Combined use of medications may hold more promise. Acamprosate plus naltrexone has been shown to be more effective than either medication alone [78, 79], and the same was true for acamprosate plus disulfiram, compared to acamprosate alone [80]. The main question that remains here is when combined use of different medications should be considered: (1) right at the start of treatment to prevent treatment dropout due to non-response, but with the risk of more side effects; or (2) only after treatment with a single medication failed, but with the risk of further damage during the unsuccessful single medication treatment.

In our view, the most promising way to improve the (cost-)effectiveness of alcohol use disorder treatments is the use of personalized medicine, that is, tailoring treatments to specific patients based on direct observable clinical characteristics (phenotype), indirectly observable brain functions (endophenotype), and/or genetic indicators (genotype). With regard to the intensity of treatment, it is well known that inpatient treatment is generally more expensive, but not more effective than (intensive) outpatient treatment [81], probably with the exception of some very severely alcohol-dependent patients and those with serious social problems, especially those with unstable housing or being homeless [82].

With regard to psychotherapy, there have been some (very) large studies looking at patient–treatment matching, but none of these studies have found that patients with certain patient and/or environment characteristics (level of alcohol involvement, cognitive impairment, conceptual level, gender, meaning seeking, motivational stage, psychiatric comorbidity, sociopathy, social support for drinking, alcoholism typology) do clearly better with specific types of psychotherapy [83, 84]. However, in a re-analysis of the study MATCH, there were some indications that MET was performing better than CBT in patients with lower baseline motivation for change [85].

With regard to the pharmacotherapy of alcohol dependence, there are some very promising matching findings (Table 50.2).

Table 50.2 Personalized pharmacotherapy model for alcohol dependence

Treatment goal	First choice	Second choice	Third choice
Abstinence	Acamprosate (<i>anxiety, withdrawal, GATA4</i>) Naltrexone * (<i>FH +, ASPD, SL, OPRM1</i>)	Disulfiram (partner)	Baclofen HD (<i>anxiety, withdrawal</i>) Gabapentin (<i>sleep problems</i>) GHB*
Reduced drinking	Naltrexone (<i>FH +, ASPD, SL, OPRM1</i>) Nalmefene (<i>dysphoria?</i>)	Topiramate (<i>GRIK1</i>)	Modafinil (<i>high impulsivity</i>) Varenicline (<i>smoking</i>) Doxazosin (<i>FH +</i>)

Personal characteristics for treatment choice within brackets in italics; bold medications are registered for the treatment of alcohol dependence.

GATA4, gene encoding a member of the GATA family of zinc finger transcription factors; FH +, positive family history of alcohol use disorder; ASPD, antisocial personality disorder; SL, sweet-liking; OPRM1, mu opioid receptor gene; GRIK1, gene encoding the glutamate ionotropic receptor kainate type subunit 1; GHB, gamma-hydroxybutyric acid/sodium oxybate.

* Naltrexone is registered for indication 'abstinence', but seems to work better for indication 'reduced drinking'.

Only used for treatment of alcohol dependence in Austria and Italy.

For example, in a review of studies on the use of naltrexone in the treatment of alcohol dependence, it was shown that patients with one or more of the following characteristics tended to do better with naltrexone: positive family history of alcohol problems, Asn40Asp polymorphism of the MOR (*OPRM1*) gene, pretreatment abstinence, and sweet-liking [86]. Genetic variations in the *GATA4* gene seem to have an effect on the treatment response to acamprosate in alcohol-dependent patients via modulation of atrial natriuretic peptide (ANP) plasma levels [87]. Probably the most robust pharmacogenetic finding so far is the moderating effect of the glutamatergic *GRIK1* gene on the effect of topiramate in treating patients with alcohol dependence [88]; in a prospective placebo-controlled RCT, topiramate was only effective in rs2832407 C allele homozygotic patients (42%), and not in A allele carriers (58%). Finally, modafinil has been shown in one study to have a favourable effect in alcohol-dependent patients with high motor impulsivity, whereas it had a detrimental effect in alcohol-dependent patients with low motor impulsivity, indicating that individual patient characteristics cannot only be predictive of benefits, but also of potential harms [89].

These and similar findings may explain why trials find no or only very small treatment effects in unstratified, heterogenous patient populations. On the other hand, such findings often arise in secondary analysis of trial data and thus require replication. For example, a prospective RCT failed to confirm the matching effect of the Asn40Asp polymorphism of the *OPRM1* gene [90]. All future studies must clearly be informed by our growing understanding of individual or subgroup differences in complex disorders.

Conclusions

Alcohol use disorders are frequently occurring problems that involve severe personal suffering and create substantial societal costs. The definition of these disorders is still under debate, but the existing working definitions have made it possible to investigate their neurobiology and to study the effectiveness and cost-effectiveness of psychotherapeutic and pharmacological interventions. These studies have shown that there are many proven effective interventions, albeit with limited effect sizes. Research has also shown that early detection and treatment (for example, with online interventions), combinations of treatments (polypharmacy), and a better system of patient–treatment matching can lead to a better outcome and a better future for patients with an alcohol use disorder.

Opioids

Heroin, methadone, and buprenorphine

Michael Farrell, Briony Larance, and Courtney Breen

What are opioids?

The term *opioid* is a general term applied to drugs derived from the opium poppy (*Papaver somniferum*) and the range of naturally occurring, synthetic, and semi-synthetic compounds derived from them [1]. These drugs relieve pain (*analgesic* effect) and create a sense of euphoria (*narcotic* effect). Opioids produce most of their effects by binding to three main opioid receptor subtypes in the brain: mu (μ), delta (δ), and kappa (κ) [1]. There are also endogenous opioids, such as endorphins, that help the body regulate the sensation of pain, although mostly, the term *opioid* is used to describe a class of exogenous drugs (such as heroin and morphine). Examples of different opioids and their mode of action (that is, *agonists*, *partial agonists*, *antagonists*, and *agonist-antagonists*) [1] are provided in [Table 51.1](#). Opioid *agonists* include heroin, morphine, and methadone; a *partial agonist* is buprenorphine, and opioid *antagonists* include naltrexone and naloxone.

The role of opioid medications

Pharmaceutical opioids have an important, legitimate role in medical practice and contribute to the health and well-being of many patients. There are two broad clinical indications for their use: (1) the management of pain that is either acute or chronic; and (2) the management of opioid dependence through opioid substitution therapy (OST). The World Health Organization (WHO) states that opioid medications are ‘*absolutely necessary*’ for the management of severe cancer pain [2, p. 7] and ‘*essential medicines*’ for the treatment of opioid dependence [3]. Although the optimal use of opioids in the management of chronic non-cancer pain is increasingly debated and a subject of significant controversy in North America [4], there are clear statements from pain organizations supporting their continuing use [5, 6].

Common opioids

Opium is extracted from the opium poppy, and heroin (diacetylmorphine) is synthesized from the extraction; both are short-acting opioid agonists [1, 7]. Heroin has medical applications in some countries, with a long tradition of medical use for analgesia in England

(for example, [8, 9]). In other countries, including Australia, both heroin and opium are illegal and their use is heavily stigmatized because of the health and social harms associated with illicit use [10]. A large number of pharmaceutical opioids have been developed for medical purposes.

Many of the opioid medications used most commonly in the management of pain (both acute and chronic) are longer acting than heroin and include morphine, oxycodone, hydromorphone, propoxyphene, fentanyl, pethidine, codeine, and less commonly methadone and buprenorphine ([Table 51.1](#)) [11]. Methadone and buprenorphine are the most commonly used opioids for the management of opioid dependence.

The effects of opioids—desirable and adverse

The desirable effects of opioid agonists and partial agonists include euphoria, analgesia, and sedation [10]. The more common adverse effects associated with opioid use include nausea, vomiting, respiratory depression, constipation, drowsiness, and confusion [14, 15]. These side effects often limit the dosing and effectiveness of opioids, leading to early discontinuation, under-dosing, and adequate analgesia [14]. Prolonged use of opioids may result in additional adverse consequences such as tolerance hyperalgesia, decreases in testosterone, oestrogen, and other hormones, and immunosuppression [14]. Higher doses, particularly deliberate overdoses, can produce severe respiratory depression, circulatory failure, coma, and death [10, 16, 17].

When opioid medications are used outside the guidelines for safe and effective use, adverse effects are more likely, particularly those associated with higher doses and injection. Additional risks are associated with concurrent use of sedative drugs (for example, [18, 19–21]) and the presence of pre-existing conditions like impairment of liver function in which medicinal opioid use may be contraindicated [1, 17]. The injection of opioids also carries risks such as the potential transmission of blood-borne virus (BBV) infection if injecting equipment is shared, as well as harms related to injection of a non-sterile medication that is intended for administration by another route. The risk of developing opioid dependence may also be greater if used outside of, or without, medical supervision.

Table 51.1 Common pharmaceutical opioids

Type of opioid	Common drug names	Main medical indication	Half-life*
Agonist	Codeine	Pain	3 hours
	Fentanyl	Pain	3 hours ¹
	Hydromorphone	Pain	2.5 hours
	Methadone	Pain/opioid dependence	15–60 hours
	Morphine	Pain	3 hours
	Oxycodone	Pain	2.5 hours
	Pethidine	Pain	3 hours
	Dextropropoxyphene	Pain	6–12 hours
Partial agonist	Buprenorphine	Pain/opioid dependence	35 hours ²
Antagonist	Naltrexone	Opioid dependence	4–13 hours
	Naloxone	Emergency treatment of opioid overdose	1–1.5 hours

* Half-life for immediate-release formulation.

¹ Following an intravenous dose.

² Following a sublingual dose.

Regardless of whether opioids are used with or without medical supervision, tolerance will develop following a period of regular use [22]. Opioid tolerance is a predictable pharmacological adaptation, and patients may require increasing amounts of the drug to maintain the same pharmacological effects [22, 23]. Tolerance develops to the analgesic, euphoric, sedative, respiratory depressant, and nauseating effects of opioids, but not to their peripheral effects on miosis (constriction of the pupils) and constipation [22].

If use ceases after tolerance has developed, withdrawal symptoms usually occur. Common withdrawal symptoms include body aches, diarrhoea, gooseflesh, loss of appetite, nervousness, restlessness, runny nose, sneezing, tremors or shivering, stomach cramps, nausea, insomnia, increased sweating, lethargy, tachycardia, and fever [16, 22]. With appropriate medical supervision and gradual withdrawal, these symptoms are usually mild. When opioids are stopped abruptly, however, these symptoms are more severe.

Opioid dependence

The clinical features of opioid dependence

The repeated, ongoing use of heroin, opium, or pharmaceutical opioids can result in people developing the chronic, often relapsing, condition known as *opioid dependence*. Opioid dependence causes significant burden to the user, their family, and the broader community [10]. It can result in significant costs to society through unemployment, homelessness, family disruption, loss of economic productivity, social instability, criminal activity, and/or ill health [24, 25]. It is typically characterized by the symptoms of tolerance, withdrawal upon cessation, compulsive use, loss of control over use, escalation in dose or length of use, unsuccessful quit attempts, progressive neglect of usual interests and responsibilities, continued use despite harm, and/or increased time spent obtaining, using, or recovering from use (Table 51.2) [26, 27].

Table 51.2 Criteria for past year ICD-10/DSM-IV opioid dependence

Both classifications require three or more of the following criteria to have been present together during the previous 12 months:		
	ICD-10	DSM-IV
Compulsive use	✓	
Loss of control (onset, termination, or levels of use)	✓	
Escalation in dose or length of use		✓
Unsuccessful attempts to cease or control use		✓
Withdrawal	✓	✓
Tolerance	✓	✓
Progressive neglect of usual interests/responsibilities	✓	✓
Continued use despite harm	✓	✓
Increased time spent obtaining, using, or recovering from use		✓

The major health consequences of illicit opioid dependence include an increased risk of blood-borne infections such as HIV, HCV, and HBV through injection [24], overdose, and highly elevated risks of premature mortality [28–30]. In the 2000 WHO Global Burden of Disease estimates, it was thought that illicit drug use caused around 200,000 deaths worldwide, of which opioid overdose was estimated to account for around 70,000 (around 35%), and AIDS around 105,000 (around 53%) [28].

People affected by opioid dependence frequently fluctuate between the physical states of intoxication and withdrawal [31]. This pharmacological instability can disrupt the neurobiological systems that regulate, among other things, emotion, mood, and sleep, and the individual can experience dysphoria and persistent drug cravings [32, 33]. Comorbid psychiatric disorders are common, including elevated levels of depression, anxiety, suicidality, personality disorders, and post-traumatic stress disorder [34, 35]. Among people who are opioid-dependent, the daily challenge of obtaining opioids tends to dominate their experience and activities. The chaotic lifestyle of opioid dependence has profound social effects on the person and the people around them—managing dependence and the associated harms is often a long-term issue [10].

Currently, there are two main systems of classification for the diagnosis of opioid use disorders internationally: (1) the International Classification of Diseases, tenth revision (ICD-10) produced by the WHO and typically preferred in health epidemiology; and (2) the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR, DSM-5) preferred by the mental health sector and the United States in particular [26, 27]. Both ICD-10 and DSM-IV-TR historically used the term *opioid dependence* to describe a pattern of ‘maladaptive behaviours’, such as loss of control over use, craving, preoccupation with use, and continued use despite causing harm [26, 27], but both classification systems have recently undergone revisions, with ICD-11 still in draft form.

The newest edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) made substantial changes to the way in which opioid use disorders were conceptualized. DSM-5 no longer uses the terms ‘abuse’ and ‘dependence’, in favour of a single

continuum of opioid use disorders classified as mild, moderate, or severe, depending on the number of diagnostic criteria met [36]. In addition, tolerance and withdrawal were previously included as features of the drug use disorder *opioid dependence* but, on their own, were not sufficient for the opioid dependence diagnosis. In DSM-5, tolerance and withdrawal are excluded as features of an opioid use disorder where an individual is prescribed an opioid and taking it as directed [36].

Epidemiology and natural history of problematic opioid use

Illicit opioid use, typically involving heroin, but increasingly involving the extra-medical use of other pharmaceutical opioids, is a significant health problem internationally. In many developed countries, dependent heroin users are typically daily, or near daily, injectors of heroin, and other opioid and sedative drugs in combination with, or as an alternative to, heroin. They continue to use heroin despite the significant social and health problems arising from use, such as being arrested for drug or property crimes, with subsequent imprisonment, exposure to BBVs and increased potential for contracting infectious diseases, and fatal or non-fatal opioid overdose. Increasingly, in countries such as the United States, there are new populations of people who developed opioid dependence through the extra-medical use of pharmaceutical opioids [37] and there is evidence of people transitioning from problematic use of pharmaceutical opioids to heroin injection [38].

Research with prospective cohort studies of dependent opioid users in the United Kingdom, Australia, and the United States indicates that many dependent heroin users who seek treatment or come to attention through the legal system continue to use heroin for decades [39–42]. In this population, daily heroin use is punctuated by periods of abstinence, drug treatment, and imprisonment [10]. When periods of voluntary and involuntary abstinence during treatment or imprisonment are included, it has been estimated that dependent heroin users use heroin daily for 40–60% of their 20-year use careers [43, 44]. ‘Remission’ rates for heroin dependence are half those for other illicit drugs [45]. It is this long-term pattern of problematic opioid use that presents challenges to clinicians and researchers in determining the best management approaches and in ensuring that the extent of the adverse social and health consequences are minimized.

The illegality of opioids, such as heroin, makes the accurate assessment of how many people use these drugs difficult; however, recent estimates suggest there are 15.5 million problem opioid users worldwide [46, 47], and although the prevalence of opioid dependence is low (0.7–0.9% of the global population [48]), it is the largest direct contributor to the burden of illicit drug use [46, 48]. The harms to the individual and the community are significant, with large burden associated with infectious diseases (for example, HIV, HBV, and HBC) and overdose deaths [30, 46].

Risk factors for opioid use and dependence

Very few studies have examined the risk factors and life pathways that lead young people to use, and become dependent on, heroin. This makes strong statements about the precursors of illicit opioid use difficult. There is, however, a large literature on risk factors for early use of alcohol and cannabis which indicates that young people who are the earliest initiators and heaviest users of alcohol and cannabis are those who are most likely to use heroin [49–51].

Two aspects of the family environment are associated with increased rates of licit and illicit drug use among children and adolescents. The first is the extent to which the child is exposed to a disadvantaged home environment, with parental conflict and poor discipline and supervision [52]. The second is the extent to which the child’s parents and siblings use alcohol and other drugs [52]. These family environment factors can give rise to chronic childhood adversity but specifically predispose to drug use.

Children who perform poorly in school, those with impulsive or problem behaviour or conduct disorder in childhood, and those who are early users of alcohol and other drugs are more likely to use drugs like heroin [52, 53]. The nature of the relationship between peer affiliations and adolescent substance use remains controversial, but affiliation with drug-using peers is an important risk factor for drug use, which operates independently of individual and family risk factors [49].

Exposures to these family and social risk factors are highly correlated. Young people who initiate substance use at an early age have often been exposed to multiple social and family disadvantages. They also tend to be impulsive, to have performed poorly at school, to come from families with problems and a history of parental substance use, and to affiliate with delinquent peers [49, 51, 52]. These psychosocial factors are confounded by genetic factors predisposing to substance use. The genetics of addiction are described in more detail in Chapter 49.

North America is currently experiencing escalating pharmaceutical opioid use and harm [37], recently labelled a ‘public health emergency’ by the Trump administration, with substantial increases in opioid-related deaths [54] and strain upon the health and drug treatment system [55]. The problems observed across North America appear to have been driven by widespread prescribing of controlled-release and ‘strong opioids’ such as oxycodone and fentanyl [56]. In this context, non-medical use of pharmaceutical opioids in childhood and early adolescence is a strong predictor of heroin use onset among adolescents and young adults [57]. Other countries, such as Australia, have also documented increasing opioid exposure across the general population, paralleled by increasing harms, including opioid-related hospital admissions, overdose, and opioid dependence and treatment-seeking [58].

Treatment of opioid dependence

Worldwide, of all the illicit drugs, the demand for treatment is highest for opioids. The chronic, relapsing nature of opioid dependence often results in repeated treatment episodes and prolonged treatment need. The aims of any opioid treatment programme should be guided by the principles of reducing or ceasing opioid use, preventing future harms associated with opioid use, minimizing mortality risk, and improving quality of life and well-being [59].

Treatment ideologies

Like alcohol, the dependence or addiction to illicit opioids has sometimes been viewed as a moral fault; however, increasingly, heroin dependence is being managed as a medical disorder. While early attempts to achieve abstinence were prominent, the recognition that opioid dependence is a chronic, relapsing disorder led to a focus on methods that would address the issue of relapse. Pharmacological

treatments using methadone were viewed as a means of achieving neurobiological stability, thus maintaining the person in treatment, minimizing their relapse to illicit opioid use, and reducing the risk of fatal opioid overdose.

Other than methadone maintenance clinics, the treatment approaches for opioid dependence in many countries (for example, the United States) were largely non-medically orientated, predominantly focusing on psychosocial approaches to achieving and maintaining abstinence. There is a long tradition of using residential rehabilitation through a range of models and philosophies including Concept House and 12-Step models derived from Alcoholics Anonymous (usually referred to as Narcotics Anonymous). More recently, the introduction of buprenorphine for use in general practice was viewed in many countries (including the United States and France) as an opportunity to move away from more specialist clinics into primary care and to broaden access to opioid maintenance treatment [60]. Pharmacotherapies, such as methadone and buprenorphine, have been and remain the mainstays of effective management of opioid dependence.

Opioid agonist (maintenance) treatments

Opioid agonist (maintenance) treatments, typically oral methadone or sublingual buprenorphine (\pm naloxone), used at the optimal dose range, are effective in treating opioid dependence. Maintenance treatment is designed to be an ongoing treatment. Maintenance use of pharmaceutical-grade opioids with a long duration of action, in known doses and purity, provides an opportunity to stabilize the person by eliminating withdrawal, craving, participation in obtaining illegal opioids, and the need for frequent (and risky) drug injection. When provided in the context of high-quality treatment services, these medications interrupt the cycle of intoxication and withdrawal, greatly reducing heroin and other illicit opioid use, crime, and the risk of death through overdose [59].

Methadone

The real breakthrough in the treatment of opioid dependence was the development of opioid agonists for maintenance treatment. Methadone was the first of these agonist drugs, introduced by Dole and Nyswander in New York in the early 1960s. They defined opioid dependence as a 'physiological disease characterised by a permanent metabolic deficiency', which was best managed by administering the opioid-dependent person 'a sufficient amount of drug to stabilise the metabolic deficiency' [61]. They introduced orally administered high or 'blockade' oral methadone doses at stabilization levels of between 50 mg to 150 mg/day as maintenance treatment [62]. Methadone treatment was administered as a component of a long-term supporting programme with maintenance, rather than opioid abstinence, as the original treatment goal [63].

This original maintenance model has sometimes been altered by lowering methadone doses, time-limiting treatment programmes, and responding to 'treatment failure' (for example, ongoing illicit opioid use) in a punitive fashion such as expelling the individual from treatment [63]. A systematic review found methadone doses of 60–100 mg/day are more effective than lower dosages in retaining patients and in reducing the use of heroin and cocaine during treatment. The optimal dose will vary for individuals and requires clinical judgement, but clinical guidelines should reflect the evidence [64].

The most effective methadone programmes are those that follow the original Dole and Nyswander dose range [63]. There have been a small number of RCTs on the efficacy of methadone treatment in comparison to control conditions, and they have shown that methadone maintenance was more effective than detoxification, no treatment, or placebo at retaining subjects in treatment and in reducing opioid use [65, 66]. To confirm these findings, similar efficacy has been noted in observational studies, with the additional finding that methadone-maintained individuals report reduced participation in criminal activity and reduced mortality [30, 67, 68].

With the spread of HIV/AIDS in the 1980s, methadone treatment received additional support and funding in countries around the world in the effort to slow the spread of the virus among the population of injecting drug users. There is reasonable evidence that methadone treatment was effective in this goal, if given at adequate dose levels and if patients remained in treatment [69, 70]. Its efficacy in helping reduce the prevalence of other established blood-borne epidemics such as HCV and HBV was and remains less clear, although there is evidence that good coverage of opioid maintenance treatment, combined with needle-syringe programmes, results in lower HCV incidence [71, 72]. Partly in recognition of its role in reducing the spread of HIV, methadone was included in the WHO's *Model List of Essential Medicines* in 2005 [73].

Buprenorphine

The partial opioid agonist buprenorphine was developed in the 1970s as an analgesic and was soon after investigated for the treatment of opioid dependence. Early work using buprenorphine administered by the subcutaneous route characterized it as an opioid with low physical dependence liability, with minimal withdrawal syndrome [74]. Subsequently, evidence has suggested that buprenorphine does produce mild to moderate withdrawal syndrome [75]. Substantial international research effort has established the efficacy of buprenorphine maintenance therapy in RCTs [76].

France went from having no opioid maintenance treatments to registering both methadone and buprenorphine in 1995. By the next year, all registered doctors in France were able to prescribe buprenorphine without any additional training or licensing (the number of places in methadone treatment remained limited) [77]. This has resulted in approximately 65,000 patients per year being treated with buprenorphine, ten times the number treated there with methadone [78]. While other countries have not adopted France's more liberal buprenorphine-prescribing policies, it has been registered for use in the maintenance treatment of opioid dependence in Australia since 2001 and the United States since 2002, and many European countries. In Australia, medical practitioners have to be registered as buprenorphine prescribers in a similar accreditation process to methadone prescribing. In the United States, buprenorphine is less strictly regulated than methadone [79].

Buprenorphine is poorly absorbed when taken orally, so the usual route of administration is sublingual. Because the opioid effects plateau at increasing doses, buprenorphine carries a lower overdose risk than methadone, even if taken with other opioids [80]. It may still cause respiratory depression, however [81], particularly if taken with other sedative drugs such as alcohol or benzodiazepines [20, 21]. Buprenorphine dissociates from opioid receptor binding sites very slowly, possibly explaining the limited withdrawal syndrome observed with its use [82, 83]. Like methadone, buprenorphine has

applications in both the management of pain and the treatment of opioid dependence. High-dose formulations have been used increasingly as maintenance treatment, and buprenorphine joined methadone in 2005 on the WHO's *Model List of Medicines* [84] as maintenance treatment for opioid dependence.

Buprenorphine–naloxone

A newer formulation, also developed as a sublingual tablet and, more recently, as a sublingual film, contains both buprenorphine and naloxone (a μ , κ , and δ -receptor antagonist with no agonist effects) in a 4:1 ratio [85]. Buprenorphine–naloxone was specifically designed to minimize the risk of intravenous misuse among people who are opioid-dependent [85].

Buprenorphine–naloxone has clinical actions that are similar to those of buprenorphine. Addition of naloxone reduces the abuse liability of buprenorphine by attenuating the effects of its opioid agonist action and impacting withdrawal in certain circumstances [85]. When *injected* by opioid-tolerant individuals (an unintended route of administration), the formulation can precipitate unpleasant withdrawal symptoms [86]. This is because a sublingual dose of naloxone has a potent antagonist effect if injected, consistent with its use in emergency reversal of acute adverse opioid effects [1].

Long-acting (depot and implant) formulations of buprenorphine

There is considerable interest in the development of long-acting (depot and implant) preparations of buprenorphine that would potentially improve adherence and pharmacological stability and allow the patient to undertake activities without having to attend their local pharmacy/clinic on a daily basis. Studies are under way to evaluate a number of different long-acting formulations. This is likely to become a significant treatment option in many countries over the next few years.

Other opioid agonist treatments

The use of diacetylmorphine (heroin) as maintenance treatment was investigated decades ago, and again more recently [87]. Unfortunately, the stigma associated with heroin use means reasoned debate about its utility as a maintenance agent has been limited. Its use as a therapeutic agent is limited by its illicit status in many countries, but some countries have adopted the use of heroin as a maintenance agent for heroin dependence [88, 89].

Other opioid agonist treatments include dihydrocodeine and long-acting morphine [90]. Some countries have opted for introducing injectable opioid treatment for those people who do not respond well in first-line treatment with oral methadone or sublingual buprenorphine, for example the UK [87], Switzerland [91], and the Netherlands [88].

Benefits and risks of agonist maintenance treatments

Opioid agonist treatments result in significant reductions in the negative health consequences and adverse effects of heroin dependence on public order [92]. There is strong evidence that methadone and buprenorphine are effective in reducing drug use [65, 93] and the spread of HIV [94]. Opioid agonist treatments have been demonstrated to improve physical and mental health and social functioning [65, 93] and to substantially reduce criminality [65, 95].

Demand for treatment, however, typically far exceeds the number of treatment places that are needed [96].

Despite its advantages, methadone is a full opioid agonist, and there is no ceiling to the level of respiratory depression or sedation which methadone can induce; thus, an overdose can be fatal [97]. In some countries and settings, the inconvenience of daily dosing and clinic visits may be unattractive to clients, and restrictions imposed by the daily dosing schedule on clients' general lifestyle and on opportunities to sustain employment may also limit its acceptance by people who are opioid-dependent.

The provision of unsupervised doses of methadone or buprenorphine results in diversion of the drug for illicit use by those not in treatment. The extent of this problem varies within and between countries, reflecting different policy and regulatory approaches. Under supervised dosing conditions, buprenorphine may be easier to divert than methadone, given its tablet formulation. It may also be easier to prepare for injection (an unintended route of administration), hence the development of buprenorphine–naloxone. Since buprenorphine is a partial agonist, it is safer in overdose [98]. Other benefits of buprenorphine may include an easier withdrawal phase and, because of a longer duration of action, the option of alternate-day dosing.

Management of opioid withdrawal

In opioid-dependent patients, management of opioid withdrawal alone does not represent a treatment in and of itself, since relapse to opioid use is common following medication cessation [99]. Symptomatic treatment of the physical effects of opioid withdrawal with clonidine or lofexidine is sometimes used in settings where it is not possible to prescribe effective opioid substitution. However, buprenorphine is more effective than clonidine or lofexidine for the management of opioid withdrawal and may offer some advantages over methadone in terms of quicker resolution of withdrawal symptoms and possibly slightly higher rates of completion of withdrawal [100].

Naltrexone for relapse prevention

Naltrexone is an opioid receptor antagonist and so can prevent an individual who was formerly using opioids from experiencing the desired effects. Oral naltrexone is not widely used; its effects are not attractive to the target population, achieves limited adherence, and does not provide any additional benefits to other standards of care in terms of relapse prevention [101]. Individuals can only commence naltrexone following a withdrawal programme; otherwise, it can result in severe and prolonged withdrawal symptoms. It appears to be suited only to a small and highly motivated formerly opioid-dependent people seeking to maintain abstinence [102]. Depot and implant formulations of naltrexone may have greater utility, but current data are only preliminary.

Psychosocial interventions

In the absence of evidence for the effectiveness of psychosocial treatments alone, they are usually adjunctive to opioid maintenance treatment [95, 103–104].

Psychological interventions

Psychological interventions can range from unstructured supportive counselling and motivational interviewing to highly structured

techniques. The choice will depend on the available resources, appropriateness to the individual's situation, patient acceptability, staff training, and cultural appropriateness.

The two main evidence-based therapy approaches include cognitive behavioural therapy (CBT) [105] and contingency management [106]. Applied to opioid dependence, CBT is based on the principle that addictions are learnt behaviours that can be modified most effectively by changing the faulty cognitions that maintain behaviour and by promoting positive cognitions and behaviour change. Variants of this approach include 'cognitive therapy' and 'motivational enhancement therapy'. CBT is typically delivered by trained clinicians [107].

Somewhat differently, contingency management assumes that behaviours are underpinned by conditioned learning, specifically classical and operant conditioning [106]. This approach aims to extinguish the classically conditioned responses using techniques like cue exposure, and to reinforce positive behaviour using instrumental conditioning where behaviours, such as abstinence, are rewarded using strategies such as contingency management. Typically, contingency management programmes clearly define the desired behaviour (for example, opioid-free days), conduct regular monitoring (for example, urine drug screening), specify rewards such as money or vouchers, and provide personalized, positive feedback from the treating staff.

Social interventions

Social interventions provide practical assistance in addressing basic needs, such as food or housing, as well as education and employment support, and access to broader community resources (such as government benefits, recreational/leisure opportunities, etc.) [107, 108]. Typically, the patient's needs are assessed and met using a key worker or a case management system outside the treatment service) [107, 108].

Self-help groups

Typically, these groups are abstinence-based and provide emotional support. Many also promote a particular ideology or values through which members may develop a strong sense of identity. The most common framework for self-help groups is the 12-Step programme (for example, Narcotics Anonymous). Little research has been conducted on this approach, but observational studies indicate positive treatment effects. Self-help groups are inexpensive and are a valued source of psychosocial support among participants. An important component is voluntary participation.

Clinical management and considerations

Assessment and diagnosis of opioid dependence

Substance use

A detailed substance use history takes into account the use of all psychoactive substances, including illicit and pharmaceutical opioids, alcohol, cannabis, stimulants, and benzodiazepines. The assessment should establish past and current substance use, duration of use, quantity and frequency of recent use, route of administration, and time of last use [107–109]. In addition to current substance use, it is important to assess the patient's experiences of previous treatment

episodes, including their perspectives on what worked previously, the factors leading to relapse, and the types of treatment they are prepared to consider [107].

Physical examination

Physical examination should include assessment of intoxication and withdrawal (as observable indicators of neuroadaptation), relative to the patient's report of last drug use. Withdrawal severity can assist in indicating the severity of dependence, as well as the timing and amount of the first dose of methadone or buprenorphine [109]. Recent use of opioids increases the likelihood of withdrawal being precipitated by buprenorphine or naloxone. Intoxication with central nervous system depressants, such as alcohol or benzodiazepines, in combination with methadone or buprenorphine, increases the risk of overdose [109]; this is a critical consideration during induction and needs ongoing assessment and review.

Among people who inject opioids, physical examination of injection sites can also provide useful information on the timing and duration of injecting drug use, as well as any related complications such as site infections [107–109]. A combination of recent and old injection sites will normally be seen in an opioid-dependent patient with current neuroadaptation [107].

Urine drug screening

Urine drug screening is useful to corroborate patient history and establish recent opioid and other substance use [107–109]. Negative urine drug screening, combined with the absence of withdrawal symptoms, indicates caution is needed in the initiation of opioid maintenance therapy or other sedative medication [109] due to increased risk of overdose. Urine testing, in combination with patient history, is also useful in identifying other substances that have recently been consumed. International guidelines recommend against using a naloxone challenge to confirm current neuroadaptation, as this can induce significant withdrawal effects unnecessarily [107]. Delays in obtaining urine drug screening results should not delay treatment initiation where the diagnosis can be clearly established [107–109]. Urine drug screening can be perceived as punitive by patients, so it is important to explain the purpose clearly [109].

Other investigations

Investigations for other conditions, either related to the presenting condition or related to the patient's drug use (for example, BBVs, liver disease) should also be undertaken to inform future care planning. A high proportion of people who inject drugs may also be infected with HBV or HCV. This is unlikely to pose problems for induction of methadone or buprenorphine, unless advanced liver disease is detectable at clinical examination [109], but it is an important clinical consideration. Voluntary testing for HIV, hepatitis C, and common infectious diseases should be offered as part of an individual assessment, accompanied by counselling before and after the test [107]. Serology testing and vaccination for hepatitis B are also recommended [107]. Other infectious diseases that should be taken into consideration include tuberculosis and sexually transmitted infections.

Pregnancy testing should be offered to all women, particularly those contemplating opioid withdrawal, because it may influence the choice of treatment [107].

Diagnosis of opioid dependence

Typically, opioid dependence is established according to standard definitions in the ICD or DSM [107–109]. It can be more challenging to assess dependence in a patient using pharmaceutical opioids for chronic pain. Tolerance and withdrawal can arise due to neuroadaptation associated with regular use of opioids for pain, and on their own, these features are not sufficient to diagnose dependence in this context. Features consistent with diminished control over opioid use (for example, multiple dose escalations, unsanctioned routes of administration, use for reasons other than pain, etc.) should also be examined. The diagnosis of opioid dependence is typically based on the patient history, corroborated by physical examination and/or other investigations [107].

Other biopsychosocial considerations

General health

Beyond establishing substance use and opioid dependence, it is good practice to assess the general health of patients being considered for methadone or buprenorphine maintenance treatment. The aim is to identify unmet health care needs and any health problems that could interact with methadone or buprenorphine [108]. Such assessments might include: past medical issues, operations, injuries, and periods in hospital; current prescription medications; psychiatric history; drug-related complications such as injection-related injuries or diseases; family planning and contraception; sexual health; dental health; and allergies or sensitivities [108]. Additional investigations may include liver, thyroid, and renal function and haematological indices [108].

Patients with prolongation of the QTc interval (that is, >500 ms between the onset of ventricular depolarization and completion of ventricular repolarization) who are treated with methadone and, less commonly, buprenorphine are at increased risk of adverse cardiac-related events [109].

Psychiatric comorbidity

Depression, anxiety, and post-traumatic stress disorder are common among people who are opioid-dependent [110], and psychiatric assessment and referral should be incorporated into care planning.

Social issues

Social exclusion and issues, such as housing, financial, and relationship problems, are also important clinical considerations and may impact on the choice of treatment and setting.

Risk assessment

Assessing risks that may impact on the safety or efficacy of treatment is essential, including risk behaviours such as overdose, polydrug use, problematic alcohol use, unsafe injecting practices, and unsafe sex. Wider risk may include self-harm or risk of harm to others. Risks to dependent children should also be assessed and responded to, according to local child protection requirements [108]. Risk assessments should be ongoing throughout treatment and involve the relevant health and welfare providers.

Care planning

The challenge in the management of opioid dependence does not simply come from the need for knowledge and expertise around

diagnosing and managing opioid dependence. A structured and compassionate approach to some of the more complex aspects of drug dependence and related lifestyle complications is required to assess and plan sensible care. In the first instance, current injectors will need advice about harm reduction, safer injection practices, and overdose prevention and management. Discussion about the choice of agonist maintenance treatment should take into account patient preferences, but local policies and guidelines will also be important factors.

Current evidence suggests that key treatment outcomes for methadone and buprenorphine are comparable under optimal treatment conditions. Other factors that may impact upon treatment choice include patient or clinician preferences and previous responses to treatment. There may be considerable individual variation in absorption, metabolism, and clearance of methadone or buprenorphine. Patients who continue to use opioids, while receiving high doses of buprenorphine, may be better suited to higher doses of a full agonist like methadone. On the other hand, the less sedating effects of buprenorphine may be preferred by some patients.

Specific groups and issues

There are some patient groups with additional or complex needs, and specific treatment settings that may raise important considerations in planning treatment of opioids dependence.

Adolescents

Some adolescents are brought to the clinic by families concerned about their drug use. Others come from socially disadvantaged backgrounds, may be homeless, and may have more severe presentations. Assessment of adolescents should include medical, psychological, education, family, and other aspects of the adolescent's life.

Treatment approaches should take into account the higher levels of risk-taking, novelty-seeking, and peer pressure among adolescents, compared to older people. Treatment needs to be individualized and comprehensive, taking into consideration an adolescent's strengths, psychosocial supports, education, legal status, health, and pattern of illicit drug use. Agonist maintenance treatments in adolescent populations need further study, but early findings are promising [111, 112]. The clinical profile of opioid-dependent adolescents can be complex, with a high prevalence of comorbid depression, post-traumatic stress disorder, conduct disorder, and attention-deficit/hyperactivity disorder. Where there is supportive family or carers, family counselling may be helpful.

Women

Women may be more vulnerable to the adverse medical and social consequences of opioid dependence. Compared to men, women with opioid dependence tend to have lower levels of education, fewer financial resources, and elevated histories of childhood trauma and physical and sexual abuse [113, 114].

Women typically use less quantity of opioids than men but transition more rapidly to dependence and treatment-seeking, with more benzodiazepine use [109]. They are more likely to have childcare responsibilities that could impede their access to treatments, and they may be reluctant to participate in group support activities with men [113]. Some evidence indicates that women are less likely to drop out of women-only programmes, which is likely to lead to better outcomes [113]. However, data are lacking on the relative efficacy of

gender-specific services for women. To be responsive to the needs of women, it has been suggested services need to provide individual or female-only group counselling and childcare facilities and take measures to prevent sexual harassment of female patients by male staff [109].

Pregnancy and breastfeeding

Maintaining or initiating opioid agonist maintenance treatment is the preferred approach to the management of opioid dependence in women who are pregnant or breastfeeding [108, 115]. Methadone is frequently preferred to buprenorphine because it has been in use longer in this context [107, 109]. Among opioid-dependent women who are pregnant, methadone is associated with improved maternal and neonatal outcomes, compared to the pregnancies of women not receiving opioid agonist treatment. Although both methadone and buprenorphine are associated with neonatal abstinence syndrome, this can be resolved by administering morphine with supportive care [108].

Detoxification during pregnancy is not recommended. In the first trimester, detoxification carries significant risk of miscarriage. In the third trimester, it can cause significant fetal distress and premature labour [109]. Typically, pregnant women are encouraged to remain on agonist maintenance therapy during pregnancy and the postnatal period [107]. Agonist maintenance treatment is thought to have minimal long-term developmental impacts on children, when compared to the risk of maternal heroin use and resulting harms [109].

Both methadone and buprenorphine are detectable in breast milk at low levels, which are not thought to affect infant outcomes [107]. Thus, opioid-dependent mothers are normally encouraged to breastfeed; however, where there is polydrug dependence, caution may be necessary.

Blood-borne virus infections and tuberculosis

Early in the HIV epidemic of the 1980s, it was established that provision of sterile injecting equipment and increased coverage of opioid dependence treatment could reduce the spread of BBVs. This approach combines a public health strategy with a high standard of individual treatment.

England and Australia, for example, have achieved major success, with <2% of people who inject drugs contracting HIV over the past few decades [116]. Unfortunately there are many countries, particularly in the Asia Pacific region, Eastern Europe, and Russia, that still report major rates of HIV infection among injecting drug users [116].

For those who are infected, combined treatment of both HIV with available antiretroviral medications and agonist maintenance treatment to manage the opioid dependence can achieve reasonable levels of adherence [116].

The new treatments for hepatitis C are also acceptable to patients and are associated with very high levels of clearance [117]. The challenge for treatment systems is to develop integrated approaches that enable all current and former injectors to benefit.

Tuberculosis is a new and increasing concern because of multi-resistant cases in vulnerable populations of prisoners [118], the homeless, and migrant populations.

Forensic and prison populations

Between a third and a half of most prison populations have a history of opioid dependence.

This poses risks for individuals both at the point of entry and at the point of departure from prison. On entry, there is a need for a proper assessment of both physical and mental health status and plans for appropriate care and management of their drug dependence. Ideally, the provision of ongoing maintenance should be made available [119, 120]. This will reduce the risk of both suicide and unnatural death during the period of imprisonment [119]. It will also reduce very significantly the risk of overdose death in the first month after release [121]. In addition, provision of this treatment should help to engage individuals in help and support and care for other aspects of their mental and physical well-being, including possible treatment for hepatitis C [122].

Most individuals are in prison for short periods of time. A system works best when it aims to create continuity between treatment in the prison and treatment in the community that works to promote health and well-being and to assist in the reintegration into the community after prison release.

Psychiatric comorbidity and polysubstance use

There are well-recognized overlaps between substance dependence and psychiatric comorbidity, so all assessments need to take into consideration the risks for self-harm and suicide and manage appropriately. However, polysubstance use poses a significant challenge for treatment planning and ensuring appropriate prescribing. Such individuals require careful assessment, ideally by a specialist practitioner who has both inpatient facilities and community arrangements where daily supervision of prescribed medication can be undertaken. Careful and cautious approaches can stabilize such individuals and reduce the immediate risk of overdose death.

Conclusions

Over the past few decades, the treatment of opioid dependence has been well developed and the benefits and outcomes of treatment have been well documented. It has, however, remained a controversial treatment. The advent of prescription opioid dependence has further highlighted some of the complexities for doctors prescribing opioids in the longer term. The lifesaving benefits of good management of opioid dependence are beyond question. The opportunity to use such treatment to engage individuals in a broader range of medical and social interventions that will assist them to get their lives back on track is substantial. The issues of addiction in modern medicine are such that they require all competent and trained clinicians to have a full knowledge of basic assessment and management of drug dependence as core clinical skills. We look forward to the day when all doctors grasp this opportunity and extend it to their most vulnerable patients.

Cannabis and mental illness

David J. Castle

Introduction

Cannabis sativa has long been of interest to psychiatrists, mostly, it is reasonable to say, for its perceived negative effects on mental health in certain key domains, including mood, psychosis, and cognition. The last decade, in particular, has seen a flurry of activities aimed at trying to understand the associations between psychotic disorders, such as schizophrenia, and exposure to cannabis. There has also been increasing concern about negative effects on cognitive functioning in people who use large quantities of high-potency cannabis.

This occurs in the context of major changes to the potency of the plant product, as new strains and hydroponically grown cannabis have increasingly higher concentrations of the main psychotomimetic constituent delta-9-tetrahydrocannabinol (THC) and less of the putatively antipsychotic constituent cannabidiol (CBD). Also, the evolution of numerous synthetic cannabinoids makes tracking and policing of THC-like chemicals very difficult.

On the other side is a broader global debate about decriminalization, and even legalization, of cannabis. In part, this is driven by the clear failure of the ‘war on drugs’ to curb cannabis consumption and the understanding that criminal legislation and policing approaches to curtailing use are too simplistic and take up massive policing and legal resources. Also, many people believe that for most people, modest consumption of cannabis is not particularly harmful; one could argue that alcohol is a far more destructive drug at a population level and is associated with a myriad of physical and mental health problems.

Also, there is a resurgence of interest in cannabis as medicine. There is a long history of cannabis being used for various medical indications, including certain severe epilepsies, chronic pain syndromes, nausea associated with chemotherapy, painful spasm associated with multiple sclerosis, and appetite stimulation in people with cancer and HIV-AIDS. Thus, numerous jurisdictions around the globe are making cannabis available as a medication, and some are going further than this and essentially legalizing it. All these aspects are important in appreciating the place of cannabis in society and in informing debate about its availability. For a thoughtful discussion of these matters, including policy implications, the reader is referred to Hall and Degenhardt [1].

Henceforth, this chapter focuses on the psychiatric aspects of cannabis. A brief overview is provided of the cannabis plant and its

constituents, followed by a discussion about the human cannabinoid system. The impact of cannabis on anxiety and mood symptoms is then covered, followed by a consideration of cannabis as a psychotomimetic agent and its impact on psychotic disorders, including whether it can be considered a cumulative causal factor for schizophrenia. Finally, the impact of cannabis on cognitive functioning, both short- and long-term, is discussed.

The cannabis plant

Cannabis sativa has been used for centuries by humans for its effects on the mind. Mostly it is smoked, sometimes mixed with tobacco. As it burns very hot, the smoke is often bubbled through water to cool it for ease of inhalation. It can also be eaten, usually cooked in a cookie or cake. It can also be made into an oily formulation that can be imbibed as an oil or in capsule form. Inhaled cannabis enters the brain within seconds and has a very abrupt onset of CNS effects, while eating the product results in a much slower onset of action.

The plant is constituted of numerous chemicals, the most important of which, for psychiatry at least, is THC, the major psychotomimetic agent in the plant. There is also growing psychiatric interest in another cannabinoid, namely CBD, which appears to have some antipsychotic properties [2], as well as anti-inflammatory and neuroprotective effects [3]. Thus, the ratio of CBD to THC in the plant can be construed as an indicator of its potency in terms of its ability to induce psychotic symptoms.

There is a wide variation in the THC content of *Cannabis sativa*, dependent upon the precise strain, the manner in which it is grown, the part of the plant imbibed, and the manner in which it is prepared. Generally speaking, the leaves are less potent than the flowering parts [4]. The age of the plant is also of relevance, as the chemical constituents change with age; for example, THC is degraded to CBD. There is some confusion about the terms used to describe various preparations of cannabis. Here we follow the suggestion of Slade *et al.* [5]—thus, marijuana (also known as ‘herbal’) is a combination of buds and leaves of pollinated female plants, usually cultivated outdoors; sinsemilla (also known as ‘skunk’) comprises unfertilized buds of the female plant, usually cultivated indoors; and cannabis oil (also known as ‘hash oil’) is an oily product produced by solvent extraction or distillation of the plant product.

There are good longitudinal data to suggest that street cannabis is becoming more potent in terms of THC content, expressly over the last two decades. Slade and colleagues [5] provide a comprehensive overview of longitudinal drug seizure data from the United States covering the period 1975–2009. Two main trends emerge, namely that an increasingly higher proportion of products is sinsemilla, rather than herbal marijuana and that the THC content of cannabis of all forms (that is, marijuana, sinsemilla, and hash oil) has increased, from under 1% in 1975 to around 10% in 2009. In terms of the CBD:THC ratio, for sinsemilla, this was around 9.5% over the period 1981–1996, dropping to 5.6% in 1997–2009 [5]. Thus, in terms of both THC content and CBD:THC ratio, street cannabis is becoming more potent. Data from jurisdictions other than the United States point in the same direction. This has important implication for psychiatry, as described in the next section.

The cannabinoid system

The human cannabinoid system is increasingly better understood. This has been spurred inter alia by the synthesis of THC and the discovery of the cannabinoid CB1 and CB2 receptors and the naturally occurring substrate of the CB1 receptor, anadamide. The CB2 receptor is expressed mainly in the spleen and testis and seems to be associated with immune function and, to a lesser extent, in the CNS where it has a role in inflammatory and degenerative processes [6]. We shall not address the CB2 system further here.

The CB1 receptor is expressed diffusely throughout the CNS, including the frontal cortex, basal ganglia, caudate, anterior cingulate cortex, cerebellum, hippocampus, and hypothalamus. The receptor is predominantly presynaptic and plays a role in the mediation of release of a number of neurotransmitters, including dopamine, nor-adrenaline, acetylcholine, glutamate, serotonin, and GABA. It is the receptor subtype relevant to the drug's psychotropic effects.

The advent of antagonists at the CB1 receptor allows a dissection of cause and effect in terms of what is mediated by the CB1 system. In particular, the CB1 receptor antagonist rimonabant (also referred to as SR141716) was employed in a number of such studies and showed great promise in its effects on weight reduction and reduction in hypercholesterolaemia and diabetes in animal and human experiments. Unfortunately, it carried a risk of depression and suicidality, so it was withdrawn from the market [7].

The cannabinoid system has a wide range of functions, including the modulation of pain (there are close interactions with the opiate system), memory, psychomotor control, and sleep and appetitive functions. Iversen [6] has summarized these main effects and outlined the major neural networks involved; this is summarized here, and the reader is referred to Iversen [6] for a full list of references. THC has acute effects on *motor control*, with a tendency to impaired fine motor movements and a wide-based gait, suggestive of cerebellar pathology. Impaired *short-term memory* is well described in the setting of cannabis intoxication, with particular impairment of attention, presumably mediated by hippocampal pathways. There has been a suggestion that this might indicate a role for THC in the extinction of aversive memories in post-traumatic stress disorder. There is a well-established association of THC exposure with a *craving for high-fat, high-sugar foods* (the so-called 'munchies'), operating via hypothalamic mechanisms. This has led to the use

of THC and synthetic cannabinoids in the stimulation of appetite in people with HIV-AIDS and some cancers. The appetitive effect and weight gain are blocked by rimonabant, which had therapeutic use in weight reduction, interestingly initially through a reduction in craving such foodstuffs, but after a number of weeks via direct metabolic effects. THC also has established *anti-nausea* properties and has been used in amelioration of nausea associated with chemotherapy.

Cascio and Pertwee [7] provided an overview of the effects of THC on *acute and chronic pain syndromes*, pointing out the distribution of CB1 (and CB2) receptors on pain pathways in the brain and spinal cord, as well as peripheral sensory nerves. There is an intricate interaction between the cannabinoid and opioid systems which might explain some of the analgesic effects. The synthetic cannabinoid receptor agonist nabilone has been shown to ameliorate chronic neuropathic pain, headache, and fibromyalgic pain, while Sativex[®] (which contains both THC and CBD) has been employed in the management of pain associated with multiple sclerosis and advanced malignancies (for references, see [7]).

A matter which is still debated is whether THC is an addictive substance. Certainly, animal models show that tolerance develops to many of the behavioural and other effects of THC, and there is a withdrawal syndrome [8]. A dependence syndrome has also been shown in humans, albeit tolerance does not necessarily occur for all its effects and many users do not increase their use once they have reached some sort of plateau. Withdrawal is not as rapid and dramatic as with substances such as nicotine or alcohol—the highly lipophilic nature of THC means that it remains for weeks in the brain and is excreted only slowly upon cessation in regular heavy users. This said, withdrawal effects which have been reliably documented include sleep difficulties, loss of appetite and weight loss, and, in some individuals, restlessness, irritability, and anger [9]. This syndrome can be precipitated by rimonabant in animal models [10].

Effects on anxiety and mood

Many users of cannabis report that it reduces anxiety, enhances mood, and results in a relaxed sense of well-being. Its sedative properties are also reportedly helpful in individuals with chronic sleep disorders, albeit this has not been an area of rigorous scientific study.

In terms of anxiety, animal work has found that CB1 receptor knockout mice show increased anxiety-related behaviours, while CB1 receptor antagonists can reduce such behaviours in animal models of anxiety [7]. Also, rimonabant caused substantial anxiety symptoms in some individuals. This suggests that the cannabinoid system might have a potential therapeutic role in anxiety disorders; however, this has not been a major focus of scientific endeavour to date. Also, paradoxically, some individuals suffer extreme anxiety, and even panic attacks, upon exposure to THC; presumably this is mediated, in part at least, by tachycardia induced by THC, which could precipitate panic in vulnerable individuals.

The mood effects of cannabis are complex. It is very well known that acute intoxication is associated with a child-like mirthful laughter which is very intoxicating, but short-lived. Some early reports of cannabis having more enduring mood effects, and even being effective for some people with treatment-resistant depression, have not been supported by rigorous studies. Indeed, most

work on mood effects of cannabis has reported an association with depression. However, albeit there is an established increased risk of depressive disorders in habitual cannabis users, the association is confounded by numerous psychosocial factors, including socioeconomic status, as well as by the use of other substances such as alcohol. The most informative studies in this area are cohort studies, which follow large groups of people prospectively and attempt to control for confounders, as well as establish the temporal sequence between exposure (that is, cannabis) and the putative outcome (depression). Degenhardt *et al.* [11] reviewed such studies and concluded that there is a lack of consistent evidence supporting a causal relationship between cannabis exposure and depression or suicide. They point out the inconsistency in the data and variable methodology. Most such studies have been performed in young people, and cannabis/depression associations that do appear to survive controlling for confounding factors are strongest for young females.

There has been surprisingly little scientific scrutiny of cannabis in relation to bipolar disorder, despite its widespread use by people with this malady, and reports of benefits in both mood and sleep modulation. Again, large prospective studies are required to inform our understanding of cannabis use in the context of a bipolar diathesis. Silberberg *et al.* [12] selectively reviewed some such studies and found fairly mixed results, albeit the larger and more methodologically robust studies suggested worse outcomes for people with bipolar disorder who use cannabis. For example, van Rossum *et al.* [13] studied 3459 bipolar patients and found that those who were cannabis users had more manic relapses and worse psychosocial outcomes, but they were also less likely to adhere to medications, and one cannot exclude the possibility that people with more severe illness are inherently more likely to use cannabis.

There is more debate about whether cannabis use can independently increase the risk of bipolar disorder and/or bring forward the onset. In a general population study of 4815 people, Henquet *et al.* [14] reported an association between cannabis consumption and later manic symptoms, which was robust after controlling for a number of sociodemographic confounders, as well as for the evolution of psychotic symptoms. Similarly, van Laar *et al.* [15] reported a 5-fold increased risk of bipolar disorder associated with cannabis use in a sample of 3881 individuals from the general population. Some evidence suggests that cannabis use is associated with an earlier onset of bipolar disorder. Overall, it seems sage to suggest that cannabis might increase the risk of bipolar disorder in vulnerable individuals and also result in an earlier first manifestation. Also, cannabis use in people with an established illness should be strongly discouraged. That said, attention to other substances of abuse, as well as broader psychosocial and illness-related parameters and adherence to medication, is very important.

Cannabis and psychosis

Arguably, consumption of cannabis can produce psychotic phenomena in anybody, but individual predisposition depends upon experience with the drug, the context in which it is consumed, the THC content (and the CBD:THC ratio), and crucially the individual's psychosis proneness. The latter is a measure of how vulnerable the individual is to the manifestation of psychotic symptoms. It is well known that anything up to 15% of the population have experienced psychotic phenomena at

some time, and elegant work from Verdoux and colleagues [16] has shown that increased psychosis proneness is associated with a higher likelihood of psychotic symptoms on exposure to cannabis.

People with established psychotic illnesses, such as schizophrenia, have a very high psychotic predisposition and thus are likely to manifest psychotic symptoms when imbibing cannabis. This has been confirmed in people with schizophrenia given intravenous TCH [17]. This is certainly seen clinically, and the negative impact of cannabis on the longitudinal course of schizophrenia is well recognized in longitudinal studies, albeit there is still some debate about the direction of causality and the contribution of confounding factors such as other illicit substances [18].

What is also of interest is that people with psychotic disorders still remain liable to psychotic relapse upon using cannabis, even if they are taking medications which effectively block dopamine D2 receptors. Indeed, D'Souza and colleagues [17] found that people with schizophrenia were more likely than healthy controls to experience psychotic symptoms when exposed to intravenous THC, even when they were on dopamine antagonist drugs. Thus, the induction of psychotic symptoms by THC is more complex than simply a release of dopamine. What is clear is that the effects are mediated by the CB1 receptor. Thus, Huestis and colleagues [19] administered rimonabant to volunteers, then gave them a cannabis cigarette to smoke, and found that rimonabant effectively blocked the psychotomimetic effects of cannabis.

An important area of investigation is to understand why people with established psychotic disorders smoke cannabis to the extent that they do. A number of studies have explored this and have generally concluded that the motivation lies largely in the area of alleviation of negative affect (for example, boredom, insomnia, anxiety, depression) [14, 20]. Importantly, very little support has been found for the notion that people with schizophrenia 'self-medicate' positive symptoms or try to alleviate medication side effects with cannabis; if there is a 'self-medication' component, it is the negative, rather than the positive, symptoms of psychosis that are targeted by users. This has clinical applicability in that understanding the reasons for use can help engage individuals in effective programmes to assist them in reducing their cannabis use [21].

There are also fairly consistent data to support the notion that cannabis use in youth can 'bring forward' the onset of schizophrenia. For example, using a large Australian data set, Stefanis and colleagues [22] estimated this effect to be of the order of 7–8 years, which obviously has a major impact on the individual, as they stand to lose a substantial period of early adulthood to the illness. Not all studies [23] have reported this effect, and controlling for all potential confounders is difficult.

A rather more contentious aspect of the cannabis/schizophrenia debate is whether cannabis consumption can actually contribute causally to schizophrenia—that is, do some people who have used cannabis and who later develop schizophrenia only manifest the disorder because they used cannabis? Clearly the vast majority of people who do use cannabis do not go on to develop schizophrenia, and the rate of schizophrenia across the globe does not vary in alignment with the rates of use of cannabis. Any studies in this area face the fact that some of the genes involved in the predisposition to schizophrenia also predispose to cannabis consumption [24]; there are many potential confounding factors, including socioeconomic factors and the use of other illicit drugs—and even the

licit drugs alcohol and tobacco—and it is hard to establish the true temporal sequence of exposure (that is, cannabis) and outcome (that is, schizophrenia). Many people with schizophrenia have very protracted prodromes (which may last for years) and are characterized largely by negative affect, which could (as outlined previously) directly lead to the consumption of cannabis and spurious assumptions about the direction of causality [25, 26]

Nevertheless, high-quality longitudinal cohort studies are now available that have fairly consistently reported an association between the use of cannabis in youth and later psychotic symptoms, and so support a causal connection [27]. There are fewer such studies with a specific schizophrenia outcome, but Zammit and colleagues [27] have provided a thorough overview of this area and suggest there is sufficient evidence to support public health campaigns regarding the potential risk of cannabis use and later schizophrenia, albeit conceding that the ‘number needed to prevent’ (NNP) one case of schizophrenia is very high; Hickman *et al.* [28] suggested that for every prevented case, some 2800 males (95% confidence limits 2018, 4530) aged 20–24 would need to become entirely abstinent (the estimates are even higher for older people and females). These estimates do not account for the fact that higher-potency cannabis (that is, sinsemilla) appears to carry a particularly strong association with schizophrenia [29], and this might be a specific focus of public health education and regulation where cannabis is effectively legalized.

Health campaigns could also target those individuals who seem particularly liable to develop schizophrenia upon exposure to cannabis. It seems obvious to warn people with psychosis proneness, those who have experienced a particularly strong psychotic reaction to acute exposure to cannabis, and those with a family history of schizophrenia. Certain genetic profiles may also signal vulnerability. For example, Caspi *et al.* [30] reported that, in the Dunedin cohort study, individuals homozygous for the valine allele at Val-158-Met within the catechol-*O*-methyltransferase (*COMT*) gene were more vulnerable than those with other variants to develop a psychotic disorder upon exposure to cannabis before the age of 18 years. This finding has not been convincingly replicated, but more recent interest in the *AKT1* gene does seem to be bearing fruit in terms of our understanding of interaction effects between certain genotypes and the use of cannabis [31].

Cannabis and cognition

As outlined in previous sections, acute intoxication with cannabis carries with it associated impairment in cognitive functions, notably registration and short-term memory. What is more contentious and more worrying from a general and public health perspective is whether cannabis can cause lasting cognitive dysfunction.

Solowij and Pesa [32] reviewed animal and human investigations of the effects of cannabis on cognition in both short- and long-term studies. They confirm that in the short term, there are effects on attention, memory, executive, and inhibitory processes. They also cite evidence of some longer-lasting effects in heavy users where early use (that is, adolescence) of high-potency cannabis seems most concerning. This reflects increasing concern about high-THC cannabis use at sensitive stages of brain development [33].

There is a well-described ‘amotivational’ syndrome associated with chronic heavy use of cannabis. Characteristics include elements

of dependence, such as craving, salience, and prioritization of drug acquisition above other pursuits, as well as some cognitive impairment in the domains outlined previously [34]. A debated issue is whether these cognitive problems revert if the individual stops using cannabis. The weight of evidence is that most of the effects do not endure, as long as the cannabis is given sufficient time to wash out of the brain (and this might take up to a month) [35, 36]. However, some research suggests not all cognitive functioning returns to baseline.

Neuroimaging studies have been highly inconsistent regarding structural brain abnormalities in association with prolonged heavy cannabis consumption. It is very difficult to control for the amount of exposure to cannabis, as well as to all potential confounding factors, not least the use of other drugs, such as alcohol, which are known brain toxins. Yucel *et al.* [37] have reported a unique group of individuals who were heavy long-term cannabis users but who apparently had no history of the use of other drugs; there were subtle volume reduction in the hippocampus and amygdala. Other studies have failed to replicate these findings, and particularly when alcohol exposure has been controlled for [33]. What is rather more consistent has been the finding of abnormalities in the white matter and impaired neuronal connectivity, including hippocampal connections and axons in the corpus callosum [38].

Conclusions

Cannabis sativa remains the most widely used illicit drug worldwide. Its relevance to psychiatry lies in balancing its potentially harmful effects vs its potentially therapeutic benefits. Certainly, it is a drug of potential dependence but is less habit-forming than, for example, tobacco, and the withdrawal syndrome less dangerous than for, say, alcohol. It has effects on anxiety (these effects are somewhat dose-dependent), and it may have a therapeutic place in the treatment of some aspects of post-traumatic stress disorder. The association with depression has probably been overstated, and cohort studies suggest the association is more reverse causality than direct causality, and the population-attributable fraction (PAF) is very modest at around 2%. Effects on people with bipolar disorder have been under-researched, but the weight of evidence is that it is associated with an increased risk of manic relapse. THC, acting via CB1 receptors, can produce psychotic phenomena, notably in individuals with psychosis proneness and particularly in people with schizophrenia. It may also ‘bring forward’ the onset of schizophrenia by some years and be a cumulative causal factor for schizophrenia, albeit again the PAF is low (the highest estimates are 15%, but many researchers would put it around the 8% mark). Acute cognitive effects of cannabis are well described, as is an amotivational syndrome which appears largely reversible with cessation of the drug. Some evidence suggests enduring neurocognitive effects in heavy users, but the extent of the effect is much lower than, for example, sustained heavy alcohol use.

All this needs to be balanced by a consideration of the established and potential medical benefits of the cannabinoids. The role of CBD in the management of psychotic disorders is particularly alluring, as is the potential role of other non-THC cannabinoids in various disease states. It is hoped that moves to reignite the role of cannabis as medicine will have therapeutic benefits for many, and that the ongoing exploration of the cannabinoid systems will enhance our understanding and treatment of a number of psychiatric disorders.

Stimulants, ecstasy, and other ‘party drugs’

Adam R. Winstock and Remy Flechais

Introduction

Stimulant drugs, such as cocaine, amphetamine, and 3,4-methylenedioxymethamphetamine (MDMA), remain the most commonly used group of illicit psychoactive drugs after cannabis. Their use crosses cultures, age groups, functions, and socio-economic profiles. For most users, the risks related to acute intoxication will be the most commonly experienced harm, with dependence being relatively rare. While variations in precise neuropharmacological action, potency, preparations, route of synthesis, and administration lead to discrete populations of users adopting diverse patterns of use with associated risks and harms, stimulant drugs share a common neurobiology, with similar effect profile and treatment options. Dose-related intoxication with these drugs can result in acute psychopathology that may require assessment, treatment, and follow-up by the general psychiatrist. It is important to note that few people will use these drugs in isolation and that polydrug use contributes significantly to the harm profiles associated with these drugs. In recent years, the appearance of a wide range of novel psychoactive substances (NPS) that mimic the effects of more traditional drugs has posed a challenge to policy-makers and added a level of unpredictability for both users and treatment providers [1]. The appearance of a more robust ‘chem-sex’ (this refers to the use of drugs to chemically enhance sexual experience) scene in the UK has led to drugs such as crystal methamphetamine, gamma hydroxybutyrate (GHB), and mephedrone being added to the list of those drugs psychiatrists need to be able to assess and treat most effectively within a multi-disciplinary team [2].

ICD/DSM classifications

The ICD-10 definition for a dependence syndrome to any substance revolves around having at least three of the following symptoms present together for at least 1 month, or if lasting less than 1 month have been present together repeatedly in the last 12 months: a strong desire to take the drug, difficulties in controlling its use, persisting in its use despite harmful consequences, a higher priority given to drug use than to other activities and obligations, increased tolerance, and sometimes a physical withdrawal state. The ICD codes then vary according to substances, and relevant to this chapter are: F14—mental

and behavioural disorder due to the use of cocaine; and F15—mental and behavioural disorder due to the use of other stimulants, including caffeine. There are further specifiers such as .0 acute intoxication, .1 harmful use, .2 dependence syndrome, .3 withdrawal state, .4 withdrawal state with delirium, .5 psychotic disorder (and many more; see ICD 10 for further details).

DSM-5 classifies substance use disorders according to symptoms of dependence similar in nature to ICD, but there are 11 of them. DSM-5 describes a continuum of substance use disorders and divides this into mild (2–3), moderate (4–5), and severe (>6) categories, based on how many symptoms are present at the same time. The codes relevant to this chapter are: mild 305.70 (amphetamine-type substance) 305.60 (cocaine); moderate 304.40 (amphetamine-type substance) 304.20 (cocaine); and severe 304.40 (amphetamine-type substance) 304.20 (cocaine). There are other specifiers in DSM-5 such as acute intoxication, withdrawal, and other substance-induced disorders (for example, psychotic disorder, anxiety disorder, etc.) (see DSM-5 for further details).

Assessment and investigations

Assessing a person who reports the use of stimulant or other party drugs follows the same principles as for other drug use assessments. A focus on the type of drug/s, pattern, and frequency of use, including the amount used on the day of use (usually in grams or fractions thereof, or monetary spend), the preparation used, polydrug use, including route of use, is mandatory. Asking about key psychosocial and life event determinants that accompanied the progress from initial use to current use patterns, combined with assessment of perceived function (for example, work, managing stress/anxiety, enhanced sexual function, partying) and the level of control over use, are useful. Any history of overdose, treatment-seeking, and involvement in associated high-risk behaviours, such as sex, crimes, and violence, should be noted. Specific assessment to determine the presence of dependence and withdrawal can usually be done by enquiring about a typical day of use, from waking to sleep, with assessment of risk behaviours, drug use prioritization, and craving. Asking what happens if the person goes without the drug for more than a day or two can help you identify the levels of control over use and the presence of withdrawal. Withdrawal needs to be differentiated from

a shorter-lived comedown that many users of stimulants experience in the days following use more akin to a hangover. Blood-borne virus (BBV) screening should be offered routinely to injectors and those involved in high-risk sexual activities. Urinary drug screens (UDS) may be useful to corroborate which substances were used or confirm abstinence, though drugs such as GHB and many NPS may not be detected on routine UDS. Most stimulant drugs will be detectable in the urine for 2–3 days following use.

Amphetamine (speed) and methamphetamine— 'crystalline methamphetamine hydrochloride' (ice, crystal, shabu, yaba, meth, tina)

Background

Amphetamine-type stimulants are the most commonly used synthetic stimulant drugs in the world. Originally developed as medicines (initially as nasal decongestants, appetite suppressants/weight loss agents, and mood enhancers), their abuse potential and ability to induce a range of psychopathologies, most notably transient psychotic episodes, are well recognized. Still used in the treatment of narcolepsy and ADHD, dexamphetamine differs from methamphetamine only by the addition of a methyl group, which lowers its melting point (allowing it to be smoked) and increases its potency and ability to cross the blood–brain barrier. Despite observed differences in the way the drugs are used, the problems they cause, and their clinical presentations, in laboratory double-blind conditions, the subjective experience of the two drugs is remarkably similar [3].

Until recently, the dominant form of amphetamine seen in the UK was low-purity amphetamine sulfate (typically 4–10% purity, comprising both D- and L-isomers). While methamphetamine use has historically been problematic in the United States, Australia, and South East Asian countries, such as Thailand, Japan, and Korea, for many years, its appearance in the UK is actually a recent phenomenon. Its arrival coincides with the rise of the gay 'chem-sex' scene in major cities in the UK, and methamphetamine is now starting to make its presence felt within both emergency departments and sexual health and addiction services. In the UK, methamphetamine was reclassified as a Class A drug in 2007, and amphetamine is a Class B drug. In the UK, a gram of amphetamine sulfate costs about £10, and a gram of methamphetamine sulfate between £100 and £150.

Preparation, purity, and routes of use

Amphetamine sulfate (speed) is usually sold as a white/off white/beige crystalline powder and is most commonly snorted or taken orally, dissolved in a drink, or wrapped in cigarette paper and swallowed (known as bombing or parachuting). Amphetamine sulfate is water-soluble and can be injected, though because of its high melting point, it cannot be effectively smoked. Purities are typically very low in the UK, with common bulking agents being caffeine and lactose. Purities of over 30% are not uncommon across the European Union. Diversion of prescribed dexamphetamine tablets (and the closely related methylphenidate) occurs and is a major problem in countries such as the United States where rates of prescription for conditions such as ADHD are much higher than in the UK.

Unlike illicit amphetamine sulfate powder, methamphetamine is often of very high purity. Its physical form varies, depending on its

route of synthesis and purity. Crystalline methamphetamine hydrochloride (known as ice because it can resemble shards of glass) can be up to 80% pure. Base amphetamine (sometimes known as paste), is an oily, waxy intermediate product on the way to the manufacture of the crystalline hydrochloride salt of methamphetamine and has a lower purity of about 40–50%. Methamphetamine is a versatile drug and can be smoked, snorted, injected, and taken orally.

Mechanism of action and metabolism

Methamphetamine closely resembles amphetamine sulfate (commonly referred to as speed) in structure and mechanism of action but is more potent in its sympathomimetic effects and has a longer duration of action (half-life of about 12 hours, compared to 2–4 hours for amphetamine sulfate). Amphetamine has both direct sympathomimetic effects secondary to disruption of vesicular storage of monoamines and inhibition of their breakdown by MAOIs and indirect actions through inhibition of central presynaptic reuptake of catecholamines.

Prevalence and patterns of use

The use of amphetamine in the UK is less common than that of either cocaine or MDMA. A total of 0.6% of 16- to 59-year olds report using amphetamine in the last year, and 1.3% of 16- to 24-year olds—0.1% and 0.2%, respectively, of those age groups for methamphetamine. Lifetime ever use in 16- to 59-year olds is 10.1% for amphetamine and 0.9% for methamphetamine [4]. As noted in Background, p. 526, in the UK, methamphetamine is becoming more prevalent among certain segments of the population, particularly in association with the gay and dance music scene, but compared to the use of MDMA and cocaine in all its forms, the prevalence of methamphetamine use at present is still low [5].

Doses and typical patterns of use

Most consumers will use infrequently, with daily use, even among dependent users, being uncommon. Typical consumption amounts vary widely, but doses of somewhere between 0.25 g and 1 g in a session would not be uncommon. Heavier users develop tolerance and can consume considerably higher doses. Because these drugs energize people and reduce the need for sleep, use sessions can extend over several days, with prolonged insomnia being associated with the development of paranoia and hostility.

Physical and psychological effects and complications

The effects of all amphetamines are dose-related. They induce euphoria, elevation of mood and alertness, increased speed of thought and speech, and heightened perceptual awareness and lead to reduction in appetite and need for sleep. The physical manifestations of amphetamine and methamphetamine are broadly similar, characterized by sympathetic arousal with tachycardia, hypertension, hyperthermia, and increased respiration, accompanied by sweating, pupillary dilatation, increased motor activity, dry mouth, tremor, and blurred vision. Occasionally, serious medical complications arise, including malignant hyperthermia, coronary artery syndrome, seizures, and cerebral bleeds (Table 53.1). Route-related harms, such as local trauma, septal ulceration, abscesses, and BBVs from snorting and injecting, can combine with more chronic physiological tolls, including malnutrition from prolonged anorexia and hyperactivity, poor dentition, skin picking, and gastrointestinal tract ulceration, leaving users in very poor physical health.

Table 53.1 Clinical signs of intoxication with amphetamine

Physical	Psychological	Behavioural
Elevated pulse, blood pressure, temperature	Euphoria/energized	Motor hyperactivity
Increased respiratory rate	Anxious/irritable	Restless/twitching
Sweating/dehydrated	Rapid thoughts	Talkative, pressured speech
Dilated pupils	Paranoia	Aggressive
Tremor/shakiness/bruxism	Perceptual disturbance	Stereotyped movements

The acute sought-after effects of increased energy and euphoria, enhanced stamina, confidence, disinhibition, and heightened awareness can easily give way to a range of dose-related unwanted psychological effects. These include anxiety, panic, extreme agitation, paranoia, hostility, aggression, hallucinations, confusion, disorientation, and psychosis.

Other consequences of use

Dependence and withdrawal

Dependence may occur and is more common among heavy users who are male and in those who smoke or inject the drug. Methamphetamine is considered to have a higher abuse liability and potential for harm than amphetamine. Although dependent users may use every day to avoid withdrawal, more typically users tend to consume a large amount of the drug (often several grams) over several days, going without sleep (a binge) before ceasing use through physical exhaustion or an exhaustion of funds. 'Crashing' refers to the period following a binge, which is characterized by fatigue, hypersomnia, hyperphagia, and low mood due to acute monoamine depletion. The crash and subsequent comedown period may last 2–7 days. If abstinence persists, a longer-term withdrawal period may be seen, characterized by craving, low mood, anergia, irritability, sleep, and appetite disturbance. Similar neurobiological mechanisms involving alterations in the function and activity of monoamine neurotransmitters are responsible for the overlap between the symptoms of depression and those of stimulant withdrawal [6, 7]. Typically, the withdrawal gradually diminishes over 2–4 weeks, though dysphoric symptoms may persist for up to 10 weeks.

Withdrawal management and relapse prevention

Management of withdrawal is largely supportive and preferably within a safe, well-supported home environment. Inpatient admission is rarely required, other than in those with polyuse dependence and where use is accompanied by severe mental or physical illness. Despite decades of research, there are currently no widely accepted evidence-based pharmacotherapy regimes for the treatment of psychostimulant withdrawal [8]. The patient should be placed in quiet surroundings for several days and allowed to sleep and eat as much as is needed. Because a significant component of the withdrawal syndrome is probably related to neurotransmitter depletion, recovery may be delayed because of anorexia associated with amphetamine use. It may be useful in some to provide nutritional supplements or a well-balanced diet rich in monoamine precursors—phenylalanine, tyrosine, L-tryptophan, which are found in, for example, pumpkin seeds, chocolate, Marmite, and

bananas. Benzodiazepines may be prescribed on a short-term basis for agitation, though these may delay the return to normal sleep architecture. Some patients may become markedly despondent during withdrawal, and a suicide assessment may be necessary. Relapse prevention, based on cognitive behavioural therapeutic (CBT) principles and mutual aid groups, has shown to be effective in reducing relapse and should be part of any treatment intervention. Given the high rates of ADHD comorbidity among stimulant users, it is of note that there is growing interest and evidence to support the use of substitute prescribing in those with concurrent stimulant dependence and ADHD. Some of the most promising results have come from correctional facilities where methylphenidate has been used successfully to reduce both ADHD symptoms and relapse to stimulant drug use [9] (see Cocaine/crack cocaine (charlie, coke, chang, snow, white, crack), p. 528).

Low mood and depression: assessment and management

The mainstay of treatment for those with dependence on amphetamines is psychological, with medication-based treatment having a limited role in the management of withdrawal and relapse prevention, other than in addressing underlying comorbidities such as depression and ADHD. While amphetamine use can exacerbate depression in those with a primary underlying disorder, antidepressants have no specific anti-craving effects, and the efficacy of antidepressants in reducing depression is confined to those stimulant users who are depressed. Clinicians should avoid diagnosing and initiating medication-based treatment for a primary depressive disorder in those presenting during active periods of use or withdrawal. Patients should have the difficulties of making an accurate diagnosis explained to them and should be supported to achieve a period of 2–4 weeks' abstinence and have their mood reassessed before a decision is made to commence antidepressants. The advantages of waiting before deciding whether or not to prescribe antidepressants are improved diagnostic accuracy, avoidance of potentially unnecessary medication and the inaccurate attribution of low mood to drug use and not to an intrinsic disorder, and almost certainly an improvement in compliance and efficacy. Persistence of depressive symptoms beyond 2–4 weeks after stopping amphetamine use may suggest that there is an underlying depressive illness, and this should be treated [10]; left unmanaged, its presence represents a high risk for relapse. Psychosocial treatments, including CBT and motivational enhancement therapy (MET), for stimulant abuse and dependence have been found to be effective in reducing levels of use [11], with their efficacy enhanced through combining them with contingency management approaches offering non-drug reinforcers for engagement and abstinence.

Stimulant-induced psychosis

The use of high doses of methamphetamine may lead to the induction of a temporary psychotic state that may be clinically indistinguishable from paranoid schizophrenia. First recognized in 1938 in association with Benzedrine[®] nasal inhalers, it was not until Connell's classic 1958 study that the syndrome was well described. Acute transient psychotic episodes (typically characterized by suspiciousness, hostility, unusual thought content, and hallucinations) occur in about 10–15% of users. Psychotic episodes are more common in dependent users, users of methamphetamine, men, injectors, polydrug users, those with a past history of psychosis, and following a binge in association with prolonged insomnia [12].

Amphetamine-induced psychosis is characterized by persecutory delusions and hallucinations which are typically auditory but may be visual or tactile (typically formication, or the sensation of insects crawling under the skin; this can rarely lead to secondary delusions such as Ekbom's syndrome of delusional parasitosis). Little has changed in the way of management since Connell's time—he recommended 'removal of the drug and appropriate sedation'. Often, patients present with high levels of hostility and violence secondary to persecutory delusions or hallucinations, and safe containment and management of the disturbed individual can require enormous levels of both physical and chemical restraint. Benzodiazepines (often required in very high doses) should be the first-line medication, with antipsychotics used only where additional tranquillization is required. A diagnosis of a possible underlying or persistent psychotic disorder must be deferred until a reassessment can be made in a drug-free state. These often florid psychoses usually remit within a few days, and the user returns to normal functioning, although some retain a vulnerability to such episodes [13]. Only a minority (1–15%) persist beyond 1 month, and many of these patients will have underlying psychiatric disorders [14].

The prognosis is variable, with those who have experienced stimulant-induced psychotic episodes being more vulnerable to future episodes (possibly through behavioural sensitization) on re-exposure to the drug, often at lower levels. Recent PET imaging studies in chronic methamphetamine users have demonstrated a reduction in dopamine transporter concentration, and this reduction was significantly associated with the duration of methamphetamine use and closely related to the severity of persistent psychiatric symptoms. Moreover, the severity of psychiatric symptoms was significantly correlated with the duration of methamphetamine use. Cessation is still potentially important since there does appear to be some recovery of dopamine transporter function with abstinence.

From a neurotoxicity perspective, preclinical studies have shown amphetamines to be toxic to dopaminergic axon terminals in the striatum, in particular the nigrostriatal pathway. Other neurotransmitter systems (GABA, glutamate, serotonin, and ACh) may also be affected, and the underlying mechanisms causing such damage are thought to be multiple, including oxidative stress, excitotoxicity, neuroinflammation, and others [15]. Amphetamine use in humans (in particular, methamphetamine) has been associated with abnormal morphology of the substantia nigra and possible vulnerability to Parkinson's disease (PD) [16]. Epidemiological studies have suggested an increased rate (2- to 3-fold) of PD in amphetamine users [17–19]. Similarities in methamphetamine-associated dopaminergic neural damage to that seen in PD have resulted in some animal models used in PD research being based on methamphetamine exposure [20].

Stimulant overdose

Dose-related toxicity results from excessive levels of extracellular dopamine, noradrenaline, and serotonin. Acute sympathomimetic toxicity is primarily manifested through neurological and cardiovascular effects, though pathology can extend to the gastrointestinal, renal, musculoskeletal, and pulmonary systems. Clinically, stimulant overdose is recognized by a constellation of psychological (anxiety, panic, paranoia, hallucinations, confusion, and hostility), behavioural (aggression, agitation, and hyperactivity), and physiological (mydriasis, hyperthermia, dehydration, sweating, tremor, hyperreflexia, hypertension,

tachycardia, movement disorders, and seizures) symptoms. The management of sympathomimetic overdose is largely supportive, with cessation of stimulant consumption typically leading to resolution over a few hours or days. Where there is risk to self or others, either as a result of physiological overstimulation or aggressive behaviours, benzodiazepines (often in high doses) and, in some cases, medications to stabilize cardiovascular overstimulation are required. In cases where agitation, delirium, and movement disorders are unresponsive to benzodiazepines, second-line therapies, such as antipsychotics, intravenous sedation, and muscle relaxants, can be considered. Rapid cooling may be required in cases of malignant hyperthermia.

Harm reduction for stimulant users

The risks of acute harm from stimulant-type drugs are related to the dose, length of current use episode, route of use, and polydrug use and are greater among heavy frequent users. As a result, the key safer use strategies include avoiding injecting and smoking, not mixing with other drugs or alcohol, limiting the amount used during a session, avoiding the development of tolerance through taking regular breaks from use (giving both the body and brain time to recover), trying to limit periods of use to 1–2 days, avoiding prolonged insomnia which markedly increases the risks of developing psychosis, and eating and sleeping well between episodes of use.

Cocaine/crack cocaine (charlie, coke, chang, snow, white, crack)

Background

Cocaine is a major alkaloid constituent of the Andean bush *Erythroxylum coca*. Originally used for millennia to increase stamina, suppress appetite, and manage altitude sickness by indigenous groups in South America, cocaine hydrochloride (powder) production and distribution is a multi-billion dollar industry, thought to underpin much of the violence and corruption that ravages countries such as Mexico. Used recreationally to induce euphoria, energy, and confidence, cocaine is frequently combined with depressants such as alcohol and opioids. It is sold either as a water-soluble crystalline hydrochloride powder or as a smokable free alkaloid base form (no longer the salt—therefore, no longer water-soluble) known as crack. In both forms, the mechanisms of action and potential for cocaine to cause harm are remarkably similar. In fact, it is the differences in routes of use (smoking/injecting vs snorting), socio-economic status (rich vs poor), and ethnicity (white vs black) and involvement in criminality and heroin use that are mostly responsible for the observed differences in the presentation and harms seen among users of these two different preparations. In the UK, cocaine in all its forms is a Class A drug.

Mechanism of action

Cocaine is an indirect sympathomimetic agent that causes an acute, but transient, blockade of the dopamine transporter (DAT), causing an acute elevation of dopamine levels, resulting in the experienced pleasure burst. Chronic cocaine administration leads to a compensatory increase in DAT levels, such as that with abstinence, and these

increased transporter levels lead to a relative reduction in levels of dopamine outside nerve cells. Neuroimaging studies suggest that there is persistent reorganization of reward pathways, which may underlie the persistence of craving, even after many months of abstinence. Its half-life is about 50 minutes.

Route of administration

Intranasal use of cocaine powder is the major route of administration in the general population. Purity in the UK has increased in recent years, with street deals varying between 10 and 70%, giving rise to a two-tier market, with 'economy' cocaine selling for £50–60/gram and 'premium' cocaine for over £100 in some places. Intranasally, cocaine lasts about 1–3 hours and is re-dosed every 1–2 hours in small amounts (known as lines) over the course of a session. Typical amounts used on the day of use would be 0.5–1 g/day; much larger amounts can be seen in those dependent upon the drug. Intravenous use is associated with a shorter duration of action, more intense effects, and greater morbidity. Cocaine injectors sometimes administer 20 times or more in a day. In combination with heroin (known as speedballing), it has high associated mortality rates. Smoked as crack cocaine, the high lasts a matter of minutes. Intense, short-lived euphoria, followed by a rapid return to baseline or an overshoot to feeling lousy, is a recipe for enormous reinforcement and is often a gateway into heroin use, which is marketed by dealers as a way of managing the comedown from crack cocaine. Crack cocaine users can often consume many grams of the drug over a session, with the rate-limiting factor being money.

Many people may use powdered cocaine in a recreational fashion for many years and without significant problems. Others may insidiously develop problematic use, characterized by increasingly regular dosing, development of tolerance, craving, and loss of control. Concurrent consumption of alcohol is common and can lead to increased rates of acute harm and dependence. At population level in England and Wales, in 18- to 59-year olds, the reported lifetime ever use is 9.7% for cocaine powder and 1.2% for crack. Last year use in 16- to 24-year olds was 4.8% for powder and 0.1% for crack, and in the 18- to 59-year olds, 2.3% for powder and 0.1% for crack [4]. Frequently seen as a way of enhancing confidence and performance, attempts at reducing use are often accompanied by a rebound fall in self-esteem and energy and the development of depression. It is of note that crack is sold in small unit cost deals (£5–10), compared to the costlier dealing unit of cocaine. Within UK drug treatment services, coexisting crack cocaine and heroin use are common, with typical users reporting smoking 3–4 'bags' per day, equating to approximately half a gram. Although dealers usually provide the user with the preparation of their choice, some users will 'wash' their own cocaine powder with a base (ammonia or bicarbonate of soda) to make their own crack, while cocaine injectors are sometimes left with having to inject crack if powder cocaine is unavailable. It may be that there are groups of 'functional' occasional users of crack, but in those with substance use disorders, the pattern of use is often uncontrolled and leads to significant harm.

Dependence and withdrawal

Dependence to cocaine can occur with both powder and crack but is potentially more likely if smoked as crack. This is due to the more rapid onset of action, intense highs, and early withdrawals, which are very reinforcing. Features of escalating use over time, loss of control, tolerance, withdrawal symptoms, cravings, salience, and continued

use despite knowledge of harm can all manifest. Dependent users may not necessarily have to use every day—typically crack users tend to use in binges over a few days, then rest—but there are rarely many consecutive days off, and even then, dependent users often use other substances to combat the withdrawal symptoms.

The withdrawal syndrome is similar to that seen in amphetamine withdrawal, with common symptoms including dysphoric mood, fatigue, irritability, increased appetite, hypersomnia/insomnia (reflecting a homeostatic resetting response to acute intoxication-related insomnia and anorexia), irritability, craving, lethargy, or agitation. Secondary to a hypo-dopaminergic state, the predominant psychological symptoms peak on days 2–7, reducing gradually over the following 3–6 weeks.

Effects and toxicity

These are similar to those seen with amphetamines and include signs of sympathetic arousal (tachycardia, hypertension, severe agitation, hyperthermia, seizures) and severe cardiac problems such as coronary artery spasm, congestive cardiac failure, arrhythmias, ischaemia, and myocarditis. Cocaine, when consumed with alcohol, results in the formation of the less anxiogenic, but more cardiotoxic, reinforcing, and longer-lasting, cocaethylene. Concurrent consumption of alcohol, and then cocaine, leads to a 30% increase in peak plasma cocaine levels, which may increase the risk of sudden death in a vulnerable minority. Chronic use has more recently been associated with accelerated cerebrovascular ischaemia and strokes in young users.

Psychiatric comorbidity with cocaine dependence is high. About 25% have coexisting ADHD; 50% experience alcohol use disorders, and rates of depression are much higher than that of the general population. Depression predicts poorer outcome in cocaine dependence and, untreated, can lead to an increased risk of relapse. Although adverse psychological experiences are less common than among users of methamphetamine, because of cocaine's shorter half-life, transient episodes related to sympathomimetic hyperarousal, such as anxiety, panic, agitation, paranoia, and aggression (especially when consumed with alcohol), are not uncommon. Acute adverse effects are seen with crack, because of its greater intensity of effect and the dose of drug consumed.

Route-related harms

Persistent intranasal use can result in nosebleeds, with the risk of viral BBV transmission. Smoking the free alkaloid base as 'crack' is associated with a shorter, more intense high and can lead to acute lung injury in the form of 'crack lung', a progressive fibrotic condition of the lung. Users present with haemoptysis, hypoxaemia, fever, and cough, with pulmonary interstitial inflammation and peripheral eosinophilia. Injecting cocaine is associated with higher rates of sharing of intravenous equipment and HIV transmission and can also cause significant local trauma secondary to local anaesthesia that precludes pain-associated restriction in damaging injecting behaviour. Cocaine use, especially via the smoking route, is associated with marked increase in risk of stroke (once controlled for tobacco and alcohol use, odds ratio of >5) in the 24 hours following use among young adults [21].

Treatment

Hospital admission for withdrawal may be necessary in some clients, such as those with unstable living conditions, comorbid mental

health or severe physical illness, or polydrug dependence, or those in whom severe withdrawal has been experienced and attempts at outpatient detoxification have proved ineffective. Optimized nutrition, rest, and symptomatic relief with short-term, low-dose benzodiazepines [for example, diazepam 5 mg three times daily (tds)] may be helpful.

However, as with other stimulant drugs, there is little evidence to support the routine use of any specific pharmacotherapy either in the management of cocaine withdrawal or in maintaining abstinence from it, apart from situations where a comorbid psychiatric condition has been identified (see Medication-based treatments for stimulant use disorders/dependence, p. 530). The evidence suggests the most effective interventions are based on CBT (see below).

Medication-based treatments for stimulant use disorders/dependence

Despite decades of research on a wide variety of different therapeutic agents, there is still no evidence-based pharmacotherapy available for the general treatment of cocaine dependence. In the absence of primary depressive disorders, antidepressants are not useful as a treatment for cocaine dependence. In those with a primary depressive disorder, the efficacy of antidepressant medication will be very limited if the person continues to use cocaine. Untreated depression, however, is a risk factor for relapse to cocaine use, and careful assessment is required, even after several weeks of abstinence, to ensure it does not emerge late and be left untreated. There is also no evidence for the use of antipsychotics, anti-epileptics, or opioid antagonists in the treatment of cocaine dependence. There is no widely utilized or evidence-based substitute medication, as is the case for opioid dependence. However, there is growing interest in the possible role of stimulant replacement therapy in the treatment of carefully selected groups, combined with psychosocial interventions. Promising results for such approaches have been seen among those with comorbid ADHD where the provision of an oral alternative stimulant (for example, dexamphetamine or methylphenidate) has been initiated as a harm reduction approach in persistent high-risk injectors. In such groups, with appropriate assessment and monitoring (for unwanted cardiovascular and psychological effects), stimulant medications can be safe and effective. Concerns over prescribing a drug with abuse liability, risk of diversion, and difficulty with ensuring compliance mean the use of substitute prescribing is not straightforward. It is likely, however, that in combination with psychological support, including contingency management, such approaches may be currently among the most effective available [22]. Extended-release preparations may be the most effective, being less reinforcing and requiring lower levels of supervision.

Although rates of stimulant dependence are high among those with adult ADHD, there is no evidence to suggest they are significantly higher than in those with other substance use disorders, with rates among those with substance use dependence being between 20% and 25% [23]. There is growing interest in the role of substitute prescribing in those with concurrent stimulant dependence and ADHD [24]. Some of the most promising results have come from correctional facilities where methylphenidate has been used successfully to reduce both ADHD symptoms and relapse to stimulant drug use [25]. It may therefore be the case that selective treatment of adults with coexisting stimulant dependence and ADHD may have specific therapeutic benefits. Screening for ADHD in those

with stimulant disorders is therefore clinically useful. Some adults may give clues to their primary diagnosis by reporting a paradoxical response to stimulant drugs as adults (for example, feeling calm and 'normal'), as opposed to hyper and aroused which would be the normal subjective response to drugs like cocaine in those without ADHD. There is also interest in the use of non-stimulant medications in the treatment of stimulant use disorders, including modafinil, a wakefulness-promoting agent approved for the treatment of narcolepsy and shift-work sleep disorders. With both dopaminergic and glutamatergic activity, early work suggests it might be useful in the treatment of cocaine dependence, with studies showing a reduction in subjective effects, use, and craving [26].

A more recent development in the treatment of those with drug dependence has been the provision of non-drug rewards (for example, a voucher or monetary incentive) for engagement in treatment and confirmed abstinence from drugs. Such approaches are referred to as contingency management (CM). In trials where CM has been used in the treatment of stimulant use disorders, combined with other psychological approaches, such as CBT or MET, CM has been shown to increase retention in treatment, increase abstinence, and possibly enhance the efficacy of pharmacological interventions [27]. Although still uncommon in routine practice, the evidence suggests that CM should be offered as part of routine clinical interventions, in conjunction with other therapies.

Interest and clinical trial research into a vaccine for cocaine dependence continue, with the development of antibodies to bind to cocaine and prevent it from reaching receptor sites. To date, clinical trials suggest such interventions are some way off and, once developed, will no doubt face a series of ethical and biological hurdles before immunization of vulnerable groups, such as the young or those with addiction histories, becomes part of treatment anytime soon.

Ecstasy (3,4-methylenedioxymethamphetamine) (MDMA, E, X, XTC, pills, beans, Molly, Mandy)

Background

MDMA is a synthetic stimulant drug characterized by pro-social effects, euphoria, energy, and empathy. First synthesized in 1912 by Merck Pharmaceuticals, MDMA remained largely ignored until the 1950s when the United States army explored its potential as a military agent (though, unlike methamphetamine, it lacked an aggressive edge and was more likely to make someone hug their enemies than kill them!). In the late 1960s and early 1970s, recreational drug users on the west coast of America began to recognize the desirable effect profile of MDMA and the closely related drug MDA (methylenedioxymphetamine). In the mid to late 1970s, some clinicians—influenced by the biochemist and psychopharmacologist Alexander Shulgin who had resynthesized MDMA in his laboratory in 1976—started exploring its therapeutic potential to facilitate marriage counselling and individual therapy. Such usage was dismissed by the United States government, and what followed were three decades of research focusing on MDMA-related harms, with MDMA being branded a potent neurotoxin with no place in medicine. The last 10 years, however, have seen a gradual resetting and revision of both its acute harms and longer-term neurotoxicity, as well as its therapeutic potential.

Although MDMA may claim its place as the pre-eminent dance drug and possessor of the best branding in terms of name ('Ecstasy'), MDMA is only one of a large number of synthetic amphetamine-type drugs possessing varying degrees of stimulant, hallucinogenic, and empathogenic effects that are used within the dance scene. As with most stimulant drugs, desirable effects and the risk of harm are dose-related. As seen in other illicit drugs, inconsistent preparations and variations in quality (for example, the amount of MDMA in a pill) and the presence of more dangerous contaminants [such as paramethoxymethamphetamine (PMMA)] mean that informed dosing and safer use strategies have their limitations. Overall, MDMA can be considered a relatively safe drug; acutely, it has a low risk of death, and although tolerance and loss of control are reported by users [28], few, if any, users will ever seek help for problems associated with its use in isolation from other drugs. Understanding its effects and risk profile is most useful to the clinician in ensuring an accurate assessment of mood and other psychological symptoms that can occur in the presence of MDMA use or that can be worsened by its use. In the UK, MDMA is classified as a Class A drug.

Preparations, purity, and routes of use

MDMA is most commonly sold as tablets (pills) or powder (crystals) and taken orally, though it may be snorted, taken rectally, or injected. MDMA tablets vary in size, shape, and colour and are typically branded with an imprinted logo (for example, of a cartoon character, a car manufacturer, or a luxury brand). The size and shape of the tablet give no clue to its content, though, since 2015, in the UK and across much of Europe, tablets sold as ecstasy do contain MDMA, though the dose and precise composition vary. In recent years, it appears that the average dose of MDMA found in a pill has increased, with the average ecstasy pill containing 80–150 mg, though pills containing over 300 mg have been identified. These higher-dose pills have almost certainly contributed to both an escalation in the number of users seeking emergency medical treatment following the use of MDMA and an escalation in MDMA-related fatalities (from eight in 2010 to 63 in 2016, and over 56 in 2017 [29]). It is of note that while MDMA deaths are not clearly dose-related (the relationship between consumed dose and the risk of death is inconsistent and unpredictable on an individual level), higher doses of MDMA make you more vulnerable to environmental factors such as high temperature and overcrowding. The average dose of MDMA to give the user an optimal balance of positive vs negative effects is about 80–150 mg in divided doses (1.5 mg/kg). Higher-dose tablets can make it easy to take too much and expose people to dose-related unwanted effects, including agitation, panic, chest pain, overheating, hallucinations, and confusion. MDMA crystals are white, beige, or brownish in colour and can look very similar to other white crystalline drugs such as crystal meth. Typically swallowed either by wrapping in cigarette paper (known as parachuting or bombing) or taken by licking a finger and dipping it in MDMA powder (known as dabbing), MDMA powder can also be snorted or, rarely, injected. In the UK, an ecstasy tablet costs £5–10, with a gram of MDMA crystals costing around £40.

Pill testing

Because of the variations in quality, some users utilize drug testing methods (such as the Marquis test which gives colorimetric results by mixing the substance with a reagent) and websites ([http://](http://www.EcstasyData.org)

www.EcstasyData.org) which provide the contents of different pills following more elaborate analytical methods. Although these approaches have some role, not least in getting users to consider the risks and engage in conversations about harm reduction practices, these approaches are limited by accuracy of data, especially regarding the amount of each active drug present. More sophisticated analytical techniques can help in identification of more psychoactive contents such as paramethoxyamphetamine (PMA) [30]. There is a good case for an early warning system to ensure that information about high-dose MDMA pills or pills found to contain dangerous contaminants is made available to the drug-using community, though exactly what approach is the best, given resource limitations, is uncertain. However, in recent years, across many countries in Europe, the availability of on-site sophisticated analytical processes [for example, gas chromatography–mass spectrometry (GCMS), high-performance liquid chromatography (HPLC)] are offering the possibility of integrated harm reduction and chemical composition analysis, including the amount of active drug which can help people change their drug using behaviour. However, the majority of drug-related deaths remain unpredictable, and individual behaviour the biggest modifiable risk behaviour. Knowing the content of your tablet never guarantees the user a positive experience and can never reduce the risk associated with use to zero [31].

Prevalence and patterns of MDMA use as ecstasy

British population studies show that 54% of 20- to 22-year olds have been offered ecstasy at some time and 15% have tried it at least once [32]. The current prevalence in 16- to 24-year olds has increased to 5.4% in terms of last year use [4]. Use appears higher in those associated with the dance music drug scene, with over 90% reporting lifetime ever use. Similar findings have been reported from Europe [33], Australia [34], and the United States.

The typical pattern of use in the UK and Europe is 1–2 tablets a night (equivalent to 100–250 mg of MDMA powder). Most people use less than ten times per year. Tolerance develops with regular use and is associated with higher-dose consumption and higher levels of polydrug use. Ecstasy, especially within the context of dance clubs, is rarely taken in isolation, and polydrug use is the norm, with different adjunctive substances taken at different times over the course of a night [35]. For example, alcohol is taken with ecstasy at the beginning of the night to get a stronger/better high [36]. Cocaine, amphetamines, and/or additional ecstasy tablets are taken to maintain arousal and a state of alertness (the MDMA entactogenic effects fade away in 2–4 hours). Finally, depressants such as cannabis, alcohol, benzodiazepines, and more rarely opiates may be taken in the last part of the night to calm down before going home, since the untoward after-effects of ecstasy (namely irritability, insomnia, and restlessness) may persist well beyond its 'pleasurable' effects. With chronic high dosage, ecstasy users develop tolerance and experience a decrease in the desired effects over time, which could lead to use of other stimulants and hallucinogens [35].

Physical effects and complications

Physiologically sympathomimetic properties similar to amphetamine predominate, including tachycardia, anorexia, increased respiratory rate and blood pressure, increased motor activity, tremor, mydriasis, increased temperature, and sweating. Jaw tightening (bruxism), xerostomia, and teeth grinding with molar erosion may

also be seen (Table 53.2). Sleep architecture modification [37] and sexual activity alteration [38, 39] have also been described.

After MDMA intake, a number of untoward effects (often part of the ‘coming up’ phase when the effects of MDMA first manifest) may commonly occur, including nausea, vomiting, diarrhoea, tachycardia, and palpitations. Pathologies less commonly seen include arrhythmias, hypertension, potentially life-threatening metabolic acidosis, cerebral haemorrhage, convulsions, coma, rhabdomyolysis, thrombocytopenia, disseminated intravascular coagulation, syndrome of inappropriate antidiuretic hormone (SIADH), acute kidney failure, acute liver failure, dehydration, and malignant hyperthermia [40–44].

Hyperthermia, although enhanced by exertional activity and poorly ventilated environments, may occur somewhat independently from the setting in which the drug is taken, because MDMA has thermal dysregulation effects in its own right. However, in clubs, dehydration is common and thirst naturally prompts individuals to replace body fluids lost during sweating sensibly with fruit juices, other isotonic fluids, or water, or less sensibly, but quite commonly, with alcohol. Very rarely, excessive intake of hypotonic fluids, coupled with an increase in vasopressin levels, has led to the occurrence of lethal hyponatraemia [45]. Deaths as a result of SIADH are very rare but may be most associated with excessive hypotonic fluid consumption, with MDMA potentially leading to urinary retention and impairing awareness of the need to micturate. In normal subjects who take MDMA and do not develop SIADH, there does appear to be an increase in both antidiuretic hormone (ADH) (greater in females than males) and oxytocin levels [46], the latter perhaps responsible for the drug’s pro-social effects. Ninety per cent of cases of SIADH are seen in women.

MDMA is a potentially damaging cardiac stimulant [47], with reports suggesting long-term MDMA use may possibly lead to a fenfluramine-like valvular heart disease condition. Between 0.5% and 1% of last year users of MDMA report seeking emergency medical treatment in the previous 12 months, with the rate among young women being 2–3 times greater than among men. Presentations are more common in heavy regular users and those combining MDMA with alcohol and/or other drugs.

MDMA’s psychological effects and problems

(See Table 53.2 [48].) Being structurally related to both amphetamine and mescaline, ‘empathogens’ or ‘entactogens’ [49] like MDMA possess both stimulant and hallucinogenic properties, which allow them to be discriminated from other related substances. After MDMA ingestion, enhanced mood, increased energy, openness, heightened sensory perception, and mild perceptual alterations are reported [40, 42, 48].

MDMA is described as evoking ‘an easily controlled altered state of consciousness with emotional and sensual overtones’ [50], with the substance’s appeal resting in its ‘dramatic and consistent ability to induce in the user a profound feeling of attachment and connection’. With this in mind, it is perhaps not surprising that the Los Angeles dealer who coined the street name ‘ecstasy’ for MDMA would have preferred the name ‘empathy’, but he did not feel that his typical customer would know what it meant. These qualities were also what has led to recent research into its use within a clinical psychotherapeutic setting in the treatment of PTSD [51–54].

Table 53.2 Psychological and physical effects of MDMA

Physical	Psychological
Increase in physical and emotional energy	Relaxation/euphoria
Dilated pupils, dry mouth	Feelings of well-being
Tachycardia, hypertension, increased respiratory rate	Enhanced closeness and sociability
Increased sweating, dehydration	Heightened perceptual awareness
Increased motor activity, tremor	Disinhibition
Blurred/double vision	Increased response to touch/empathy
Anorexia, nausea, weight loss	Anxiety/panic/paranoia
Teeth grinding, jaw clenching (bruxism)	Agitation and restlessness

Adapted from *J Nerv Ment Dis.*, 180(6), Liester MB, Grob CS, Bravo GL, *et al.*, Phenomenology and sequelae of 3,4-methylenedioxymethamphetamine use, pp. 345–54, Copyright (1992), with permission from Wolters Kluwer Health, Inc.

Acute psychological problems associated with MDMA use

There have been reports of acute episodes of anxiety, panic, paranoia, excessive agitation, confusion, hallucinations, and rarely brief psychotic episodes following the consumption of MDMA. Many users of MDMA report ‘mid-week blues’, with some individuals reporting clinically borderline levels of depression in the days following MDMA [55], which could reflect the depletion of serotonin following the acute elevation that follows ingestion of MDMA. This could be seen as a parallel to the ‘crash’ reported after abstinence of cocaine use or as a hangover effect from all-night dancing, excessive alcohol, and minimal sleep. Although depression, anxiety, and mood fluctuations attributed to ecstasy are reported to be strongly related to the number of occasions of MDMA use [56, 57], Morgan *et al.* [58] found that higher depression scores among current heavy ecstasy users, in comparison to drug-naïve and polydrug controls, were no longer significant after treating cannabis use as a covariate.

Other consequences of use

Neurotoxicity, neuropsychological impairments, and psychiatric presentations

Significant research into MDMA has been ongoing for around 30 years. Much of the evidence for MDMA causing 5-HT neurotoxicity comes from preclinical studies in rodents and non-human primates where findings of depleted 5-HT brain tissue levels, reduced 5-hydroxyindoleacetic acid (5-HIAA) levels, reduced tyrosine hydroxylase activity, and reduction in serotonin transporter (SERT) binding have been consistently reported [59].

With regard to MDMA having 5-HT neurotoxic effects in humans, there is ongoing debate. Given the preclinical data, it is likely that similar effects would occur in humans; however, there are issues around inter-species scaling and dosing regimes (animal studies often dose multiple times per day on consecutive days, which is quite different from human recreational MDMA use patterns, and also often in higher milligrams per kilogram than humans would typically consume), which mean extrapolation from animal studies is complicated [60].

In a recent meta-analysis of both preclinical and human molecular imaging studies on MDMA, the main finding was a reduction in

SERT binding across the cerebral cortex and parts of the forebrain, especially in heavy users, but there is evidence of some recovery after cessation of MDMA use [61]. This reduction in SERT binding is thought to be indicative of serotonergic neurotoxicity; however, downregulation of SERT cannot be excluded. In a systematic review of imaging studies in moderate users (<100 tablets lifetime, or <50 lifetime episodes of MDMA use), there was no convincing evidence that moderate MDMA use was associated with structural or functional brain alterations in neuroimaging measures [62].

From a functional perspective, MDMA use in humans has been associated with a number of neuropsychological deficits which are thought to be underpinned by 5-HT system dysfunction; however, the evidence for specific MDMA-attributable deficits remains a little controversial due to inherent confounds such as purity of tablets taken, use mainly of cross-sectional studies, and comorbid polydrug use often seen in MDMA users. The latter issue has benefited from use of non-MDMA-using polydrug control groups, rather than drug-naïve controls, in more recent studies. A recent meta-analysis has shown that MDMA users show impaired executive function, relative to non-users, in particular in its sub-domains: accessing long-term/semantic memory, 'switching', and 'updating' [63]. Other functional deficits associated with MDMA use have been described in prospective memory, higher cognitive processing, such as logical reasoning, problem-solving, organizational control, and social intelligence. Other psychobiological domains affected by MDMA are sleep apnoea, visual information processing, immunocompetence, pain perception, psychomotor skill, and damage to emergent children of pregnant women [64].

MDMA intake may put users at significant risk for developing psychiatric problems [65], although some have suggested that this may occur only in vulnerable individuals [66]. Studies suggest that ecstasy users may report both childhood emotional/physical abuse [67] and a history of familial depression, anxiety, and panic attacks [68] more frequently than ecstasy-naïve controls. Many studies also report increases in psychopathology in MDMA users, relative to non-MDMA-using polydrug controls, in self-reported measures of anxiety, depression, memory, and impulsivity [69].

Depression and its management in MDMA users

In a patient presenting with psychological problems who has a history of MDMA use, the crucial assessment issues are the identification of any premorbid disorders, their position in the cycle of use/post-use, and the persistence of any symptoms beyond a 2- to 4-week period following cessation of use. As with amphetamine use, in the days after taking MDMA, there may be symptoms attributable to monoamine depletion and subsequent repletion. A period of acute 5-HT depletion due to vesicular monoamine depletion (mid-week blues) is likely to be the most potent cause for the relative reduction in monoamine neurotransmitters. Repeated use of MDMA over several days will be associated with markedly diminished effects. Recovery is delayed further by inhibition of the rate-limiting enzyme (tyrosine hydroxylase in the case of MDMA) and the relative absence, especially in chronic users, of a good source of monoamine precursors following stimulant-induced anorexia and malnutrition. It is likely that, as with other stimulant drugs, including cocaine, a period of extended, but less intense, withdrawal symptoms (mood, sleep) may be seen with persistent abstinence, which may take weeks or months to recede and are associated with the more gradual

reversal of neuroadaptive changes in dopaminergic receptor sensitivity/expression [70].

As with amphetamine and cocaine users, antidepressant treatments should usually not be commenced until 2–4 weeks after cessation of MDMA use, in order to allow for reassessment and confirmation of any disorder. There are also at least theoretical causes for concern over potentially fatal interactions between MDMA and SSRIs that have been reported very rarely, possibly because some SSRIs (that is, citalopram) can inhibit the CYP2D6 enzyme [71]. The precise effects of combining SSRIs and MDMA appear to be related to whether use of the SSRI was before or after MDMA and whether SSRI dosing is acute or chronic. For example, SSRIs given acutely after MDMA (taken by users to intensify the ecstasy effects) may theoretically increase the risk of precipitating a serotonergic syndrome. It is probable that SSRIs and other classes of antidepressants can be used effectively in this group if a diagnosis of responsive affective/anxiety disorder is confirmed and abstinence is maintained. CBT may be useful in this group, both to address their underlying drug use as well as to address any coexisting anxiety/depressive disorders.

Dependence with the development of heavy regular use patterns is possible, though there are unlikely to be any specific signs or symptoms that differentiate diagnosis or management significantly from other forms of stimulant dependence.

Assisted psychotherapy and the potential therapeutic role of MDMA

While this chapter has concentrated on the recreational use and dangers of MDMA, interest in MDMA as an empathogen predates its incarnation as a party drug. There is now serious interest in the medical use of MDMA to treat PTSD. The initiative has evolved over many years as the Multidisciplinary Association for Psychedelic Studies (MAPS) project (<http://www.maps.org/research/mdma>). Agreement has been reached with the FDA to designate MDMA as a 'breakthrough medicine'. A definitive RCT is planned, supported by philanthropic donations, and the objective is an approval by 2021.

Novel psychoactive drugs

Since the mid 2000s, a dizzying array of diverse novel psychoactive drugs have appeared in the UK and across the world. Unhelpfully labelled 'legal high' by the media, until recently, many were openly sold on the UK high streets as smokable herbal preparations, pills, and powders. They were carefully branded and labelled with 'not for human consumption' to ensure they did not contravene the law. Often attempting to mimic the effects of traditional drugs—most commonly, cannabis, stimulants, and hallucinogens—they vary widely in their desirability, potency, effect, and risk profile. These new compounds are often undetected by UDS, and statutory services are often unaware of their presence in the community until they cause clinical problems in emergency departments or are found in police seizures. Such triangulation of data sources is required to keep abreast of this rapidly developing area.

The Psychoactive Substances Bill passed in the UK in May 2016 is an attempt to reduce their widespread availability and has led to closure of over 300 'headshops' across the UK. While reducing easy

access on high streets will lead to a reduction in use, it is probable that distribution and supply will continue either through illicit street dealing networks or dark-net drugs markets. Where the effect profile, demand, and profit are attractive enough, it is likely that some classes of these drugs will remain in circulation. For the psychiatrist, the important issues are that these drugs are not picked up on routine drug screening; hence, clinicians should remain alert to the possibility that young people who present with disturbed behaviour or psychopathology may have used them. Offering a relatively cheap, but generally less desirable, high, many people who use these drugs could be considered vulnerable in other ways, through their young age, coexisting mental illness, or homelessness. At the time of writing, synthetic cannabinoid products, which are a particular problem within prisons, pose some of the greatest risks. These potent CB1 receptor agonists not only carry the risk of dependence and withdrawal, but their acute use is also at least 30 times more likely to lead to emergency medical treatment than high-potency herbal cannabis [72]. Symptoms include extreme agitation and a transient psychotic state, which will often resolve after cessation of use but may persist in some cases for weeks and may require antipsychotics. Acute psychotic mental states need appropriate monitoring and follow-up. Although deaths are still relatively rare, some of these NPS can cause significant physical harms such as seizures and arrhythmias. Collaborative management with general medical colleagues and good clinical documentation, combined with appropriate investigations such as ECGs and biochemical screens, should be undertaken.

Mephedrone (meow meow, M-CAT, 4MMC)

Background

Mephedrone (4-methylmethcathinone) is one of a number of cathinone compounds (methyline, methcathinone, MDPV, and others), which derive from the natural herbal stimulant khat (*Catha edulis*) and are β -keto analogues of amphetamine. Mephedrone came to prominence in the UK in 2009 as a cheap and easily accessible alternative to MDMA and cocaine (it was legally sold and marketed in the UK until April 2010) [73], both of which had been of poor quality in years prior to its appearance. After it was made illegal, its use among the general population diminished significantly, though access through street dealers and online markets has continued. It is most commonly associated with the gay music and 'chem-sex' scenes where it is often taken in conjunction with other drugs, including GHB and crystal methamphetamine.

Preparation and routes of use

Mephedrone hydrochloride is typically sold as a white crystalline powder. It is water-soluble and is most commonly snorted intranasally, with single doses being between 50 and 150 mg. Taken intranasally, effects come on swiftly (within 10–20 minutes) and last approximately 1–2 hours, with users re-dosing every 30–120 minutes over the course of a session; some heavy users are capable of consuming over 5 g. It can also be taken orally, often wrapped in cigarette paper, a practice known as bombing, for a slower onset of action and less intense onset of effect. It can also be used rectally and by intravenous injection—the latter being associated with

significant tissue damage. Injection among naïve injecting groups can be a particular risk factor for HIV where the sexualized injection of drugs such as mephedrone and crystal methamphetamine (known as 'slamming') can be seen in association with other risky sexual practices.

Mechanism of action and effect profile

Mephedrone consumption results in typical stimulant-related effects—euphoria, increased concentration, talkativeness, urge to move, empathy, jaw clenching, reduced appetite, and insomnia are most commonly reported. At higher doses, mephedrone has the potential to cause a toxic sympathetic syndrome, with agitation, panic, dehydration, overheating, seizures, cardiovascular dysregulation, and paranoid episodes, leading to emergency medical presentations [74]. Its mechanism of action is similar to other stimulant drugs: extracellular release of monoamine neurotransmitters (dopamine and serotonin) and inhibition of their reuptake (dopamine, serotonin, and noradrenaline). Overall, mephedrone has an effect profile similar to MDMA, but with a duration of action and abuse liability similar to that of cocaine. Animal models confirm its potential to cause dependence with mephedrone (high levels of self-administration in rat models [75]). With a short duration of action and rapid development of tolerance, dependence will be seen among a proportion of regular users. The comedown after mephedrone appears to be worse than with either cocaine or MDMA. Lowering of mood following use (presumably due to acute monoamine depletion) may be marked and can be associated with elevated suicide risk, especially in those with underlying psychiatric conditions [76].

Treatment

Treatment interventions are broadly similar to those for other stimulant drugs, with emphasis on harm reduction, self-regulation, management of acute toxicity, differentiation between drug intoxication/withdrawal, and primary underlying psychiatric condition and relapse prevention [77].

Gamma hydroxybutyrate (GHB, GBH, G, fantasy, liquid ecstasy, and GBL)

Background

GHB is an endogenous short-chain fatty acid found in the central nervous system and elsewhere in the body. It is a putative neurotransmitter, and specific binding sites have been identified in the hippocampus (linked to dopamine neurons), but its precise role is yet to be identified. Trace amounts may also be found in certain fruits such as guava. In the UK, GHB is a Class C drug. Along with its precursors, including the psychoactive pro-compounds GBL (gamma butyrolactone) and 1,4-butanediol, GHB is a colourless, odourless, slightly acidic-tasting liquid that, when consumed orally, is used for pro-social, sexual, and sedating effects.

GHB was originally developed as an anaesthetic in the 1960s. In the 1980s, it had found clinical utility as a sedative, as a treatment for narcolepsy, and as a detoxification agent (it is effective in the management of alcohol withdrawal). It is also used (with little evidence of effect) to promote muscle growth in bodybuilders (through its effect on increasing slow-wave sleep). Since the 1990s, however,

it has become best known for its place among the smorgasbord of drugs commonly used by those involved in the dance/rave scene, especially those from the LGBT community where its pro-social and aphrodisiac qualities have made it popular, particularly in conjunction with crystal methamphetamine and mephedrone. Almost unique among liquid drugs of abuse, GHB is typically consumed in doses of only 1–2 mL; combined with its narrow therapeutic index, this implies a high risk of overdose, which is increased in combination with alcohol [78].

Preparation (pro-drugs), purity, and routes of use

Until the late 1990s, GHB and its precursors were widely available in shops and the Internet as a clear liquid. As an industrial solvent and a cleaning product, it was also easy to come across these drugs in other guises. For example, GBL was sold in high-street chemists as nail polish remover and websites offered litre bottles as alloy cleaners. Because of its relative ease of manufacture, attempts at home production also occur but can result in preparations of widely varying concentrations; high concentrations can be quite caustic, resulting in gastrointestinal discomfort and nausea, with a risk of vomiting and aspiration.

Doses and typical patterns of use

Most users of GHB are not daily dependent users and will use for 1–2 days in association with other drugs, most commonly alcohol, methamphetamine, poppers, and sexual enhancers such as sildenafil. Typical doses are 1–2 mL dispensed via an eye dropper or a syringe, often mixed with juice or alcohol to disguise the taste, and taken every 2–3 hours. Heavy users may dose 3–4 mL every hour, with bigger doses at night to aid sleep. While most users will limit their use to situations which exploit its pro-social, disinhibitory, and aphrodisiac qualities, a minority of users (less than 5%) will extend their use over periods of weeks or months. Daily use for more than 1–2 weeks can lead users to developing tolerance and withdrawal symptoms upon cessation, which drives further use.

Mechanism of action

GHB readily crosses the blood–brain barrier and acutely leads to a transient decrease, followed by an increase, in dopamine levels (and an increase in endogenous opioid release). Increases in other neurotransmitters, such as GABA, ACh, and 5-HT, are also seen. At higher doses, it exhibits some partial action at GABA-B receptors (epileptogenic). GHB is usually taken orally, often mixed in fruit juice or an alcoholic beverage. It has a very rapid onset of action, with noticeable effects occurring within 15 minutes of administration; it has a relatively short duration of action (half-life 27 minutes), with effects peaking at 30–60 minutes and being over within 2–4 hours, being eliminated through its breakdown to carbon dioxide and water.

Physical effects and complications

GHB exhibits a very narrow therapeutic index, and as a result of wide inter-personal variation in tolerance and significantly enhanced toxicity (depressant effects) when combined with alcohol, overdose with GHB has been reported more frequently than for any other dance drug [79, 80]. Overdose should be suspected in someone who presents with nystagmus, ataxia, nausea, vomiting, sedation, weakness, bradycardia, hypotension, and rapid onset of unconsciousness (quite similar to severe alcohol intoxication, but without alcohol on

the breath). Management should include placing the person in the recovery position, airway management, and pulse oximetry. GCS scores may be very low (<6). If oxygen saturation drops or the patient is so unconscious that they can tolerate a Guedel airway, then ventilation should be considered. Overdoses are short-lived, and most awake somewhat aroused and disorientated after a few hours. Other clinical presentations include agitation, anxiety, coma, amnesia, seizures, and collapse. These patients, when in a coma, may require ventilation and typically suddenly emerge from their coma with high levels of agitation, arousal, and violence.

Longer-term use, behavioural risks, and dependence

GHB can cause marked disinhibition and amnesia. This can result in people engaging in high-risk sexual practices or falling victim to sexual assault. Shame and uncertainty over what may or may not have happened can cause significant emotional distress to individuals. Until recently, dependence on GHB was considered rare among users, but with the apparent escalation in use across many countries, increasing numbers of people are coming forward, seeking treatment for dependence and the management of withdrawal. Tolerance and withdrawal can be seen among users who persist with daily use for more than a few weeks. Continued use outside party environments may be motivated by GHB's amelioration of the comedown from other drugs, facilitation of sleep, or improved anxiety and confidence in social situations. Dependence is characterized by the development of tolerance (bigger doses taken at shorter intervals), intense craving, continued use despite evident harms, and a well-defined withdrawal syndrome. Withdrawal from GHB, like alcohol, sits on a spectrum and is dominated by autonomic and psychological arousal. Among severely dependent users, withdrawal commences within 2–4 hours and can escalate rapidly, from early symptoms of craving, anxiety, sweating, and tremor to confusion, disorientation, hallucinations, and seizures. Untreated/unplanned withdrawal can be life-threatening, and unplanned withdrawal can require huge doses of benzodiazepines to manage the high levels of autonomic instability, delirium, and seizure risk. Planned withdrawal can be safely done on an outpatient basis by experienced clinical teams. The basic principles of treatment are an initial planning and assessment phase, with encouragement to stop any concurrent stimulant use (as it tends to lead to larger GHB usage). A tapered reduction in dose over the following week is sometimes supported by preloading with baclofen, which seems to reduce craving for GHB and subsequently reduce the need for high-dose benzodiazepines during the active detoxification phase. The aim is to lower total daily doses to below 25 mL/day before cessation. At cessation of GHB use, the acute withdrawal syndrome is managed by diazepam (typically in the region of 30–60 mg/day), given in 3–4 divided doses, tapering down over 7–10 days. Baclofen may be continued throughout the detoxification period and can be useful to continue for 2–3 weeks following detoxification completion, to aid sleep and manage residual craving and withdrawal.

Harm reduction strategies for GHB users

Given the small difference between a dose that induces euphoria and stimulation and a toxic dose, measuring doses with a syringe (1.0–1.5 mL would be a typical dose) or using pre-filled capsules

can reduce the risk of accidental overdose. Variations in preparation purity suggest test dosing from new batches is advisable. Avoiding mixing with alcohol, which increases the risk of overdose through synergistic respiratory depressant effects, is advisable, as is additional stimulant use, which is often associated with increased GHB consumption. Finally, avoiding use on more than 2–3 consecutive days can avoid the development of tolerance and of dependence and withdrawal in the first place.

Conclusions

MDMA, cocaine, methamphetamine, and GHB are all capable of producing acute adverse psychological experiences in normal users and exacerbating symptoms in those with underlying psychological disorders. They vary widely in their ability to induce dependence and in their long-term neuropsychiatric consequences. For the psychiatrist, the most common problems will be assisting in managing acute time-limited adverse psychological reactions, including withdrawal, and ensuring adequate follow-up assessment is provided. This is required to review the need for longer-term medication and to ensure that the differentiation between an underlying primary/precipitated disorder or a *de novo* condition that is time-limited and resolved with maintained abstinence is made. Because of the significant potential of the drug to cause physical harm, attention should also be paid to clinical examination, biochemical investigation, BBV screening, and liaison with medical specialists. The provision of harm reduction advice and strategies to support self-regulation, combined with the treatment of underlying conditions that may be driving continued use, will also form important aspects of clinical practice. In those who present with acute drug-related psychological symptoms, there should be an emphasis on follow-up since, in some cases, the symptoms will represent the onset of a persistent independent disorder which requires treatment. Users who have experienced acute psychological problems should be encouraged to make the attribution that there may be something inherent in them that makes them susceptible to experiencing unpleasant reactions with a drug; they are likely to remain vulnerable to those adverse experiences. This may be difficult to accept for potentially vulnerable young people who may prefer to think that the experience was not enjoyable because the drugs were not good—‘it was a bad pill’.

Psychedelics and dissociative substances

Adam R. Winstock and James Rucker

Psychedelics

The psychedelics are a distinct group of drugs, the primary effects of which are alterations in perception, mood, and thought processing in clear consciousness and usually with retained insight. They do not cause dependence, are physiologically non-toxic, and harms to the end user and society are notably low in comparison to other illicit drugs [1].

The term ‘psychedelic’ literally translates from the Greek as ‘mind-manifesting’, a term chosen by the psychiatrist Humphrey Osmond in 1957 to denote a curious and putatively therapeutic tendency to ‘unmask’ repressed elements of the psyche. The two most commonly used psychedelics in the UK are LSD (d-lysergic acid diethylamide), a semi-synthetic compound discovered in 1938 by Albert Hofman, and psilocybin (N,N-dimethyl-4-phosphoryloxytryptamine), which is found in, among others, the psilocybe group of ‘magic’ mushrooms that grow throughout the UK and worldwide. Less commonly encountered are mescaline (3,4,5-trimethoxyphenethylamine), found in the North American peyote cactus, and DMT (N,N-dimethyltryptamine), the principal component of the South American ceremonial sacrament ayahuasca. Other examples include the ‘2C’ group of psychedelics (for example, 2C-B, 2C-B-FLY, 2C-I, and 2C-E) and a wide range of recently developed synthetic psychedelics, including the NBOMes.

Classical psychedelics are divided into members of three chemical classes (Fig. 54.1): (1) tryptamines (for example, psilocybin); (2) ergolines (for example, LSD); and (3) phenethylamines (for example, mescaline and 2C-B). There are scores, if not hundreds, of compounds subsumed within these classes that have psychedelic effects. All classical psychedelics are active at the 2a subtype of the serotonin receptor (5-HT_{2a}), with effects being strongly dose-related. Users of psychedelics typically report changes under five distinct phenomenological categories:

1. Perceptual distortions, most commonly visual, including synaesthesia (crossing of sensory modalities, for example, hearing colours).
2. Changes in somatic experience—visceral, tactile, and interoceptive.
3. Changes in affect and mood, including, but not limited to, elation, euphoria, anxiety, and paranoia.

4. Distortions in thought processing, from changes in semantic attribution and belief structures to blurring and dissolution of conceptual boundaries (for example, between ‘self’ and ‘other’, also known as ‘ego dissolution’). Increasing confusion occurs at higher doses or in cognitively destabilizing environments.
5. Entheogenic experiences: spiritual, transcendent, often ineffable experiences.

History

Psychedelics have a long relationship with the human species, which contextualizes current and evolving attitudes towards them. Evidence for the use of psychedelics (particularly psilocybin and mescaline) dates back further than for any other psychoactive substance, particularly in ceremonial, healing, and spiritual rituals. Depictions of mushrooms and temples built to mushroom ‘deities’ and use of the word *teonanácatl*, or ‘flesh of God’, to denote psilocybin-containing mushrooms in indigenous cultures in Mexico and Guatemala date back to around 7000 BC. Records of the Greek ‘Eleusian Mysteries’ suggest that the ceremony surrounding them was based on a psychedelic compound. The modern history of psychedelic use began when Arthur Heffter, a German chemist, isolated mescaline from the peyote cactus in 1897. However, it was not until the development of LSD that the medical use of psychedelics began to be investigated in earnest.

LSD was first synthesized by the Swiss chemist Albert Hofman in 1938, as part of a systematic investigation of compounds related to the 5-HT₁ receptor agonist ergotamine [2]. Ergotamine, one of the ergot alkaloids, is produced by the parasitic rye fungus *Claviceps purpurea* and was responsible for the outbreaks of mass poisoning from consumption of spoilt stocks of rye in the Middle Ages, a condition known as *St. Anthony’s fire*. LSD was found to be unremarkable in animal testing; however, Hofman resynthesized it on a hunch in 1943. After accidentally contaminating himself with a small amount, he experienced what was probably the world’s first ‘acid trip’. Further investigation of LSD found it to be extremely potent (the threshold dose for subjective effects is approximately 50 µg), but notably physiologically safe, with animals surviving overdoses that were relatively much larger than other psychoactive drugs.

Reassured by its physiological safety and recognizing that it might be of much interest to psychiatrists, LSD was marketed under the tradename Delysid[®]. Between 1947 and 1967, LSD and, to a lesser

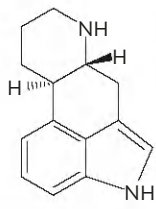

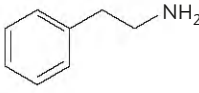

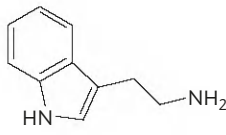

Classical psychedelic chemical classes			
Class	Ergolines	Phenethylamines	Tryptamines
Basic structure			
Common example	LSD (d-lysergic acid diethylamide)	Mescaline (3,4,5-trimethoxyphenethylamine)	Psilocybin (N,N-dimethyl-4-phosphoryloxytryptamine)

Fig. 54.1 Three chemically distinct classes of classical psychedelic compounds.

extent, mescaline and psilocybin were widely used as therapeutic agents, particularly as ‘catalysts’ in psychotherapy [3]. LSD also came to the attention of the American secret service where it was investigated as an agent of ‘mind control’ under the notorious *MK Ultra* programme, which was finally shut down in 1973 [4]. LSD was found to be ineffective for such purposes, instead rendering civilians and troops liable to disorganized behaviour and indifference to authority. The proselytization of LSD by the disgraced Harvard professor Timothy Leary led to its increasing recreational use, and it became a counter-cultural symbol against the status quo. Medical concern was raised for psychological toxicity in certain vulnerable groups [5].

Partly because of medical concern, and partly because of the counter-cultural opposition to the Vietnam War and conservative values in general, the Nixon administration of the time heavily criminalized psychedelics, along with many other psychoactive drugs. This dramatic escalation of the so-called ‘war on drugs’ stopped all medical use and scientific research, while pushing recreational use underground. A systematic media-led campaign of demonization in the 1960s and 1970s led psychedelics, particularly LSD, to be among the most heavily stigmatized of all psychoactive drugs, a stigma that is still present today.

Legal status in the UK

Almost all classical psychedelics fall under the remit of the UK Misuse of Drugs Act, 1971, where they are generally Schedule 1, Class A compounds. As such, they are legally defined as having the maximum potential for harm and dependence and no identified medical use, a definition that does not survive objective scientific scrutiny [1, 6]. Until the passing of the Psychoactive Substances Act, 2016, a number of chemical analogue compounds (for example, 2C-B-FLY and 1P-LSD) with similar effect profiles were legally available for purchase online and from so-called ‘head shops’. While head shops have now closed, the simple act of possession of these substances for personal use, unlike those classified under the 1971 Act, is not considered an offence under the 2016 Act.

Preparation, purity, and routes of use

Psilocybin occurs in a wide variety of mushrooms, including (but not limited to) the genus *Psilocybe*, which grow throughout the UK.

They are most prolific in wet periods during early autumn. Liberty cap mushrooms are the species most commonly encountered in the UK, with doses of 10–20 mushrooms being a typical starting dose. The greatest risk of harm comes from picking the wrong type of mushroom, as some are poisonous. Psilocybin-containing mushrooms can be eaten raw, cooked, or dried and are often infused in hot water or added to other foodstuffs. Psilocybin is heat-sensitive, and prolonged cooking or boiling results in its degradation. Possession of psilocybin-containing mushrooms is an offence under the Misuse of Drugs Act, 1971.

LSD can be chemically derived from the ergot alkaloids that occur in the parasitic grain fungus *Claviceps purpurea*. However, cultivation of the fungus is unusually difficult, and the sequelae of accidental ingestion potentially fatal. It is usually chemically synthesized from lysergic acid or 3-indolepropionic acid. LSD is extremely potent, with 1 g making 10,000 moderate (100 µg) oral doses. It is soluble in either water or alcohol and is colourless and tasteless; it is therefore difficult to detect without sophisticated testing apparatus and is easily concealed and transported. Drops of liquid LSD can be sold for immediate consumption from dropper bottles or, more commonly, drops are absorbed onto squares (‘tabs’) of blotting paper, gelatin, sugar cubes, or small volumes of a binding material to form what is known as a ‘microdot’. In recent years, novel potent psychedelics with a riskier effect profile have been sold as LSD tabs, such as 2-(4-iodo-2,5-dimethoxyphenyl)-N-[(2-methoxyphenyl)methyl]ethanamine (25I-NBOMe).

Mechanism of action and metabolism

Classical psychedelics are broad serotonergic agonists. However, the subjective effect appears to be derived from partial agonism at 5-HT_{2A} receptors that are predominantly expressed on pyramidal neurons within layer V of the human neocortex [7]. Thus, cross-tolerance occurs between different psychedelics, the degree of subjective potency is robustly associated with affinity at the 5-HT_{2A} receptor, and antagonists at the 5-HT_{2A} receptor (for example, risperidone) abolish the subjective effects of psychedelics. However, some 5-HT_{2A} agonists (for example, lisuride) fail to produce psychedelic effects, suggesting that 5-HT_{2A} agonism, while necessary, is not sufficient [8]. The psychedelic effect may also be dependent on the type 2 metabotropic glutamate receptor, as mice deficient in the corresponding gene are

unresponsive to psychedelics [9]. A summation of the current evidence suggests that psychedelics may act via a heteroreceptor complex of these two receptor types, modulating the balance of downstream second messenger systems and changing the phase of firing of layer V pyramidal neurons. Within cortical neural networks, there is widening of the measured local field potentials and human EEG recordings shows characteristic suppression of alpha waves; how this leads to the observed neuroimaging changes, subjective effects, and putative therapeutic effects is far from clear. While other subtypes of the 5-HT receptor are also stimulated by psychedelics, their contribution to the subjective effect is likely to be only minor.

Approximately 50% of ingested psilocybin is absorbed through the digestive tract. Psilocybin is biologically inactive but is rapidly dephosphorylated to the active molecule psilocin. Psilocin is hepatically metabolized by monoamine oxidase; however, some undergoes glucuronidation and is excreted renally. The elimination half life of psilocybin is 50 minutes and for psilocin is 1.25 - 2.5 hours, depending on whether psilocybin is administered intravenously or orally, respectively [10].

LSD is completely absorbed in the digestive tract, with a maximal plasma concentration achieved after about 90 minutes. LSD has a half-life of approximately 3.5 hours in both men and women and shows first-order kinetics. It is hepatically metabolized to a variety of different compounds, and only about 1% of the original drug is excreted in its original form in the urine. The principal metabolite is probably 2-oxo-3-hydroxy-LSD [11].

Recent brain scanning findings

Modern neuroimaging research suggests that psychedelics are neither stimulants nor depressants of brain activity. Instead, fMRI measures of 'functional connectivity' have suggested that brain network integrity is decreased under psychedelics and cross-talk between normally well-differentiated brain regions and networks is increased. There is some evidence that these effects correlate with the subjective effects of psychedelics; decreased default-mode network integrity and increased global connectivity have been found to correlate with ratings of ego dissolution under LSD, and increased communication between the primary visual cortex and the rest of the brain correlated with ratings of eyes-closed visual imagery [12].

Prevalence

Of the classical psychedelics, the lifetime prevalence of LSD and psilocybin ingestion is largely similar, while more users report past year usage of psilocybin than LSD. Use is more common among those in the dance music and rave scenes. The most recent British Crime Survey (2017/2018) suggested that, while lifetime use has remained static over the last 20 years at about 9% among 16- to 59-year olds, past year reported use of psychedelics by this group has fallen from 1.3% in 1996 to 0.7% in 2017/2018 (average 0.7%). The fall in use appears most marked in younger groups, with 6.6% of 16- to 24-year olds reporting lifetime use of psychedelics in 2017/2018, compared to 16.1% reporting lifetime usage in 1996. Past year use among younger age groups has also fallen from 5.3% in 1996 to 2.3% in 2017/2018. In the UK, psychedelic use is notably rare among Asian, Black, and Chinese ethnic groups. Psychedelic usage does not tend to cluster in particular social classes. The most common pattern of use is one of episodic experimentation fading into abstinence. Chronic use is very uncommon, but of those who have used

psychedelics for decades, it is usual that they claim no lasting harms and claim considerable benefits.

Harms

LSD, psilocybin, and mescaline

Despite politically led and media-driven rhetoric and the general lay perception that the classical psychedelics are dangerous, they are objectively one of the safest known classes of CNS drugs, and death due to direct toxicity of LSD, psilocybin, or mescaline is almost unknown in the literature despite well over 50 years of recreational use [7, 13]. This is likely attributable to their lack of activity on neurotransmitter systems that control basic physiological functions and their partial agonist property at serotonin receptors [14]. Overdose generally requires cardiac monitoring and supportive management in a comfortable, low-stimulus, reassuring environment. Benzodiazepines, such as lorazepam or diazepam, are the first-line treatment for symptomatic relief from emotional distress or behavioural disturbance. Significant behavioural disturbance after benzodiazepine treatment should raise the suspicion that other drugs have been taken.

Other psychedelics

The classical '2C' phenethylamine compounds

There are a large number of synthetically derived psychedelics. The classical '2C' phenethylamine compounds, such as 2C-B, 2C-I, and 2C-E, as well as various tryptamine-derived psychedelics, were synthesized and self-administered by the chemist Alexander Shulgin in the 1960s and 1970s. His experiences and the chemical synthesis were described in the books *TiHKAL* and *PiHKAL* and in many online reports of use. Of these, 2C-B is the most popular and is generally well tolerated. Treatment of overdose is as per the other classical psychedelics.

25I-NBOMe

A number of substituted 2C compounds have been developed since the turn of the century, and concern for physical toxicity exists for 25I-NBOMe (N-Bomb), which is the N-benzyl derivative of 2C-I. It is exceptionally potent, to the extent that it can be used as a substitute for LSD on blotter papers [15]. Unlike classical psychedelics, it is a full agonist at the 5-HT_{2A} receptor. It appears to promote both vascular constriction and platelet aggregation in overdose, placing the user at risk of acute cardiac, CNS, and limb ischaemia, as well as serotonin syndrome. Reports of deaths directly attributable to 25I-NBOMe have accumulated since its emergence as a recreationally used substance in around 2010, and it remains a concern at the time of writing. LSD is tasteless, and therefore users should be advised to be suspicious of LSD blotters tasting of anything other than the blotter paper itself.

Dimethyltryptamine

Dimethyltryptamine (DMT), the active component of ayahuasca, has recently become increasingly popular with the rise of smoked DMT and the commercialization of the ceremonial aspects of the drugs [16]. When smoked, it leads to a short-lived (less than 2 hours), but intense, psychedelic experience. Ayahuasca is an oral preparation usually derived from the *Banisteriopsis caapi* vine. DMT when taken orally needs to be consumed with harmine or another compound with monoamine oxidase-inhibiting (MAOI) activity.

Psychological effects and complications

The psychological effects of psychedelics are dependent on the psychological mind 'set' of the user and the environmental 'setting' of the experience. Experienced recreational drug users rank psilocybin and LSD as having low harm and high benefit potential in comparison to other drugs [17]. However, recreational use is not without its risks, particularly in psychologically sensitive individuals and in psychologically destabilizing environments. Those with a personal or family history of severe and enduring psychotic disorders should be particularly discouraged from experimentation with psychedelics.

In a recent web-based survey of difficult or negative experiences during psilocybin use, 62% of 1993 respondents rated the experience as being within the top ten most challenging experiences of their lives; yet 84% reported that they benefited in some way from this, and 76% reported increases in current well-being or life satisfaction. Thirty-four per cent and 31% reported the experience to be in the top five most personally meaningful and spiritually significant experiences in their lives, respectively. In contrast, 8% reported a decrease in well-being or life satisfaction as a result of the difficult experience, and three respondents reported that they had attempted suicide or suffered prolonged psychotic experiences [18]. This result is consistent with the observation that psychedelics unmask repressed (and hence somewhat unpredictable) elements of the psyche, but that the successful integration of such elements within conscious experience can be beneficial to the overall psychological well-being. This underlines the importance of set and setting and speaks to the possible therapeutic potential of psychedelics in medically controlled settings where both set and setting can be optimized and the risks minimized.

Hallucinogen persisting perceptual disorder

Hallucinogen persisting perceptual disorder (HPPD) was included in DSM-IV as an attempt to capture a syndrome whereby users of psychedelics report distressing residual effects long after the drug has cleared from the body. A summation of the evidence for HPPD in 2002 concluded that while the disorder probably existed, it was poorly defined, rare, and aetiologically opaque [19]. A variety of theories have been put forward, ranging from a direct neurotoxic effect of the drug to a negative psychological reaction to the effect of the drug. Direct neurotoxicity appears unlikely, particularly since experience with recreational use is extensive and massive overdoses of psychedelics have been survived without apparent clinical sequelae. An idiosyncratic premorbid biological sensitivity in some individuals cannot be ruled out, but it appears more likely that some users are psychologically sensitive to the effects of the psychedelic experience, perhaps becoming more 'aware' of the fluctuating functioning of various aspects of experiential processing. Consequently, the symptomatology reported within the scope of HPPD is widely variable and no particular medical treatment has become prominent. In most cases, HPPD appears to resolve over time with psychological support.

Other consequences of use

Dependence and withdrawal

There is no evidence that psychedelics cause physiological or psychological dependence. Indeed they may be a treatment for physical dependence, with the evidence most strong for alcoholism [20]. Complete tolerance to the classical psychedelics develops, usually within 72 hours, and full resensitization takes 1 week or longer. No

defined withdrawal syndrome has been identified, although tension headaches responsive to simple analgesia are common in the 24 hours after use.

Psychedelic-induced psychosis

Brief, self-limiting psychotic episodes can occur while intoxicated with psychedelics and are more common in naïve users, those with a past history of psychiatric illness, and users of longer-acting, more potent substances such as LSD. Such episodes, subsumed along with anxiety and panic reactions under the term 'bad trip', can be more likely if the drug is consumed in unfavourable environments or at a time when the person feels uncertain or unsafe.

Many people report negative or difficult-to-deal-with experiences when taking psychedelics. For many, working through the experience with the support of a caring, empathic other can itself be a useful and enriching experience. Medical management is supportive, with cessation of drug consumption, psychological support, and sedation with benzodiazepines, if necessary.

In the pre-prohibition era, psychedelic drugs were used on a wide variety of psychiatric patients and disorders. While some observed that they appeared to 'unmask' psychotic disorders in high-risk individuals, this was tempered by evidence from observational studies suggesting that the rate of psychedelic-induced schizophrenia was probably no higher than chance. Even so, the current clinical consensus is that psychedelic drugs should be avoided by those at high risk of developing psychotic disorders.

Use in therapy

Prior to prohibition in the late 1960s, thousands of patients, reported in many hundreds of academic papers, were treated with psychedelics (usually LSD) in Europe and the United States, with six international conferences on psychedelic-catalysed psychotherapy organized during this period [21]. Their use was much wider than is usually appreciated today [13]. This use swiftly declined after the 1967 United Nations declaration on drugs, which legally defined them, paradoxically, as having no medical use and placing stringent restrictions on their manufacture, supply, and prescription. While pre-prohibition studies of the therapeutic efficacy of psychedelics, in common with many clinical studies at the time, were of suboptimal standard, good-quality evidence for efficacy was found in alcoholism. A modern meta-analysis of six controlled trials found a substantial therapeutic effect of LSD over placebo in objective measures of alcohol use [20]. A recent systematic review of pre-prohibition evidence in unipolar mood disorders was also broadly encouraging [22]. Since 2006, small pilot studies have shown promising results in anxiety associated with advanced cancer [23], obsessive-compulsive disorder [24], tobacco [25] and alcohol [26] addiction, cluster headaches [27], and treatment-resistant unipolar depression (TRD) [28]. Two RCTs of psilocybin in existential distress associated with life threatening cancer were published in 2016 [29, 30]. RCTs with psilocybin for TRD are now under way [13].

Ketamine

Introduction

Ketamine is a dissociative anaesthetic that exerts its action primarily through non-competitive antagonism at the NMDA receptor. It is

almost unique as an anaesthetic in its ability to produce a 'dissociative' state, which results in higher brain structures being prevented from perceiving auditory, visual, or painful stimuli, leading to 'a lack of responsive awareness' [31]. Over the last 20 years, its use as a recreational drug has spread, and although there are concerns that longer-term use may be associated with serious physical (urinary tract) and psychological (cognitive impairment) harms, ketamine does benefit from having a wide margin of safety in overdose, with the greatest risk for most users being that of trauma or accidental harm while intoxicated.

Background and legal status

Ketamine is a versatile medication and is in widespread use in both general, paediatric, and emergency medicine (in anaesthesia and pain management). It is also a remarkably safe drug in clinical practice where the pronounced analgesia and amnesia occur without any significant depression of cardiac or respiratory function and maintenance of the gag reflex. The WHO has listed it as an essential medicine. Emergence phenomena (experienced as people recover from anaesthetic doses of the drug) encompass a range of unusual psychological experiences, including hallucinations, near-death and out-of-body experiences, delirium, and confusion; these have limited its use in wider clinical settings [32]. Ketamine has been part of the illicit drug scene in the UK since the 1990s. Currently, it is most commonly seen among those involved in the clubbing scene, especially trance music events. In June 2014, ketamine changed from a class C to a class B controlled drug in the UK.

Preparation, purity, and routes of use

Ketamine is typically sold as a crystalline powder for intranasal use (usual doses 50–250 mg), though it can also be found in liquid, tablet, or capsular form for ingestion. When obtained from diverted licit sources, the formulation of the drug is a solution prepared for intravenous use, which is then dried and taken intranasally. Ketamine may be adequately absorbed via the intranasal, intravenous, subcutaneous, intramuscular, rectal, and intrathecal routes, with snorting and injecting being the most common recreational routes of use.

Mechanism of action and metabolism

The most significant pharmacological action of ketamine is non-competitive antagonist binding at the cation channel of the NMDA receptor. Ketamine has a range of other actions; it is a weak μ receptor agonist, induces the release of dopamine, blocks muscarinic acetylcholine receptors, and may potentiate the effects of GABA synaptic inhibition. Ketamine undergoes marked first-pass metabolism with the production of its less potent metabolite norketamine. Orally ketamine results in a more sedative and less psychedelic experience. Most of the parent drug will be eliminated from the body within 24 hours.

Prevalence

Findings from the 2017/2018 Crime Survey of England and Wales suggest that the lifetime use of ketamine among 16- to 59-year olds (2.8%). Past year rates of use are on par with these more traditional hallucinogenic drugs, with 0.8% of those aged 16–59 years reporting use in the last 12 months. Rates are higher among younger users and those involved in the clubbing scene where last year rates of over 25% have been reported [33].

Patterns of use

Compared to commonly used stimulant drugs, the abuse liability of ketamine is low, but compared to LSD and psilocybin, ketamine is far more likely to be associated with compulsive patterns of use, the development of tolerance, and acute problems [34]. Ketamine may also lend itself to binge use due to its shorter duration of action, compared to LSD and psilocybin. Typically, users will consume less than 0.5 g/day, though because tolerance can develop quickly, chronic regular users may use in excess of 5 g/day. Ketamine is taken in combination with other club drugs, with polyuse typically increasing the risk of acute harm.

Psychological effects and complications

Effects are highly sensitive to age, dose, route, set, and setting. While low doses can be stimulating with elevation in mood, distortion of time and space, and enhanced sensory perception, feelings of 'melting into one's surroundings' are common. At higher doses, ketamine induces the full range of psychedelic effects with emotional, cognitive, and perceptual distortion, including out-of-body experiences and visual hallucinations [35] (Table 54.1). The Harvard academic Timothy Leary described it as 'the ultimate psychedelic journey'. Users describe entering the 'K hole' where they experience visits to god, aliens, their birth, past lives, and the 'experiences of evolution'. Some users report taking issues of set and setting into careful consideration prior to using ketamine. Such preparation cannot be performed if the drug is consumed unwittingly when it has been marketed under the guise of another drug such as ecstasy. Being an amnestic, it may become difficult to remember the total doses consumed.

The relationship between long-term ketamine use and elevated depression scores has been investigated among both current and ex-users. Although heavier users were more likely to score more highly, these were not at clinically significant levels and there was no relationship with changes in ketamine use [36].

Ketamine can also produce a psychotic picture that superficially mimics schizophrenia [37]. Both positive and negative symptoms of schizophrenia can be transiently seen in normal users, and its use can exacerbate symptoms in those with pre-existing psychotic disorders. Other adverse effects can include frightening hallucinations/out-of-body experiences, thought disorder, confusion, and dissociation. Such episodes tend to be short-lived, resolving in a few hours or at the most a few days. In many respects, these are like those adverse effects seen with LSD, though with ketamine, they come on after a shorter period following use and recede more quickly. (Table 54.1).

Acute complications and harms

Ketamine has a wide margin of safety within medical settings, and although relatively safe in overdose, in combination with ethanol or other CNS depressants, the use of ketamine can result in death. In recreational settings, the greatest risk of harm is from accidental injury, for example trauma, drowning and hypothermia secondary to immobility, and vulnerability to assault [38]. Rarely, more severe complications are reported, including severe agitation and rhabdomyolysis. Within accident and emergency departments, the most common presentations are impaired consciousness, abdominal pain (known as K cramps), lower urinary tract symptoms, and dizziness. Ketamine's cardiovascular risks are enhanced when it is taken

Table 54.1 Ketamine: psychological and physical effects

Psychological	Physical
Rapid onset, short duration of action (1 hour), wide safety margin	
Dissociative anaesthesia, 'somatosensory blockade' analgesia	Dilated pupils
Perceptual distortion/hallucinations/near death	Tachycardia
Out-of-body experience	Hypertension
Thought disorder/synaesthesia	Ataxia
Emergence phenomena	Paralysis
Cognitive impairment	Sweating
Amnesia	Hypersalivation
Derealization/depersonalization	Little effect on cough reflex

with stimulant drugs. Because of its fast urinary excretion (within 2 hours), the ability to identify ketamine in urine screens is almost impossible, and thus a level of clinical suspicion is required, especially if a history of its use is not forthcoming. Detection by clinical examination relies on identifying elevated blood pressure, moderate tachycardia, abdominal tenderness, and white powder rings on the nose [39].

Ketamine bladder

Heavy regular use of ketamine can result in progressive inflammation, ulceration, and scarring of the bladder. Known as ketamine-induced cystitis or ketamine bladder, ketamine, or one of its metabolites, is thought to induce apoptosis (cell death). Early detection and harm reduction should be part of any clinical consultation with ketamine users. Any clinical assessment of ketamine users must include enquiry as to the presence of symptoms suggestive of bladder damage, including frequency, dysuria, lower abdominal pain, and haematuria [33]. Early referral to urologists and addiction specialists for co-ordinated interventions is recommended. Complete cessation of use in cases of ketamine bladder must be encouraged, since in the worst cases, the bladder may be lost, which is an exceedingly unpleasant outcome.

Harm reduction

Like other harms, 'ketamine bladder' appears to be dose-related and is more likely to occur in heavy, dependent users. It may be more likely to be seen in those who drink alcohol when they use ketamine, and it is wise to remain well hydrated when using the drug. Purity between batches can vary, and given the marked dose–response effect of the drug, careful measurement of doses using milligram scales and test dosing new batches are advisable [40]. Intravenous use is to be avoided, being a risk for overdose and prolonged immobility, with associated vulnerability to environmental harms. Rapid referral to specialist services for those reporting bladder symptoms is advised.

Dependence and withdrawal

Animals models suggest that ketamine has the potential to cause dependence, with rats showing re-administration, conditioned place preference, and locomotor sensitization following repeated administration. However, in man, dependence on ketamine is rare, with

most of the literature coming from small case reports [41]. Regular users of ketamine report the rapid development of tolerance and compulsive patterns of use with loss of control and continued use despite harms. Evidence for a specific withdrawal syndrome is lacking, though upon cessation use, some dependent users report craving and sympathomimetic lability with shaking, sweaty, irritability, and insomnia [42]. Among those with pain associated with bladder damage, persistent use may be driven by a desire for analgesia. While cessation can be associated with mood and behavioural disturbances, a well-defined physical withdrawal syndrome is not seen. Symptomatic relief of agitation and insomnia, along with analgesia, if required, combined with good psychological support, remains the mainstay of managing withdrawal. There are no specific psychological therapies, but relapse prevention can be supported by the adaptation of CBT and MET, while addressing comorbid conditions and any other individual psychological needs.

Cognitive impairment

There has been considerable research into the neurocognitive consequences of ketamine. Among infrequent users, ketamine does not appear to be associated with any significant impairment. However, frequent, heavy use is associated with marked deficits in both short- and long-term memory [43], most notably deficits in visual recognition and spatial working memory. Cognitive impairments may not only interfere with a person's ability to perform in their normal working or social roles but can also interfere with their treatment.

Ketamine in treatment-resistant depression and alcohol dependence

Recent work has highlighted the potential of ketamine as a therapeutic agent in those with TRD, typically using intravenous infusions 2–3 times per week, usually over several weeks. Initial results have been promising [44] and suggest the drug is well tolerated and effective (see Chapter 72). An intranasal formulation of an isomer of ketamine (esketamine) has recently been licensed for the treatment of depression in the United States. Ketamine is also being explored as a treatment for those with dependence, in particular alcohol [42].

Tobacco addiction

Marcus Munafò and Meryem Grabski

Epidemiology

The tobacco epidemic

Tobacco use is the main preventable cause of premature death worldwide. Currently, about 5 million people die from smoking-related disease each year, and this number continues to grow. In most high-income countries, smoking rates have declined dramatically in the last 20 years, but they are increasing in many low- and middle-income countries [1]. The tobacco epidemic within high-income countries has been described in four stages [2] (Fig. 55.1). The first is marked by the widespread uptake of smoking in a population, especially by men, and almost no smoking-related deaths. In the second, uptake from men continues to increase and women start taking up smoking too, while smoking-related deaths begin to occur. In the third, smoking rates in men start declining, as do rates in women towards the end of this phase, and smoking-related deaths rise to about 25–30% of all deaths in men. In the fourth, smoking-related deaths in men peak early in this period, and a couple of decades later the same happens in women. Smoking rates keep declining in a similar fashion in men and women, although the rate of the decline begins to slow down. This model was developed based on observations in high-income countries, but it has been suggested that it is still largely applicable to low- and middle-income countries, although it may not be as applicable to women; the gender gap seems to remain large in many of these countries.

Smoking prevalence

The UK, along with most high-income countries, is in the fourth stage of the tobacco epidemic. Smoking rates in the UK have declined considerably—from the early 1970s when 45% of all adults were smokers to below 20% today. In particular, the UK has seen a marked narrowing of the gap between the prevalence of male and female smoking. The prevalence of smoking is highest in young adults (25- to 34-year olds), and lowest in adults over 60 years (although this is, in part, due to differential mortality between smokers and non-smokers as they age). The uptake of smoking usually occurs in mid adolescence, with two-thirds of smokers starting before the age of 18. Whereas smoking is nearly absent in 11-year olds, regular smoking (that is, at least once per week) begins to be seen among 15-years olds. Smoking prevalence is strongly patterned by

socio-economic position, with the highest proportion of smokers being from less affluent socio-economic backgrounds. Smoking is therefore a strong driver of health inequalities between the rich and the poor today [3]. Smoking rates in the UK are comparable to most other high-income countries, but there are examples of high-income countries where smoking rates are higher (for example, Russia and Greece). Many low- and middle-income countries are at the second stage of the tobacco epidemic model and have some of the highest smoking rates in males today (for example, Indonesia, China, and Jordan), whereas smoking rates in females are much lower in these countries [1].

Tobacco constituents

Tobacco is made from the cured leaves of the tobacco plant. It is predominantly consumed in the form of manufactured cigarettes (making up the vast majority of worldwide sales), but it can also be chewed, inhaled, or smoked in other forms (for example, pipes or cigars). Burning tobacco produces further chemicals as a result of the combustion process; over 7000 different chemicals and compounds have been identified in tobacco smoke from cigarettes. Many are toxic, and over 70 are carcinogenic [4]. The primary psychoactive addictive substance in tobacco is nicotine, a nicotinic acetylcholine receptor (nAChR) agonist. There is some evidence that other components of tobacco, or their metabolites, such as acetaldehyde, nor nicotine, myosmine, cotinine, anabasine, and anatabine, have synergistic effects with nicotine or have reinforcing effects on their own. The investigation of the effects of these substances presents several methodological challenges such as disentangling the direct effect of the substances from the effects of nicotine and their interactions with nicotine and one another. Moreover, these substances usually occur in tobacco smoke in very low doses and are therefore difficult to model experimentally.

Morbidity and mortality related to tobacco smoking

Diseases caused by tobacco smoking include various cancers, cardiovascular disease, and pulmonary disease, and it also has marked effects on prenatal development. Smoking is believed to be responsible for the majority of lung cancers and has also been linked to cancer of the mouth, bladder, kidney, cervix, stomach, and other organs. Smoking is responsible for much ischaemic heart disease and is a risk factor for heart attack and stroke. Two types of lung

disease—chronic bronchitis and emphysema—are also caused mainly by smoking. Inhalation of tobacco smoke damages the airway and lung tissue, which also leaves the lungs more vulnerable to environmental pollutants and infections. Smoking during pregnancy doubles the risk of pre-term delivery and stillbirth, and is linked to low birthweight, increased birth defects, and birth complications, as well as negative long-term health outcomes of the infant such as asthma, breathing problems, and learning difficulties. It is still unclear whether tobacco exposure in the prenatal environment is a direct cause of these long-term outcomes. For example, exposure to smoking during pregnancy increases the risk of the offspring becoming a smoker, but genetic predisposition or the postnatal environment, such as sharing a household with smoking parents, could be responsible for these associations. Conclusive evidence on whether the effect of prenatal tobacco exposure on offspring smoking outcomes is causal or associative, or a mixture of both, requires genetically informed investigation.

Neurobiology and pharmacokinetics

Routes of administration

Tobacco can be consumed in different ways, and the route of administration affects its addictiveness, as well as its health risk profile. Most tobacco is smoked in the form of cigarettes, but it can also be smoked in the form of water pipes, traditional pipes, and cigars, or consumed as smokeless tobacco by chewing or inhaling it through the nose or mouth. Cigarettes are manufactured from flue-cured tobacco; this lowers the pH of the saliva in the mouth, and therefore, nicotine cannot be absorbed through the oral mucosa, in contrast to tobacco used in pipes and cigars or chewing tobacco. It necessitates

the inhalation of cigarette smoke into the lungs, in order to absorb nicotine at these pH levels. Nicotine levels then rise sharply in blood returning to the heart and quickly reach the brain. The delivery of nicotine via cigarette smoking has the most immediate, strong, and addictive effect of all tobacco delivery systems. It is also related to the most negative health outcomes, due to the production of carcinogens through the burning of tobacco and the release of carbon monoxide, as well as the wide distribution of these substances into the body via the lungs. Other forms of administration of nicotine, via the oral mucosa or nasal cavities (in the case of dry snuff), do not result in such sharp increases in nicotine blood levels (Fig. 55.2). However, forms of tobacco use other than cigarette smoking also carry health risks. Pipe and cigar smoking and smokeless tobacco are related to oral and pancreatic cancers, as well as lung and heart disease.

Nicotine-containing products can be considered to lie on a continuum of harm to the user where combustible cigarettes are the most harmful and pharmaceutical nicotine replacement products the least harmful. Other products such as smokeless tobacco products and unregulated nicotine products such as nicotine lollipops occupy intermediate positions. Although the subject of some controversy, e-cigarettes are generally considered to be much less harmful than cigarettes, and closer in levels of harm to nicotine replacement products [5].

Tobacco in the brain

Nicotine binds to nAChRs, which are expressed throughout the brain. They are ligand-gated ion channels consisting of α and β subunits, which have differential profiles in their response to nicotine. Their stimulation indirectly releases a variety of neurotransmitters [6]. The primary reinforcing effect of nicotine is ascribed to the activation of nAChRs in the mesolimbic pathway, specifically those

Fig. 55.2 Venous blood concentrations of nicotine over time for various nicotine delivery systems.

projecting from the ventral tegmental area (VTA) into the nucleus accumbens (NAcc) where they release dopamine (DA). nAChR subtypes thought to be involved in this process include $\alpha 4$, $\alpha 6$, and $\beta 2$. The release of DA into the NAcc plays an important role in the processing of natural rewards and reinforcers, such as food and sex, and is a locus for the action of drugs of abuse like cocaine. Several studies using animal models have shown that nAChRs located within the VTA are involved in reinforcement behaviour to nicotine. Increases in DA after nicotine exposure have also been shown in brain imaging studies using human participants, although results are equivocal regarding the magnitude of the DA release [7]. Nicotine also promotes the release of serotonin linked to mood regulation and appetite, noradrenaline linked to arousal and appetite, and vasopressin linked to memory enhancement [8]. Other constituents of tobacco smoke also appear to play an important role in tobacco addiction. Much research has been conducted on the chronic effect of cigarette smoking on the inhibition of monoamine oxidase (MAO) A and B, which seems to enhance the direct effect of nicotine by leading to an increase of DA, noradrenaline, and serotonin in the brain [9, 10].

Tobacco reward and reinforcement

Many smokers report that smoking is pleasurable and reduces negative affect and stress, although there is conflicting evidence against such effects [11, 12]. Once tobacco dependence is established, the discontinuation of smoking causes withdrawal symptoms. Smoking is therefore associated with both positive reinforcement (that is, obtaining pleasurable consequences) and negative reinforcement (that is, avoiding aversive consequences). The primary reinforcing

constituent of tobacco is nicotine; animals will preferentially self-administer nicotine intravenously relative to placebo [13], as will humans [14, 15]. However, other factors contribute to the reinforcing effects of tobacco use. In classic nicotine self-administration studies in animals, the delivery of nicotine is often paired with a neutral stimulus such as light or noise. These studies show that after repeated pairing, this neutral stimulus becomes as important as nicotine in the maintenance, extinction, and reacquisition of self-administration of nicotine. Similarly, in humans, smokers tend to associate specific cues, such as certain moods, situations, and environmental factors, with the positive effect of smoking (see Environmental drivers of relapse, p. 549). Through conditioning, these smoking-related cues acquire motivational properties and therefore increase craving for nicotine and trigger relapse. In cue reactivity studies, nicotine-dependent individuals exhibit increases in affect, heart rate, skin conductivity, and subjective craving, following the presentation of smoking-related stimuli [16]. Other substances present in tobacco smoke may also contribute to its reinforcing actions. Much research has focused on monoamine oxidase A inhibitors, present in tobacco and tobacco smoke, which may enhance the rewarding effect of nicotine [9, 10]. Acetaldehydes, present in tobacco, also have reinforcing properties and may enhance the reinforcing properties of nicotine [17].

Genetics of nicotine addiction

Like other addictive habits, smoking behaviours are under a substantial degree of genetic influence (see Chapter 49). Twin studies suggest most smoking-related traits, such as smoking initiation [18], the development of tobacco dependence [19], and cessation [20], are genetically influenced. However, the identification of specific genetic variants that influence smoking behaviour has been challenging. Candidate gene studies have met with limited success, despite genes encoding nicotine receptor subtypes, DA receptors, and GABA receptors being plausible candidates [21]. Genome-wide association studies have identified several promising genetic variants associated with smoking behaviour, most prominently the *CHRNA5-CHRNA3-CHRNA4* gene cluster on chromosome 15 [22, 23]. These genetic variants influence consumption and titration (adjustment of nicotine intake according to the strength of the cigarette). Thus, $\alpha 5$ knockout mice (a model for humans who carry the rs16969968 risk allele) with delivery of self-administered nicotine were less able than normal mice to titrate the delivery of nicotine to a consistent, desired level [24]. Similarly, humans carrying the rs16969968 risk allele show a reduced aversive response to high doses of nicotine [25]. Therefore, deficient $\alpha 5$ signalling may attenuate the negative effects of nicotine, leading to heavier use. Nevertheless, the proportion of variance explained by such variants is much lower than the estimates of heritability indicated by twin studies. Larger sample sizes and refinement of the methodology of genotyping may enable the identification of proper pathways in the future.

Dependence and withdrawal

Tobacco withdrawal syndrome

After several hours of smoking abstinence, dependent smokers will experience tobacco withdrawal. The primary tobacco withdrawal symptoms reported by the fifth edition of *Diagnostic and Statistical*

Manual of Mental Disorders (DSM-5) are irritability/anger/frustration, anxiety, depressed mood, difficulty concentrating, increased appetite, insomnia, and restlessness [26]. Other symptoms can include constipation, dizziness, nausea, and disrupted cognitive function such as impairment of working memory [27]. Tobacco craving is also usually observed after smoking abstinence. As with most drugs of abuse, withdrawal symptoms are one of the main drivers for relapse and reinstatement of smoking behaviour following abstinence. They can persist for several months after smoking cessation, but the time course of withdrawal symptoms varies considerably between individuals. Increases in craving and negative affect are the most common symptoms after smoking cessation, and the intensity of these symptoms is predictive of relapse. Furthermore, smokers who experience more *variable* symptoms have been found to be more likely to relapse.

Environmental drivers of relapse

Environmental stimuli associated with smoking can promote smoking behaviour in several ways. Firstly, a stimulus that has repeatedly been paired with smoking (for example, the look, feel, and taste of a cigarette, a lighter, an ashtray, the effects of alcohol or coffee, etc.) can elicit a conditioned response and tobacco craving. The effect of smoking-related stimuli has been investigated experimentally with cue-exposure paradigms. Here smoking stimuli, or photographs or videos of these, are presented to the participant. Differences in outcomes, while the participant is subjected to a smoking stimulus (as compared to a neutral stimulus), can indicate which domains are influenced by smoking cues. The most reliable responses to smoking cues are increases in craving levels and heart rate [16]. Secondly, environmental stimuli related to smoking can become primary reinforcers in their own right. In animals, a formerly extinguished nicotine self-administration behaviour can be reinstated when the animal is presented with a nicotine-related cue (in this case, a neutral light or sound that was paired with nicotine administration) [28]. In humans, denicotinized cigarettes lead to a greater reduction in the consumption of nicotine-containing cigarettes than nicotine gum [29], supporting the conclusion that nicotine withdrawal is driven not only by the absence of nicotine, but also by the absence of smoking-related stimuli.

These findings have important implications for the development of smoking cessation treatments—dissociating smoking cues from the reinforcing effect of nicotine might extinguish the learnt connection between nicotine administration and the smoking cue, reducing the risk of relapse. One approach is to substitute regular cigarettes with denicotinized cigarettes; once smoking does not provide any more nicotine reinforcement, the sensorimotor cues of smoking should lose their hedonic value. The reduction of withdrawal symptoms has been found to be even more pronounced when the administration of denicotinized cigarettes is combined with nicotine replacement therapy (NRT). Similarly, varenicline, a nicotinic partial agonist, exerts its effect partly by blocking receptors that facilitate the rewarding experience of smoking. It is prescribed to be taken by smokers for a short period *before* a quit attempt, which may help to extinguish these associations. The number of cigarettes smoked per day decreases during the pre-cessation period, and cessation rates are higher than for other smoking cessation pharmacotherapies [30]. Smoking cues seem to vary in their impact on different groups of smokers; for example, females respond more strongly to smoking cues than males.

Psychological drivers of relapse

Psychological factors, such as stress and negative affect, are often cited by smokers as reasons for smoking and for relapse during a cessation attempt. Smokers often attribute the stress- and anxiety-reducing properties of cigarettes as one of the main drivers for smoking and often attribute relapse to acute stress and negative affect. An alternative explanation is that this perceived relief of stress and negative affect through smoking is actually a misattribution of withdrawal relief [31]. In recent years, ecological momentary assessment (EMA) studies have advanced our understanding of the role of negative affect and stress on acute smoking behaviour. Participants are provided with a device (for example, a smartphone-app) that allows them to provide information about craving, mood, or stress levels in real time in their everyday environment. These studies have not found a systematic relationship between negative states and acute ‘regular’ smoking behaviour. In smokers attempting to quit, on the other hand, acute negative affect, as well as stress, has been found to play an important role in smoking lapses [32]. Rapid increases in negative affect precede lapse episodes, and lapses that are triggered by stress progress more quickly to another lapse. However, studies investigating stress levels and negative affect among successful quitters have found that, even though stress initially increases after quitting, in the long run, stress levels decrease even below pre-cessation levels [33]. This could mean that smoking, in fact, *increases* stress-levels, which are then reduced back to normal after quitting, although a recent Mendelian randomization meta-analysis did not find any evidence that smoking heaviness causally influenced anxiety or depression [33]. The results may be driven by other factors, for example the adaptation of a healthier lifestyle in successful quitters. The presence of clinically significant negative affect has also been related to poor cessation success [34], and several studies found that a history of depression increases the risk for relapse [35]. Smokers diagnosed with multiple episodes of depression (rather than one) may be at higher risk for relapse [36]. The causal relationship between smoking and depression (and other mental health issues) remains unclear (see Smoking in psychiatric populations, pp.550–1).

Cognition and relapse

Many smokers report perceived cognitive benefits from smoking, and cognitive impairment during abstinence. However, it is unclear whether smoking results in genuine cognitive benefits, rather than simply relieving withdrawal symptoms that include impaired cognition. Laboratory research on tobacco addiction and cognition has focused on two issues: (1) the potentially positive effect of tobacco smoking (and specifically nicotine) on cognitive performance; and (2) the negative effect of tobacco withdrawal on cognitive performance. A meta-analysis on the effect of cigarette smoking and/or nicotine administration in non-smokers and non-deprived smokers on cognitive performance found an improvement on fine motor abilities and certain measures of attention and working memory [37]. Much of the interest in the cognition-enhancing effect of nicotine has been fuelled by its potential as a treatment for cognitive dysfunction; early research suggested benefits from nAChR agonist treatment for Alzheimer’s disease, schizophrenia, and attention-deficit/hyperactivity disorder (ADHD) but have not translated into clinical practice. The effect of withdrawal on cognitive performance is

usually investigated using an acute abstinence paradigm, in which cognitive task performance is compared between smokers who are subjected to a period of acute abstinence (of 8 hours or more) and smokers who smoke as per usual. A recent meta-analysis of these tasks found that abstinent smokers showed higher delay discounting of monetary rewards, lower response inhibition, and impaired arithmetic and recognition memory performance, compared with non-abstinent smokers [38]. Cognitive performance tasks that are sensitive to withdrawal in smokers might be useful in assessing the efficacy of novel treatments to ameliorate withdrawal symptoms. The advantage of objective cognitive performance task outcomes, such as reaction times or error rates, over self-report is that they are less biased. Nevertheless, the results of cognitive performance task studies, both investigating cognitive-enhancing effects of nicotine, as well as the effect of nicotine abstinence on task performance, should be interpreted with caution. The tasks used to assess cognitive performance are usually quite heterogeneous, even if indicated for the same cognitive domain. This is even true for the same tasks, as standardized guidelines on presentation times, stimuli, selection of participants, etc., are currently lacking.

Smoking in psychiatric populations

Schizophrenia

Even though smoking rates in the general population are declining, they remain high in people with mental illness. In particular, among people with schizophrenia, the prevalence of smoking is substantially higher than in the general population [39]. Smokers with schizophrenia are also more dependent, smoke more heavily, and have greater difficulties quitting than smokers from the general population [40, 41]. There are several hypotheses for why smoking is so common in patients with schizophrenia. The self-medication hypothesis suggests that smoking might ameliorate some of the negative symptoms of schizophrenia [42] and cognitive deficits common in schizophrenia such as reduced visuo-spatial working memory. Smoking could also counteract the effects of dopamine antagonist medications; for example, smoking rates increase after smokers with schizophrenia begin treatment with haloperidol. However, there is also emerging evidence that smoking could be an aetiological risk factor for schizophrenia [43]. Smoking usually predates the onset of psychotic symptoms, and cohort studies have found that there is a dose-response relationship between smoking and the onset of schizophrenia, so that people who smoke more heavily have a higher risk of developing schizophrenia [44, 45]. A recent genome-wide association study identified a variant in the nAChR gene cluster CHRNA5-A3-B4 (associated with smoking intensity) to be also associated with schizophrenia [46]. This association could be interpreted in two ways—smoking and schizophrenia might be influenced by this genetic variant independently, or this genetic variant may reflect a causal link between smoking and schizophrenia.

Depression and anxiety

Depression and anxiety are both associated with higher levels of smoking, and smokers are also more likely to receive a diagnosis of clinical depression or anxiety. Smoking rates among adults diagnosed with major depressive disorder (MDD) are higher than in the general population, while greater nicotine dependence is associated

with higher rates of a diagnosis of MDD [47]. Furthermore, attempts to quit smoking are more likely to fail in smokers with MDD than without [36]. In anxiety disorders, comorbidity estimates vary strongly with regard to the specific disorder investigated, the sample under investigation, and the definition of smoking behaviour. One study found a high prevalence of smoking in people with social phobia and panic disorders, whereas it was markedly lower than in the general population among people with obsessive-compulsive disorder [48]. Several hypotheses have been proposed regarding the nature of the relationship between smoking and depression/anxiety. The self-medication hypothesis suggests that depressed or anxious people smoke in order to manage their symptoms, so that symptoms lead to smoking, including smoking initiation and subsequent heaviness of use [49]. However, the misattribution hypothesis suggests that the relief of stress and negative affect attributed to smoking is actually due to relief of withdrawal symptoms, rather than the relief of the underlying emotional psychopathology [31].

Smoking could be a risk factor for the onset of depression, for example by influencing a person's response to environmental stressors via its effect on the pituitary system, as has been suggested in animal models. Evidence against this hypothesis was cited previously [33]. It is also possible that a bi-directional relationship between smoking and anxiety or depression may exist, whereby smoking initiation might be motivated by the desire to manage symptoms, but chronic smoking might negatively influence outcomes. This is supported by two meta-analyses, one of which found that mental health symptoms generally improve after smoking cessation [50], and one that concluded that compelling evidence for either hypothesis is currently lacking [51]. Finally, shared genetic influences on both smoking levels and anxiety and depression could also be responsible for the high comorbidity of smoking and depression [52].

Other mental health problems

Higher rates of smoking than in the general population have been recorded in people with several other mental health problems such as ADHD, conduct disorder, bipolar disorder (BP), and eating disorders [53]. In ADHD, the self-medication hypothesis has been suggested as a potential reason for smoking uptake. As dopaminergic function is altered in ADHD, this might be related to higher initial rewarding effects of nicotine, which could lead to higher rates of smoking uptake. Nicotine has also been shown to improve some of the typical deficits in executive function seen in ADHD [54]. Epidemiological research has focused on the consistent association between maternal smoking during pregnancy and ADHD, as well as conduct disorder (which shows comorbidity with ADHD). Whether smoking during pregnancy is a risk factor for later development of these disorders in offspring or whether a common environment or common genetic variants drive this relationship is unclear [55]. A high rate of maternal smoking in people diagnosed with ADHD and conduct disorder could explain the high rates of smoking in later life in these populations. High rates of smoking have been found in people diagnosed with BP. It has been proposed that the mechanisms are similar to those underlying depression, such as mood dysregulation and heavy dependence, which lead to difficulties in quitting, but comparatively little research has been done in BP patients yet [56]. The relationship between smoking and eating disorders has typically been investigated in the context of smoking as an appetite and weight control method. Smoking rates are higher

in people with eating disorders [57] and concerns about weight gain following cessation are cited by many smokers as a major reason for continued smoking.

Smoking in mental health service settings

As smoking is the greatest single contributor to the 10 to 20 year reduced life expectancy among people with severe mental illness, special attention should be given to smoking cessation in patients in mental health settings [58]. In the UK, mental health units have been required by law to ban smoking in all enclosed spaces since July 2008. A survey in 2014 in medium- and low-secure mental health facilities showed that 83% prohibited smoking within buildings but allowed it within gardens and outside of the secure perimeter such as hospital grounds. A complete ban on smoking in all hospital buildings and grounds has been recommended but is currently enforced by only 9% of facilities [59]. However, implementing smoking bans in mental health service settings brings specific challenges. There is often a long-standing culture of smoking among both patients and staff; cigarettes may be used as rewards for patients for meeting therapeutic goals, and smoking together may help staff and patients to create therapeutic relationships. Other potential barriers to the introduction of smoking bans may include increased aggression and stress in patients, weight gain in patients, unpredictable interactions of smoking cessation with psychotic medication, security issues (for example, due to patients smoking in their bedroom), and increased costs for implementation of smoking-free facilities. Several of these concerns have been reviewed in recent years and could either be alleviated or are unfounded. For example, disruptive behaviour and verbal aggression decrease after the implementation of smoking bans in many cases, while stress and anxiety levels have been found to decrease after smoking cessation in many studies and may only be a concern in the short term (see Dependence and withdrawal, pp. 548–9). Smoking cessation often leads to improved efficacy of psychotropic medication, as smoking increases the metabolism of many drugs [60]. The dose should be carefully monitored during a smoking cessation attempt, but a reduction of antipsychotic medication is typically seen as a positive outcome, as it may lead to a reduction of negative side effects.

Interventions: treatment and prevention

Pharmacological treatments

Several pharmacological treatments to support smoking cessation are available today. The most widely used are NRT, varenicline, and bupropion, which are available as first-line treatments in many countries, including the UK. In the UK, NRT is available over the counter and in several formulations. The most commonly used method is the transdermal patch, which is available in several doses and strengths and allows nicotine to be absorbed slowly through the skin. Other forms of NRT include chewing gum, lozenges, sublingual tablets, sprays, and inhalers. With these, nicotine is absorbed via the nasal or oral mucosa; the rate of nicotine absorption is more rapid than with transdermal patches, but not as rapid as when smoking a cigarette. The aim of NRT is to provide nicotine during smoking cessation attempts in order to ameliorate physiological and psychological withdrawal symptoms and the motivation to smoke. The combination of different methods of NRT, such as patch and nasal spray

or patch and gum, may be more effective than using any of these methods alone [61]. Varenicline is a selective nicotinic receptor partial agonist, licensed as a prescription-only treatment. It binds to the $\alpha 4\beta 2$ -nAChR, which is responsible for mediating the reinforcing properties of nicotine. This alleviates craving and withdrawal during smoking cessation. During nicotine exposure, the receptor occupancy of varenicline blocks reinforcing effects of smoking [62]. Since varenicline is prescribed to be taken for 2 weeks prior to a quit attempt, during which the smoker continues to smoke as usual, this may lead to extinction of the conditioned cues associated with smoking and may contribute, in part, to its superior efficacy relative to NRT. Bupropion was originally developed as a drug for depression and is now licensed in sustained-release formulation for use in smoking cessation. Its antidepressant properties may make bupropion helpful for smoking cessation if nicotine withdrawal produces depressive symptoms. Nicotine itself may also have antidepressant properties, which are substituted for by bupropion [63]. The efficacy of varenicline for smoking cessation is somewhat greater than that of NRT or bupropion, while NRT and bupropion have similar efficacy [61]. However, the absolute quit rates achieved remain low—only about 20% of smokers using any of these methods are able to quit successfully and remain abstinent [64]. There are many reasons for this such as the importance of smoking cues and the sensorimotor stimulation in maintaining smoking behaviour (see Environmental drivers of relapse, p. 549), which are both lacking in pharmacological treatment.

E-cigarettes

Electronic cigarettes, or 'e-cigarettes', are handheld electronic devices that heat a liquid ('e-liquid') to create an aerosol, which the user inhales ('vaping'). The e-liquid usually comprises propylene glycol and flavourings, with or without nicotine; there is wide variation in the exact composition of the fluid and in the different models of e-cigarettes available. The common features include a cartridge, which holds the e-liquid, a heating device, and a power source. Some e-cigarettes are manufactured for one time-use only, while others are refillable.

Currently, there are considerable differences between countries in the regulation of the sale of e-cigarettes; their sale is completely banned in some countries. In Europe, new regulations concerning e-cigarettes have been introduced into the European Tobacco Products Directive (TPD). These new regulations came into force in May 2016, and all products now have to be fully compliant with the TPD since May 2017. The major changes in the regulation of e-cigarette products were as follows: (1) new products and changes to existing products must be notified to the Medicines and Healthcare products Regulatory Agency (MHRA); (2) information on the content and safety of the products must be provided to the MHRA; (3) products will have to be child-safe, so that they do not leak or break easily; (4) newspapers, radio, and TV advertisement for e-cigarette products are now banned (but not billboard and poster advertisement); and (5) e-liquids containing more than 20 mg of nicotine per millilitre need a medical licence authorized by the MHRA.

Since their widespread introduction in 2006, the use of e-cigarettes has grown rapidly and many smokers report successfully using e-cigarettes as an alternative form of nicotine delivery. There are some reasons to believe that they will be superior to other smoking

cessation methods, as they give the smoker a sensory and behavioural experience, with rapid delivery of nicotine to the brain, which resembles that achieved from a conventional cigarette. Experienced users of second- and third-generation e-cigarettes have been found to achieve nicotine levels very similar to those achieved through regular cigarette use. A recent Cochrane review concluded that e-cigarettes containing nicotine are effective for smoking cessation [65], and a recent randomized controlled trial found that e-cigarettes were more effective for smoking cessation than nicotine-replacement therapy, when both products were accompanied by behavioural support [65a].

At the same time, there has been controversy surrounding e-cigarettes. One concern has been the potential uptake of e-cigarettes by non-smokers, particularly children, and their potential as a gateway to smoking conventional cigarettes. Current evidence suggests that while children and young people are experimenting with e-cigarettes, this is rare in never-smokers. Thus, there is little evidence that vaping will readily progress to smoking. The long-term health consequences of using e-cigarettes are also unknown, so definitive statements about the toxicity of e-cigarettes are currently impossible. The range of products and liquids available and the length of time most tobacco-related diseases take to become apparent are problematic. However, the models of e-cigarettes tested to date have been found to provide the users with substantially lower levels of potentially harmful chemicals than conventional cigarettes [5, 66]. A recent report of the Royal College of Physicians concluded that the using risk of e-cigarettes 'is unlikely to exceed 5% of the harm from smoking tobacco' [67]. The risk of second-hand exposure is likely to be correspondingly low as well.

Behavioural treatments

Behavioural treatments also play a role in smoking cessation; the combination of pharmacological and behavioural treatments is more effective than any one treatment method alone [68, 69]. There is evidence for the efficacy of low-level interventions such as providing smokers with print-based self-help materials about cessation [70] and telephone support [71]. However, more intensive counselling and behavioural therapies are generally superior to these low-level interventions [72–74]. Motivational interviewing (MI) is a client-centred counselling style, with the aim of eliciting behaviour change by exploring and resolving ambivalence. The MI approach was originally developed for use in substance abuse and has since been applied specifically to smoking cessation. A recent review on the current evidence found that MI is superior to brief advice and usual care when provided by a general practitioner. Interestingly, shorter sessions were found to be more effective than longer ones [75]. Other methods, such as mindfulness training and meditation, have claimed positive results, but the evidence is currently preliminary. A positive effect of exercise interventions on smoking cessation has also been reported in several studies, but more substantial evidence of positive long-term effects is still needed [76]. Determining the ideal intervention in terms of content and intensity for each smoking population is challenging due to the difficulty of identifying the specific aspects that make an intervention effective and the specific needs of different smoking populations.

Prevention and policy

Tobacco control policies have contributed to the fall in smoking prevalence since the post-war period in many high-income

countries. Within Europe, the strength of tobacco control policies varies across countries and is considered strongest in the UK. Specific policies that have been found to be effective in decreasing smoking rates include taxation, bans on smoking in public places, bans on the advertising of tobacco products, health warnings on tobacco products, and plain (or standardized) packaging. The retail price of tobacco products can be increased by governments by raising taxes on them. The amount to which consumers will continue or cease to buy a product depending on its price is referred to as 'price elasticity'. Compared to many other consumer products, the demand for tobacco products is only moderately elastic. A meta-analysis estimated the average price elasticity of demand for tobacco products at about -0.48 , which is consistent with other findings [77, 78]. This means that a 10% increase in price will be followed by a decrease in consumption of about 4.8%. Nevertheless, as increases in tobacco taxes result in higher prices of tobacco for a whole population, even small reductions have a big impact. Increasing tobacco taxes has, in fact, been found to be the most effective way to decrease consumption in a population [79, 80]. Currently, 77% of the price of a packet of cigarettes account for taxes in the UK, and taxes have increased by 30% over the last 10 years.

Banning smoking in public enclosed places has several obvious benefits. Apart from the fact that non-smokers are not subjected to second-hand smoke, it also decreases opportunities for smokers to smoke, thus supporting smoking cessation. It also makes smoking less socially acceptable, which, in turn, reduces smoking and exposure to tobacco smoke. The banning of advertisement of tobacco products is another important step in order to decrease smoking rates, specifically in teenagers and young people. In order to be effective, an advertisement ban has to be comprehensive and include all types of media and outdoor advertisement. In the UK, all forms of tobacco advertising and promotion are banned since the Tobacco Advertising and Promotion Act 2002. This now includes the display of tobacco products at the point of sale since 2015 and the implementation of standardized plain packaging for all tobacco products since May 2017, which requires the removal of all branding on any tobacco product. Finally, health warnings on tobacco packaging, as well as in media campaigns, have been found to increase health awareness in the population and to change the image of smoking. The last point is crucial in order to prevent young people from taking up smoking. In the UK, picture warnings on tobacco products have been implemented in 2008.

Comorbidity of substance use and psychiatric disorders

Julia M.A. Sinclair and Anne Lingford-Hughes

Introduction

For any individual, it is likely that a number of factors contribute to the comorbidity of psychiatric and substance use disorder (SUD). These may include genetics, family history, environmental factors (for example, stress, childhood experiences, current life events), and personality traits (for example, impulsivity). Such vulnerability factors may be common to both the psychiatric disorder and the SUD, rather than one being a consequence of the other (Fig. 56.1). For instance, higher levels of impulsivity are seen in alcohol use disorder (AUD) and bipolar disorder and likely contribute to their high comorbidity [1]. The same symptom may also be either a cause or a consequence; for instance, depression or anxiety may increase the likelihood of substance use, which then is likely to exacerbate the mental state, resulting in greater anxiety and depression symptoms and fuelling further alcohol or other substance use which patients may regard as treating their anxiety or depression. Epidemiological studies in major depressive disorder (as opposed to depressive symptoms) and AUD have shown that either may predate the other. It appears that such independent mood disorder may be common in those with SUD who present for treatment [2]. Consequently, it should be determined how any substance use may be contributing to a patient's psychiatric symptoms and discussed with them in order to optimize a treatment approach. It may be unhelpful to refer to either the psychiatric disorder or SUD as primary or secondary, since this may imply that treating one will improve the other; this is not borne out in many studies and so has limited clinical utility. Both disorders will need to be treated concurrently for any improvement to be robust.

Assessment principles

The assessment of patients who have AUD or SUD comorbid with one or more other psychiatric disorder follows the same principles as those highlighted in other sections, including the importance of a collateral history from family members or carers. The priority is to ensure that a full history is taken to identify the range of comorbidities, and an accurate assessment of the frequency and

levels of use of any substances. The evidence is that this is, in general, poorly done [3], and patient outcomes are likely to be substantially worse where an AUD or SUD is not identified accurately [4].

Screening for nicotine, alcohol, and drug use should be a routine part of any psychiatric assessment and integrated into the history of the presenting complaint, given the impact these substances have on the mental state. For patients not presenting primarily with an SUD, it is especially important that these questions are asked in an objective, non-judgemental way, explaining to the patient that it is important that you fully understand the factors that may be contributing to their current distress in order to most effectively help them. Patients may (understandably) be hesitant to disclose their alcohol or substance use if they believe that it may result in sanctions or being denied treatment.

Clinicians need to be competent in understanding how to calculate units of alcohol in order to accurately assess levels of use, understand the likely contribution that alcohol is making to the presenting complaint (both acutely and chronically), and make a competent risk assessment of the likelihood of symptoms on alcohol withdrawal [3, 5]. Full assessment of the need for alcohol detoxification is covered elsewhere (see Chapter 52) and is no different for patients with comorbid conditions.

Quantifying substance use

This is potentially more challenging given both the range and routes of consumption of other drugs. The terminology for substances may be unfamiliar to clinicians and frequently changes. Illicitly obtained drugs also vary in strength and purity, frequently containing fillers or adulterants, which may themselves have psychotropic properties. Patients can be reluctant to disclose their level of use or over-report it through fear of withdrawal and being undertreated, or as a form of active drug-seeking behaviour. There is no practical and reliable way to reconcile these issues. Record what is reported, ask for a collateral history, and regularly reassess the patient if they are presenting in an acutely disturbed state. Urine drug screens (where available) may be helpful to detect opioids, some stimulants, and cannabis, but the availability of novel psychoactive substances (NPS) means that

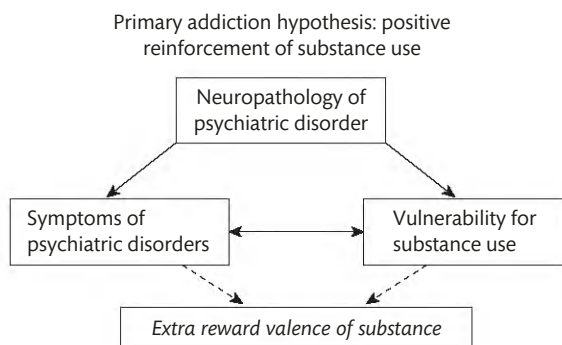

Fig. 56.1 Comorbid addiction vulnerability.

increasingly clinicians will need to rely on the history and empirical observation of the effect of the psychopharmacological properties of any substance use on the patient's presentation. These can be divided broadly into three main categories: sedatives, stimulants, and hallucinogens—the properties and management of which are covered elsewhere (see Chapters 53, 54, 55, and 56).

Diagnosis and goals of treatment

One major challenge in the management of patients with comorbidity is that they may present requesting treatment for one condition (for example, depression) and not be aware, or willing to consider, the impact that comorbid alcohol or other substance use has on their presentation or outcome.

A patient-centred approach to treatment needs to begin where the patient is, in terms of their own explanation for their illness, and to agree on some preliminary, achievable goals that build trust in the therapeutic relationship and increase the patient's self-efficacy.

For patients who are not physically dependent on alcohol or other substances, psychosocial approaches may be sufficient; brief interventions, based on motivational interviewing principles for behaviour change, are as appropriate for patients with a comorbid psychiatric disorder and can be delivered within general psychiatric settings as part of a holistic management plan. Essentially, what works in other settings should be tried but may be less effective [6].

Patients presenting with comorbid substance dependence (particularly with alcohol) require a clear management plan, integrating a combination of psychosocial and pharmacological treatments targeted at BOTH conditions, which is likely to be more effective for patients who have often tried and failed with a less co-ordinated approach.

Establishing patients who are dependent on nicotine or opioids on some form of substitution therapy is beneficial, but there is no evidence for any pharmacological approaches in the management of comorbid cannabis use, stimulant use, or any of the NPS. For these, psychosocial approaches are the mainstay of treatment.

The individual substances

Nicotine dependence

Individuals with severe mental illness (SMI) have among the highest prevalence rates of current nicotine smoking, at 50–85% [7]. Tobacco smoking is a substantial contributor to the reduction in

life expectancy for such individuals. The introduction of a smoking ban in hospitals presented some challenges to inpatient psychiatric units, particularly where individuals may be residing involuntarily for some time. Individuals with schizophrenia are three times more likely to initiate smoking, and although they are equally as interested in quitting smoking, including taking nicotine replacement therapy (NRT), they are five times less likely to be successful at so doing than the general population [7]. It is therefore important that support to stop or change smoking behaviour should be offered. The role of e-cigarettes in helping such individuals change is not currently clear.

In a meta-analysis of efficacy and tolerability of adjunctive pharmacotherapy for smoking cessation in adults with SMI, trials included schizophrenia, schizoaffective disorder, and bipolar disorder, and both bupropion and varenicline were superior to placebo, with no differences in tolerability [8]. However, the quality of the trials was noted as low. Systematic reviews of varenicline concluded that it is superior to placebo in smoking cessation in individuals with SMI [8, 9]. Varenicline increased the chances of successful long-term smoking cessation by between 2–3 times, compared with pharmacologically unassisted quit attempts [9]. The most common side effect reported was nausea. However, it is the risk of neuropsychiatric side effects from varenicline that has been debated. One systematic review and meta-analysis did not find a significant difference in risk of suicide, attempted suicide or suicidal ideation, depression, or death between varenicline and placebo, and no evidence that the presence of psychiatric illness impacted on depression or suicidal ideation [10]. The Evaluating Adverse Events in a Global Smoking Cessation Study (EAGLES) investigated neuropsychiatric complications from varenicline in over 8000 motivated-to-quit individuals with and without a psychiatric disorder [11]. There was no significant increase in neuropsychiatric adverse events attributable to varenicline or bupropion relative to nicotine patch or placebo. Varenicline was more effective than placebo, nicotine patch, and bupropion in helping smokers with a psychiatric disorder (including psychosis and mood and anxiety disorders) achieve abstinence, and bupropion and nicotine patch were more effective than placebo. It is therefore suggested that all patients quitting smoking should be told about the small chance they may experience severe mood changes and all clinicians should be alert for these changes. It is notable that the majority of trials only included those who were motivated to quit and whose psychiatric disorder was stable and so may not be generalizable to all individuals or psychiatric patients.

Alcohol dependence

Usual medication regimens for alcohol detoxification can be used in patients with comorbid psychiatric illness, with due consideration for doses required to avoid complications, for example seizures, and any liver or renal impairment altering pharmacokinetics. Mentally ill patients are more likely to require inpatient admission for detoxification, and so relapse prevention plans should be established and implemented at this time.

There are three main relapse prevention medications to be considered for patients with AUD: acamprosate, naltrexone, and disulfiram [12]. The limited evidence for their use in different comorbid conditions will be considered later, but the principle of active treatment of alcohol dependence as part of overall patient management and treatment plan is key [13]. Where there is no specific evidence for use in an individual comorbid condition, data on

the drug's pharmacokinetics and other safety data can be used to extrapolate from the treatment of AUD alone to help determine a risk–benefit profile of treatment with a specific medication in individual patients.

Opioid dependence

The most robust evidence for the pharmacological treatment of opioid dependence in patients with a range of psychiatric conditions is to engage in opiate substitution therapy (OST) programmes such as methadone or buprenorphine [13].

Psychiatric disorders

Schizophrenia

Managing patients with schizophrenia who also use substances is a common and substantial challenge. While the focus is often on cannabinoids, comorbidity with nicotine and alcohol is more common and, as such, has a significant impact on life expectancy. Stimulant use disorder, which can be associated with psychotic phenomena, has been reported to be higher in the schizophrenia spectrum than in the general population at 10.4% but varies considerably, depending on the setting, geographical location, etc.; notably, cannabis use disorder was strongly linked with stimulant use disorder [14]. While there is some evidence that residential 'dual diagnosis' treatment programmes may lead to improvements, their availability is likely to be very limited, at least in the UK. Most individuals will be treated in the community, with occasional admissions to a general psychiatric ward and varying input from specialist addiction services.

There are a range of clinical guidelines providing approaches to treating individuals with SUD and schizophrenia [15, 16]. Negative symptoms and cognitive impairment can make it particularly challenging to engage an individual with schizophrenia in psychological approaches to reduce their drug use or prevent relapse, as well as contributing to poor adherence to medication. The UK NICE guidelines for such comorbidity recommend that the severity of both disorders, the individual's social and treatment context, and their readiness to change should be considered [16]. In addition, clear advice about reducing the risk of their substance abuse (for example, by not injecting, avoiding to use multiple drugs concurrently, etc.) and reminders of adverse consequences of their substance abuse, as well as not taking their drugs for psychosis, should not be forgotten [15].

Psychosocial approaches

Cochrane reviews have concluded that there was no good evidence for effectiveness of any one particular psychosocial treatment in psychotic spectrum disorders comorbid with substance abuse or for those with serious mental illness, of which the majority had schizophrenia or psychotic illness [17]. However, this should be seen in the context of a very limited evidence base. Motivational interviewing is the most common approach studied, often in addition to CBT, and other models investigated include contingency management and skills training.

In the UK, a trial in schizophrenia, schizophreniform disorder, or schizoaffective disorder and substance (drug and/or alcohol) use disorder did not find that integrated motivational interviewing and CBT plus standard care were superior to standard care alone in improving outcomes, for example hospitalization, symptom outcomes, and functioning [18]. Alcohol was the most commonly

misused substance, followed by cannabis. Integrated therapy resulted in a reduction in the amount of substance used for at least 1 year after completion of therapy. It is interesting to note that this reduction in substance use was not associated with improvements in outcomes for their psychotic illness and is in keeping with other studies. To test the theory that more prolonged treatment was needed, a further trial compared treatment as usual with shorter-term intervention (12 sessions over 4.5 months) and with a longer-term delivery (24 sessions over 9 months) [19]. This again showed no differences between groups in any of the outcomes regarding psychosis or cannabis use. Though no association was found between sessions attended and outcome, the median number of sessions attended was 12 of the 24 available, despite good therapeutic relationships and meeting in the patient's home. The authors note that this result is in keeping with trials treating cannabis use disorder alone; focus on associated problems, rather than cannabis use itself, may be more helpful.

Pharmacological approaches to treating schizophrenia

There are few randomized trials comparing different medications to guide clinical practice. Published studies mostly describe uncontrolled designs with small numbers of participants, comparison of the impact of switching the type of medicines, or case series. Dopamine-blocking activity in the dopaminergic mesolimbic pathway was originally seen as an appropriate therapeutic strategy for substance misuse, since it would reduce their rewarding effects; it is now recognized that dopaminergic activity may be blunted in patients with SUD. Thus, further blockade is likely to be counterproductive, with the potential to increase substance use as a way to boost the hypodopaminergic mesolimbic system. It was hypothesized that newer drugs with weaker DRD2 antagonism (and less impact on the dopaminergic system) would result in less substance misuse when used to treat patients with schizophrenia. The Clinical Antipsychotic Trial of Intervention Effectiveness (CATIE) compared olanzapine, risperidone, ziprasidone, quetiapine, and perphenazine; the CATIE study participants included 37% with a current SUD, and of these, 87% drank alcohol, 44% used cannabis, and 36% used cocaine. While the CATIE study showed that olanzapine was superior to other drugs on the primary outcome of 'time to all-cause discontinuation' over 18 months, illicit drug use attenuated this superiority [20]. There was little between the different drugs for psychosis on measures of smoking, alcohol, and drug use in multiple subgroups with reductions evident across all groups. Nevertheless, there is no large randomized trial a priori comparing different dopamine antagonists on substance use outcomes.

The role of clozapine in treating schizophrenia comorbid with SUD is of considerable interest, given its efficacy in treatment-resistant populations. In routine clinical practice, these patients would include those with comorbidity and there are case reports and case series describing beneficial effects of clozapine [13]. However, there has been no randomized prospective trial of clozapine in this clinical population. In summary, clinical guidance is that the choice of drugs for psychosis can be based on the side effect profile and tolerability for each patient without regard to their SUD.

Treating SUD in the context of schizophrenia

Alcohol dependence

There are a number of alcohol relapse prevention medications that should be considered to improve drinking behaviour, but there is limited evidence to guide practice [13]. For both acamprosate and

naltrexone, no adverse effects are apparent of additional particular relevance, compared with a non-comorbid population. A placebo-controlled RCT reported that the opiate antagonist naltrexone was associated with fewer drinking days, fewer heavy drinking days, and less craving, though psychosis did not concurrently improve [21].

Use of disulfiram in patients with psychosis is relatively contraindicated because its use in high doses will result in higher dopamine levels and potentially acutely increase psychosis [22]. However, more recent studies in patients with psychosis—not all with schizophrenia [13, 21]—have reported disulfiram reduced alcohol consumption, with limited adverse events.

Cannabis use disorders

A systematic review and meta-analysis reported that motivational interviewing, with or without CBT, reduced the quantity of cannabis use (but not the frequency) and positive symptoms of schizophrenia; however, there was limited impact on negative symptoms [23]. Delivery of MI + CBT to a group, rather than an individual, did not improve cannabis or psychotic outcomes, though the quality of life did improve [24]. One trial compared ‘treatment as usual’ with combined MI and CBT in patients with schizophrenia spectrum psychosis and cannabis use disorder [25]. The combined intervention showed a possible reduction in the number of monthly joints, but not days of cannabis use, and did not reduce psychotic symptoms. However, further analysis revealed that those who received the combined intervention had more visits to a psychiatric emergency department and hospitalizations but spent less time in hospital.

If focusing on the patient alone may not be particularly beneficial, does involving the family improve outcomes? A recent trial in recent-onset schizophrenia with cannabis use found that family-based MI and interaction skills were superior to routine family support for some outcomes. Thus, training parents helped reduce cannabis use but did not reduce the parent’s stress and sense of burden or their general level of functioning. Notably, this benefit in reducing cannabis use was maintained at 15-month follow-up. While statistically there was no difference between groups or during trial of follow-up in other substance use, it is interesting to note that alcohol use did increase in the intervention group where a reduction in cannabis use was seen [26].

No single medicine has superiority over another; for example, olanzapine and risperidone are similar in impact on substance use and psychosis [13]. A pilot study comparing clozapine (mean: 225 mg/day) with ziprasidone (mean: 200 mg/day) in patients with schizophrenia and cannabis use disorder found that cannabis use similarly decreased in both groups over 12 months [27]. While clozapine was associated with fewer positive symptoms, it also incurred more side effects and poorer compliance. Thus, the available data support clinical guidance that the choice of drugs for psychosis can be based on the side effect profile and tolerability for each patient without consideration of their SUD.

Stimulant use disorder

Psychological approaches are the mainstay of treatments for stimulant use disorders, with contingency management showing effectiveness [13]. An RCT compared 3 months of contingency management for stimulant abstinence plus treatment as usual, and treatment as usual with reinforcement for study participation only in patient with serious mental illness [28]. Of the participants, about 33% had

schizoaffective spectrum disorder, 34% had bipolar disorder, and 27% had major depression. Though they were less likely to remain in the 3-month trial, those who received contingency management were 2.4 times more likely to have a stimulant-negative urine. In addition, they had less use of stimulants in the following 3 months and significantly lower levels of alcohol use, injection drug use, and psychiatric symptoms, and were less likely to be admitted for psychiatric hospitalization.

Bipolar disorder

Substance misuse in bipolar disorder provides clinical, diagnostic, and management challenges [15, 16]. AUDs are particularly highly prevalent in bipolar disorder and may complicate both manic and depressive presentations. There is no evidence that a particular mood stabilizer is superior to another in improving either substance misuse or bipolar disorder [13]. The combination of sodium valproate and lithium may be better than lithium alone in improving alcohol outcomes, though not necessarily manic and depressive symptoms. Due to the scant evidence base, clinical guidance generally recommends following usual practice in managing their bipolar disorder.

Treatment of substance use disorder

Again, there is limited evidence and it mainly applies to alcohol dependence. There is evidence to suggest that naltrexone or disulfiram are superior to placebo in improving drinking behaviours in those with alcohol dependence and a psychotic disorder, of whom the majority (73%) had bipolar disorder [21]. However, they did complain more about side effects. Acamprosate has been used safely in patients with bipolar disorder and alcohol dependence, in addition to their mood-stabilizing medication, but without benefit in a preliminary report [29]. Despite such limited evidence, medication should be considered for management of comorbid alcohol dependence. In addition and also for other substances, psychosocial approaches should be used. As with other psychiatric disorders, the key is assessing and diagnosing any substance misuse and how it may contribute to their bipolar disorder in order to manage it optimally.

Depression

The co-occurrence of mood and SUD is common, yet studies specifically investigating effective management of both conditions are limited. There have been three systematic reviews [30–32], all examining slightly different, but related, questions. These used the same 11 RCTs (published between 1990 and 2010), evaluating the efficacy of different medicines in depression with comorbid alcohol dependence, as the basis of their analysis. Nunes and Levin (2004) [30] analysed 14 studies, eight with depression and comorbid alcohol dependence, two with depression and cocaine use, and four with depression and comorbid opioid dependence (on methadone maintenance treatment). They concluded that overall, drugs for depression had a modest beneficial effect, but that ‘concurrent therapy directly targeting the addiction was also required’. The meta-analysis by Torrens et al (2005) [31] investigated whether sertraline, tricyclic reuptake inhibitors, and nefazadone were an effective treatment for patients with SUD in a wider range of studies (nine with depression and comorbid alcohol dependence, five with cocaine, and seven with opioid dependence comorbid with depression), combined with another 40 studies examining the efficacy of drugs for depression in nicotine, cocaine, and alcohol dependence alone. They concluded

there was no significant effect for sertraline on depressive symptoms in the comorbid alcohol group. There was some benefit for medicines with broader pharmacology (imipramine, desipramine, and nefazodone) on depressive symptoms in the comorbid group, although safety concerns in overdose limit their usefulness. In terms of reducing alcohol consumption, neither SSRIs nor the other drugs for depression on their own had any significant impact. The most recent meta-analysis [32] compared 11 RCTs of drug efficacy in alcohol and comorbid depression (involving 891 patients), with the clinical trial data of over 46,000 patients with depression alone. Response rates to the active treatment was 50–60% in both the depression-only group and the depression comorbid with alcohol use group. However, placebo response differed significantly across the groups, with 37.7–39.3% in the non-comorbid depression group and 47.1–53.1% in the comorbid alcohol group. A limitation with all three meta-analyses is that they do not include any data on SSRIs (other than sertraline and fluoxetine), mirtazapine, or venlafaxine. A recent small ($N = 14$) double-blind, placebo-controlled pilot trial of mirtazapine in depressed patients and comorbid AUD suggests that it is safe and tolerated, and may have an effect on depressive symptoms, but not alcohol consumption, although it was extremely underpowered for confidence in its conclusions [33].

Treatment of substance use disorder

While drugs for depression have a modest effect on levels of depression in the comorbid group, they have not been shown to cause a direct or consequent reduction in alcohol consumption [30], and similarly use of relapse prevention medication alone (without treating the underlying psychiatric disorder) had minimal effect on outcomes [21]. Improved outcomes have been shown by combined treatment for depression (with sertraline 200 mg daily) and alcohol dependence (naltrexone 100 mg daily) in a placebo-controlled four-arm study. Only the active combination of both drugs was significantly better in improving drinking behaviour and also had a marginally better effect on depression, relative to placebo [34]. Overall the safety profile for use of acamprosate and naltrexone in patients with comorbid depression is good; a thorough risk assessment needs to be undertaken prior to the use of disulfiram, due to potential dangers of interaction with alcohol in suicidal patients [35], but active treatment of both conditions is recommended [13].

It is less common for patients dependent on opioids to present with depression, and beyond establishing them on OST, there is limited benefit of treating patients with a drug for depression [31, 36]. For patients with depression and use of dopamine-releasing drugs ('stimulants') or cannabis, there is no evidence for the benefit of pharmacological treatment for their substance use, and management is primarily psychosocial.

PTSD and other anxiety disorders

Anxiety symptoms are common in patients with SUD and may be present as part of intoxication, withdrawal, or early abstinence from substances, depending on the substance used, and a thorough history is required to ascertain the role that they play in the presenting mental state. For example, patients with severe alcohol dependence frequently develop panic symptoms, which resolve on detoxification and abstinence. Patients with anxiety disorders also frequently have SUD, and the temporal relationship between the two conditions are

frequently difficult to untangle, as PTSD has often been present for many years before patients present.

In PTSD, SUD is 2–3 times more likely than in the general population, and outcomes in the comorbid population are worse than outcomes for either disorder alone. A recent review of the evidence base for PTSD co-occurring with AUD [37] showed that pharmacological interventions for AUD (naltrexone, disulfiram, and topiramate) or PTSD (sertraline, desipramine, prazosin) were mainly effective in reducing drinking outcomes (including one study with adjuvant psychotherapy), but only one study with sertraline demonstrated an effect over placebo in the reduction of PTSD symptoms. The review concludes that the safety profile for topiramate is likely to limit its usefulness in clinical practice, but that naltrexone and disulfiram are relatively safe to use, although further studies are required to test the efficacy of pharmacological and psychotherapeutic interventions in combination for both disorders [13, 37].

Patients with social anxiety disorder (SAD) have often had symptoms from childhood and start using substances (especially alcohol) as a form of self-management during adolescence, with SAD being the primary condition in 80% of cases. Despite the significant comorbidity between the two conditions, the only studies conducted have been with paroxetine, and a recent Cochrane review found the quality of studies to be low [38]. The same review found a single RCT for the treatment of generalized anxiety disorder comorbid with AUD using buspirone but reported the quality of study design and reporting to be low, such that limited conclusions can be drawn.

Overall, anxiety disorders, despite substantial comorbidity with SUD, especially alcohol, have a very limited evidence base for treatment, and extrapolation from what works in the non-comorbid condition is needed in clinical settings, in the absence of clear research evidence.

There is some evidence that the GABA agonist baclofen may have a role to play in relapse prevention from alcohol in patients with anxiety symptoms, and at time of writing, it has a 'temporary recommendation for use' in France for the maintenance of alcohol abstinence or for the reduction of consumption to low levels in patients with alcohol dependence who have not responded to other treatments. However, evidence for its effectiveness has yet to be fully demonstrated, and there are concerns about its safety profile in overdose [35].

Attention-deficit/hyperactivity disorder

Substance use is six times more common in adolescents with ADHD than the general population. Atomoxetine is recommended as a first-line treatment in adults with ADHD comorbid with SUD due to the lack of abuse potential, although evidence of efficacy is limited. A single study of ADHD adults with comorbid AUD found significant effects on ADHD symptoms, but inconsistent effects on drinking behaviour; more research is required to investigate effective treatments [39].

Training needs

While professionals working in psychiatric services are highly likely to have had sufficient training and experience in managing mood and psychotic disorders, as well as other less common psychiatric disorders, the same is not the case for substance use and addiction.

For example, in the UK, the reduced psychiatric expertise in specialist addiction services also means that general psychiatric services are more likely to have to be involved in managing individuals with comorbidity.

While there is a small evidence base for the effectiveness of treatments targeting comorbid SUD and psychiatric disorder, the frequency of their occurrence and the negative impact on outcomes mean that psychiatrists need to develop a degree of clinical expertise in managing these complex conditions. Being aware of the evidence available, extrapolating from what is known to be effective in the single condition, and making a balanced risk assessment prior to a trial of treatment will be necessary to optimize treatments.

The core dimensions of schizophrenia

Nancy C. Andreasen

Introduction

Schizophrenia is probably the most devastating illness that psychiatrists treat. An estimated 1% of the population has schizophrenia, which claims its victims at a youthful age and often prevents their full participation in society. Schizophrenia also creates an enormous economic burden, calculated at \$65 billion annually in direct and indirect costs [1]. Despite its emotional and economic costs, schizophrenia has yet to receive sufficient recognition as a major public health concern or adequate research support to investigate its causes, treatments, and prevention.

History

Schizophrenia and other psychotic disorders have been recognized in almost all cultures and described and/or portrayed throughout much of recorded time.

Although schizophrenia was only demarcated as a specific diagnostic entity at the end of the nineteenth century, earlier accounts appear in the literature. Many characters 'become mad' in classical tragedy, although the patterns of illness do not map precisely on the modern conceptions of schizophrenia—a fact probably due to both literary licence and to the fact that the nosology of mental illness was not highly refined at that time. By the era of Elizabethan drama, however, we have portrayals of schizophrenia that closely resemble the modern concept. The madness of Ophelia in *Hamlet* is quite similar to modern schizophrenia, and the portrayal of 'Poor Tom', son of Gloucester pretending to be a 'Bedlam beggar' escaped from the large Bethlehem Hospital where mental patients were housed, is a near-perfect portrayal of both hallucinations and disorganized speech:

Who gives anything to Poor Tom? Whom the foul fiend
hath led through fire and through flame ... ? Tom's
a-cold,— O, do de, do de, do de ... Do poor Tom some
charity, whom the foul fiend vexes. There I could have
him now,—and there, and there again, and there.

King Lear III.iv.51

Its modern history dates to Emil Kraepelin, who is credited with identifying schizophrenia [2]. His original term for schizophrenia

dementia praecox was based on his observations that these patients developed their illness at a relatively early age (praecox) and were likely to have a chronic and deteriorating course (dementia). Kraepelin was also instrumental in separating dementia praecox from manic-depressive illness, which had its onset distributed throughout life and a more episodic course.

Dementia praecox was eventually renamed *schizophrenia*, a term coined by Eugen Bleuler to emphasize the cognitive impairment that occurs, which he conceptualized as a splitting of the psychic processes [3]. Bleuler believed that certain symptoms were fundamental to the illness, including affective blunting, disturbances of association (that is, fragmented thinking), autism, and ambivalence (for example, fragmented emotional responses). These eventually enjoyed widespread acceptance as 'Bleuler's four As'. Other symptoms, such as delusions and hallucinations, were considered by him to be 'accessory symptoms', which occurred in other disorders such as manic-depressive illness.

Bleuler's ideas enjoyed widespread acceptance, and generations of psychiatrists were taught the importance of his fundamental symptoms (the four As). Unlike hallucinations and delusions, these symptoms are on a continuum with normality and can be present in relatively mild forms, even in psychiatrically healthy persons. Consequently, the conceptualization of schizophrenia in the United States became increasingly broad. Later, the ideas of the German psychiatrist Kurt Schneider, who emphasized first-rank or specific psychotic symptoms, were introduced, helping to reshape the concept of schizophrenia into one of a relatively severe psychotic disorder, bringing it back to the original ideas of Kraepelin [4]. DSM-5 represents a convergence of various points of view, with its Kraepelinian emphasis on course, specific delusions, and hallucinations thought important by Kurt Schneider, and acknowledgement of the importance of Bleuler's fundamental symptoms.

Definition

In DSM-5, schizophrenia is defined by a group of characteristic positive or negative symptoms; deterioration in social, work, or interpersonal relationships; and continuous signs of the disturbance for at least 6 months [5]. In addition, schizoaffective disorder and

mood disorder with psychotic features have been ruled out, and the disturbance is not due to the direct physiological effects of a substance or a general medical condition. When an illness otherwise meets the criteria but has a duration of less than 6 months, it is called *schizophreniform disorder*. When the duration is less than 4 weeks, it may be classified as either a *brief psychotic disorder* or a *psychotic disorder not otherwise specified*, which is a residual category for psychotic disturbances that cannot be better classified.

Differential diagnosis

Schizophrenia should be thought of as a diagnosis of exclusion because the consequences of the diagnosis are severe and limit therapeutic options. There are no definitive tests for schizophrenia, so the diagnosis rests on historical and clinical information.

A thorough physical examination and history are required to rule out other medical causes for schizophrenic symptoms. Psychotic symptoms are found in many other illnesses, including substance abuse (for example, hallucinogens, phencyclidine, amphetamines, cocaine, alcohol), intoxication due to commonly prescribed medications (for example, corticosteroids, anticholinergics, levodopa), infections, metabolic and endocrine disorders, tumours and mass lesions, and temporal lobe epilepsy. Laboratory tests may be helpful in ruling out these aetiologies, and magnetic resonance imaging may be useful in selected patients to rule out alternative diagnoses or during the initial workup for new-onset cases.

The major differential diagnosis involves separating schizophrenia from mood disorder, delusional disorder, or personality disorder. The chief distinction from mood disorders is that with schizophrenia, a full depressive or manic syndrome is either absent or develops after the psychotic symptoms, or is brief in duration relative to the duration of psychotic symptoms. Unlike delusional disorder, schizophrenia is characterized by bizarre delusions and hallucinations are common. Patients with personality disorders, particularly those disorders within the eccentric cluster (for example, schizoid, schizotypal, or paranoid), may be characterized by indifference to social relationships and have a restricted affect, bizarre ideation, or odd speech but are not psychotic.

Other psychiatric disorders also must be ruled out, including schizophreniform disorder, brief psychotic disorder, factitious disorder with psychological symptoms, and malingering. When symptoms persist for more than 6 months, schizophreniform disorder can be ruled out. The history of how the illness presents will help to rule out a brief psychotic disorder, because schizophrenia generally has an insidious onset and there are usually no precipitating stressors. Factitious disorder may be difficult to distinguish from schizophrenia, especially when the patient is knowledgeable about mental illness or is medically trained, but careful observation should enable the clinician to make the distinction between real or feigned psychosis. Likewise, a malingeringer could attempt to simulate schizophrenia, but careful observation and history-taking will help to distinguish the disorders. With the malingeringer, there will be evidence of obvious secondary gain, such as avoiding incarceration or severe punishment, and the history may suggest antisocial personality disorder.

Dimensional approaches

A variety of methods have been developed to describe and classify the symptoms in schizophrenia. Traditionally, schizophrenia is considered to be a type of 'psychosis', yet the definition of psychosis has been elusive. Older definitions stressed the subjective and internal psychological experience and defined psychosis as an 'impairment in reality testing'. Moreover, psychosis has been defined objectively and operationally as the occurrence of hallucinations and delusions. Because schizophrenia is characterized by so many different types of symptoms, clinicians and scientists have tried to simplify the description of the clinical presentation by categorizing symptoms along dimensions, rather than discrete categories of psychopathology.

Recent research suggests there are three symptom dimensions. The first—psychoticism—involves hallucinations and delusions, the classic symptoms of psychosis. The second—disorganization—involves bizarre speech and behaviour and incongruous affect. The third—negative symptoms—involves alogia, affective blunting, anhedonia, and avolition. The author has developed the Scale for the Assessment of Positive Symptoms (SAPS) and the Scale for the Assessment of Negative Symptoms (SANS) to evaluate these symptoms [6, 7]. (See [Table 57.1](#) for a description of the frequencies of positive and negative symptoms.)

The psychotic dimension

This symptom dimension refers to two classic 'psychotic' symptoms that reflect a patient's confusion about the loss of boundaries between himself or herself and the external world: hallucinations and delusions. Both symptoms reflect a 'loss of ego boundaries'—the patient is unable to distinguish between his or her own thoughts and perceptions and those that he or she obtains by observing the external world.

Hallucinations have sometimes been considered to be the hallmark of schizophrenia, although they may occur in other disorders, including mood disorders and disorders induced by medical illness or various substances. Hallucinations are perceptions experienced without an external stimulus to the sense organs and with a quality similar to a true perception. Schizophrenic patients commonly report auditory, visual, tactile, gustatory, or olfactory hallucinations, or a combination of these. Auditory hallucinations are the most frequent; they are commonly experienced as voices but may also be noises or music. The voices come from outside the person's head, and they usually speak words, phrases, or sentences. Visual hallucinations may be simple or complex and include flashes of light, persons, animals, or objects. Olfactory and gustatory hallucinations are often experienced together, especially as unpleasant tastes or odours. Tactile hallucinations may be experienced as sensations of being touched or pricked, electrical sensations, or sensations of insects crawling under the skin, which is called *formication*.

Delusions involve disturbance in thought, rather than perception; they are firmly held beliefs that are untrue, as well as contrary to a person's educational and cultural background. Delusions occurring in schizophrenic patients may have somatic, grandiose, religious, nihilistic, or persecutory themes. The type and frequency of delusions tend to differ according to culture. For example, in the United States,

Table 57.1 Frequency of symptoms in schizophrenia patients

Symptoms	%	Symptoms	%
NEGATIVE SYMPTOMS		POSITIVE SYMPTOMS	
Affective flattening		Hallucinations	
Unchanging facial expression	96	Auditory	75
Decreased spontaneous movements	66	Voices commenting	58
Few expressive gestures	81	Voices conversing	57
Poor eye contact	71	Somatic–tactile	20
Affective non-responsivity	64	Olfactory	6
Inappropriate affect	63	Visual	49
Lack of vocal inflections	73	Delusions	
Alogia		Persecutory	81
Poverty of speech	53	Jealous	4
Poverty of content of speech	51	Guilt, sin	26
Blocking	23	Grandiose	39
Increased response latency	31	Religious	31
		Somatic	28

a patient might worry about being spied on by the FBI or CIA; in sub-Saharan Africa, a Bantu or Zulu patient is more likely to worry about persecution by demons or spirits. (See [Table 57.2](#) for a detailed description of the various types of delusions.)

Table 57.2 Varied content in delusions

Delusions	Foci of preoccupation
Grandiose	Possessing wealth or great beauty, or having a special ability (for example, extrasensory perception); having influential friends; being an important figure (for example, Napoleon, Hitler)
Nihilistic	Believing that one is dead or dying; believing that one does not exist or that the world does not exist
Persecutory	Being persecuted by friends, neighbours, or spouses; being followed, monitored, or spied upon by the government
Somatic	Believing that one's organs have stopped functioning (for example, that the heart is no longer beating) or are rotting away; believing that the nose or other body part is terribly misshapen or disfigured
Sexual	Belief that one's sexual behaviour is commonly known; that one is a prostitute, paedophile, or rapist; that masturbation has led to illness or insanity; that one's sexual abilities are legendary
Religious	Belief that one has sinned against God; that one has a special relationship to God or some other deity; that one has a special religious mission; that one is the Devil or is condemned to burn in Hell

Certain types of hallucinations and delusions were considered 'first rank' by Kurt Schneider [4]. These hallucinations include clearly audible voices commenting on a person's actions, or arguing with each other about a patient, or repeating aloud the patient's thoughts. The delusions include thought broadcasting, thought withdrawal, thought insertion, or being controlled. These symptoms commonly occur in schizophrenic patients but are also found in patients with psychoses due to mood disorders, medical illness, or the effect of substances. (See [Table 57.3](#) for a description of Schneider's 'first-rank' symptoms.)

The disorganization dimension

The disorganization dimension includes disorganized speech, disorganized or bizarre behaviour, and incongruous affect.

Disorganized speech, or *thought disorder*, was regarded as the most important symptom of schizophrenia by Bleuler. Historically, the types of thought disorder have included associative loosening, illogical thinking, over-inclusive thinking, and loss of the ability to engage in abstract thinking. Standard definitions for various types of thought disorders have been developed that stress objective aspects of language and communication (which are empirical indicators of 'thought'), such as derailment, poverty of speech, poverty of content of speech, or tangential replies, and all have been found to occur in both schizophrenia and mood disorders. Manic patients often have a thought disorder characterized by tangentiality, derailment (loose associations), and illogicality. Depressed patients manifest thought disorder less frequently than manic patients but may display poverty of speech, tangentiality, or circumstantiality. Other types of formal thought disorder include perseveration, distractibility, clanging, neologisms, echolalia, and blocking; with the possible exception of clanging in mania, none appears to be disorder-specific.

An example of speech from a schizophrenia patient with a prominent thought disorder, especially derailment, follows:

Let's see, there was one I would have liked if it wasn't for the instructor, well I go along with his, he was always wanted me to do the worse in the class, it seemed, like, and I'd always get bad, the grade,

Table 57.3 Schneider's first-rank symptoms

Thought echo	Hearing one's thoughts being spoken aloud
Voices commenting	Hearing a voice making a running commentary about oneself
Voices conversing	Hearing several voices talking or arguing about oneself
Somatic hallucination	A hallucination involving the perception of a physical experience within the body
Thought withdrawal or insertion	Belief that thoughts are being withdrawn or inserted into the patient's mind by an outside force
Thought broadcasting	Belief that the person's thoughts are being broadcast so that his/her private thoughts are known to others
Delusional perceptions	A true perception, to which the person attributes a false meaning
Delusions of passivity	Being influenced or forced to do things or want things the patient does not wish to do and does not want
Delusions of control	Being made to feel emotions or sensations that are not the patient's own

in my grading, and he tried to make other people like they were good enough to be in Hollywood or something, you know I's be the last one down the ladder. That, that's the way they wanted the grading to be in the first place according to whose, theirs, they, they have all different reasons than I, I, I think that they use that they want one, won't come out.¹

Many schizophrenic patients display various types of disorganized motor and social behaviour, another aspect of this dimension. Abnormal motor behaviours range from catatonic stupor to excitement. In a *catatonic stupor*, the patient may be immobile, mute, and unresponsive, yet fully conscious. With catatonic excitement, the patient may exhibit uncontrolled and aimless motor activity. Patients sometimes assume bizarre or uncomfortable postures, such as squatting, and maintain them for long periods. Patients may exhibit a *stereotypy*, which is repeated, but non-goal-directed, movement such as back and forth rocking. They may also display *mannerisms*, which are normal goal-directed activities, but are either odd in appearance or out of context such as grimacing. Other common symptoms are *echopraxia*, or imitating the movements and gestures of another person; *automatic obedience*, or carrying out simple commands in a robot-like fashion; and *negativism*, or refusing to cooperate with simple requests for no apparent reason.

Deterioration of social behaviour often occurs along with social withdrawal. Patients may neglect themselves, become messy or unkempt, and wear dirty or inappropriate clothing. Patients may ignore their surroundings, so that they become cluttered and untidy. Patients may develop other odd behaviours that break social conventions such as masturbating in public, foraging through garbage bins, or shouting obscenities. Many of today's street people suffer from schizophrenia.

Incongruity of affect is another component of the disorganized dimension. Patients may smile inappropriately when speaking of neutral or sad topics, or giggle for no apparent reason. This symptom

1. Reproduced from Andreasen NC, *The Broken Brain: The biological revolution in psychiatry*, pp. 61, Copyright (1984), with permission from HarperCollins Publishers.

should not be confused with the nervous smiling or giggling that sometimes occurs in anxious patients.

The negative dimension

DSM-5 lists two negative symptoms as characteristic of schizophrenia: affective blunting (diminished emotional expression) and avolition. Other negative symptoms that are common in schizophrenia include alogia (poverty of speech), anhedonia, and attentional impairment. Taken together, they may be considered to represent a new 'five As'. Negative symptoms reflect a deficiency of mental functioning that is normally present.

Affective flattening or blunting is a reduced intensity of emotional expression and response. It is manifested by unchanging facial expression, decreased spontaneous movements, poverty of expressive gestures, poor eye contact, lack of voice inflections, and slowed speech.

Avolition is a loss of the ability to initiate goal-directed behaviour and carry it through to completion. Patients seem to have lost their will or drive. They may initiate a project and then abandon it for a few days or weeks, and then fail to appear or wander aimlessly away while at work. This symptom is sometimes interpreted as laziness but, in fact, represents the loss or diminution of basic drives and the capacity to formulate and pursue long-range plans.

Alogia is characterized by a diminution in the amount of spontaneous speech, as well as a tendency to produce speech that is empty or impoverished in content when the amount is adequate. It is the external expression in language of the impoverishment of thought that occurs in many patients with schizophrenia. Patients may have great difficulty in producing fluent responses to questions.

Anhedonia, or the inability to experience pleasure, is also very common. Many patients describe themselves as feeling emotionally empty. They are no longer able to enjoy activities that previously gave them pleasure such as playing sports or seeing family or friends. Their awareness that they have lost the capacity to enjoy themselves may be a source of great psychological pain.

Attentional impairment is reflected in an inability to concentrate or by stimuli that they cannot process or filter; this, in turn, causes them to feel confused or to experience fragmented thoughts.

Another aspect of this dimension is a *reduced intensity of emotional response* that leaves schizophrenic patients indifferent and apathetic.

Depressive symptoms occur in up to 60% of schizophrenic patients. Depression is often difficult to diagnose because symptoms of schizophrenia and depression frequently overlap. Dopamine antagonists may also cause what may appear to be depression but is actually drug-induced akinesia.

Other symptoms

Lack of insight is common in schizophrenia. A patient may not believe that he or she is ill or abnormal in any way. To the patient, the hallucinations and delusions are real, not imagined. Poor insight is one of the most difficult symptoms to treat, and it may persist even when other symptoms, such as hallucinations or delusions, respond to treatment. Orientation and memory are usually normal, unless they are impaired by the patient's psychotic symptoms, inattention, or distractibility.

Non-localizing neurological soft signs occur in a substantial proportion of patients and include abnormalities in stereognosis,

graphesthesia, balance, and proprioception [11]. A disorder of the visual tracking of smoothly moving targets (that is, smooth pursuit eye movement) has been observed in both schizophrenia patients and their relatives. Other ocular abnormalities commonly include the absence and avoidance of eye contact and staring for long periods. Decreased or rapid blink rates and bouts of rapid blinking may occur. Some patients display disturbances of sleep, sexual interest, and other bodily functions. A variety of disrupted sleep measures have been reported, but decreased delta sleep with diminished stage 4 is the most consistent finding. Many schizophrenia patients have inactive sex drives and derive little or no pleasure from sexual activity.

Premorbid personality

Several early writers, including Kraepelin and Bleuler, observed that patients with schizophrenia often had abnormal premorbid personalities. A review of early studies of personality and schizophrenia showed that premorbid schizoid traits were present in one-fourth of schizophrenic patients, but one-sixth had a range of other personality disturbances [12]. Poor premorbid adjustment has been shown to correlate with early disease onset, poor overall prognosis, negative symptoms, cognitive deficits, and poor social functioning.

Alcohol and drug abuse

Alcohol and drug abuse is especially common in patients with schizophrenia. Drug-using patients tend to be young, male, and poorly compliant with treatment; they also tend to have frequent hospitalizations. It is believed that many abuse drugs in an attempt to treat their depression or their medication side effects (for example, akinesia) or to ameliorate their lack of motivation and pleasure.

Other problems

People who suffer from schizophrenia are at high risk of committing suicidal acts [13]. About one-third will attempt suicide, and 1 in 10 will eventually complete suicide. Risk factors for suicide include male gender, age under 30 years, unemployment, chronic course, prior depression, past treatment for depression, history of substance abuse, and recent hospital discharge.

Recent research shows that patients with schizophrenia and other severe mental disorders exhibit relatively high rates of violent behaviour and criminality. In the Epidemiologic Catchment Area study [14], schizophrenic patients had rates of violent behaviour five times higher than persons without mental illness, although the rate was about half that seen in persons with alcohol abuse or dependence. Schizophrenic patients with coexisting alcoholism are even more likely to commit violent acts.

Course of illness

Schizophrenia is typically viewed as a chronic disorder that begins early in life and has a poor long-term outcome. Its onset generally begins with a *prodromal phase* characterized by social withdrawal and other subtle changes in behaviour and emotional responsiveness, peculiar behaviour, deterioration in personal hygiene and grooming, and strange ideation. The prodrome varies in length but typically lasts from months to years.

The prodrome is followed by an *active phase*, in which psychotic symptoms first appear. At this point, the clinical disorder becomes evident, and a diagnosis of schizophrenia can be made. This phase is characterized by hallucinations and delusions, alarming both friends and family members, and often leading to medical intervention. A *residual phase* follows the resolution of the active phase and is similar to the prodrome. Psychotic symptoms may persist during this phase, but at a lower level of intensity, and they may not be as troublesome to the patient. Active phase symptoms may occur episodically ('acute exacerbations'), with variable levels of remission seen between episodes. The frequency and timing of these episodes are unpredictable, although stressful situations may precede these relapses or, in some instances, drug abuse. The stages of schizophrenia are described in Table 57.4.

Relapses are often preceded by changes in thought, feeling, or behaviour noticed by the patient and family members. Symptoms preceding relapse may include dysphoria, seclusiveness, sleep disturbance, anxiety, and ideas of reference. Patients gradually accrue increased levels of morbidity in the form of residual or persistent symptoms and decrements in function from their premorbid status. Relatively severe psychosis is continuous and unrelenting in some patients. Schizophrenia may reach a plateau of severity at about 5 years without further deterioration.

Several long-term follow-up studies have been published using contemporary definitions of schizophrenia [15, 16]. One of the best known is the 'Iowa 500,' in which 186 schizophrenic patients admitted to the University of Iowa Psychiatric Hospital between 1934 and 1944 were followed up [15]. Twenty per cent were reported to be psychiatrically well at follow-up, but 54% had incapacitating psychiatric symptoms; 21% were married or widowed, but 67% had never married; 34% lived in their own home or with a relative, but 18% were in mental institutions (including transitional institutions such as halfway houses); 35% were economically productive, but 58% had never worked. The group experienced excessive mortality from both natural and unnatural causes, and more than 10% committed suicide.

In summary, modern outcome studies show that schizophrenia can be a devastating illness that may affect multiple aspects of a patient's life. However, some patients with schizophrenia will have a relatively good outcome and do not experience the severe deterioration sometimes considered to be a hallmark of the disorder.

Outcome predictors

It is difficult to predict outcome in individual patients based on these studies. However, factors associated with a good outcome include

Table 57.4 Typical stages of schizophrenia

Stages	Typical features
Prodromal	Insidious onset over months or years; subtle behaviour changes, including social withdrawal, work impairment, inappropriate affect, avolition, and strange ideation
Active phase	Psychotic symptoms develop, including hallucinations, delusions, or disorganized speech and behaviour. These florid symptoms are alarming and lead to medical intervention. Acute phase symptoms may re-emerge during the residual phase ('acute exacerbation')
Residual phase	Active phase symptoms are absent or no longer prominent. There is role impairment, negative symptoms, or attenuated positive symptoms

Table 57.5 Features associated with good and poor outcome

Feature	Good outcome	Poor outcome
Onset	Acute	Insidious
Duration	Short	Chronic
Mood symptoms	Present	Absent
Sensorium	Clouded	Clear
Premorbid function	Good	Poor
Marital functioning	Married	Never married
Psychosexual functioning	Good	Poor
Neurological functioning	Normal	Soft signs present
Structural brain abnormalities	None	Present
Parental education	High	Low
Family history/schizophrenia	Negative	Positive

acute onset, short duration of illness, lack of prior psychiatric history, presence of affective symptoms or confusion, good premorbid adjustment, steady work history, marriage, and older age at onset. Poor prognostic features include insidious onset, long duration of symptoms, affective blunting, obsessive–compulsive symptoms, assaultiveness, premorbid personality disorder, poor work history, celibacy, and young age at onset. Prognostic features in schizophrenia are summarized in [Table 57.5](#).

Schizophrenic patients are more likely to experience a good outcome now than 100 years ago. There are several possible explanations for this finding: (1) the illness has changed; (2) neuroleptic medication and other treatments have altered the natural history of the illness; or (3) our definitions of good outcome have changed. For example, good outcome now may include patients living in care facilities who have minimal symptoms but are clearly not well. For reasons that are not well understood, cross-cultural studies have shown that patients in less developed countries tend to have better outcomes than those in more developed countries [17]. It may be that a person suffering from schizophrenia is better accepted in less developed societies, has fewer external demands, and is more likely to be taken care of by family members. Women, in general, tend to have a better outcome than men in their response to medication and in long-term course.

Mechanisms of schizophrenia

Many thinkers have considered schizophrenia to be a neurocognitive disorder, with the various signs and symptoms reflecting the downstream effects of a fundamental cognitive deficit. Schizophrenia poses special challenges to the development of cognitive models because of its breadth and diversity of symptoms. The symptoms include nearly all domains of cognitive function: perception (hallucinations), inferential thinking (delusions), fluency of thought and speech (alogia), clarity and organization of thought and speech (formal thought disorder), motor activity (catatonia), emotional expression (affective blunting), ability to initiate and complete goal-directed behaviour (avolition), and ability to seek out and experience emotional gratification (anhedonia).

An initial survey of the diversity of symptoms might suggest that multiple brain regions are involved in schizophrenia, in a spotty

pattern much as once occurred in neurosyphilis. In the absence of visible lesions and known pathogens, investigators have turned to the exploration of models that could explain the diversity of symptoms through a single cognitive mechanism. The convergent conclusions of these different models are striking.

An approach some investigators have taken is to divide the symptoms into three broad groups: (1) disorders of willed action (which lead to symptoms such as alogia and avolition); (2) disorders of self-monitoring (which lead to symptoms such as auditory hallucinations of alien control); and (3) disorders in monitoring the intentions of others ('mentalizing') (which lead to symptoms such as formal thought disorder and delusions of persecution). These could represent a more general underlying mechanism—a disorder of consciousness or self-awareness that impairs the ability to think with 'meta-representations' (higher-order abstract concepts that are representations of mental states) [18–24].

One popular model suggests that the fundamental impairment in schizophrenia is an inability to guide behaviour by representations, often referred to as a defect in working memory [19]. *Working memory* involves the ability to hold a representation 'online' and perform cognitive operations in a flexible manner, to formulate and modify plans, and to base behaviour on internally held ideas and thoughts, rather than being driven by external stimuli. A defect in this ability can explain a variety of symptoms in schizophrenia. For example, the inability to hold a discourse plan in mind and monitor speech output may lead to disorganized speech and thought disorder; the inability to maintain a plan for behavioural activities could lead to negative symptoms such as avolition or alogia; the inability to reference a specific external or internal experience against associative memories (mediated by cortical and subcortical circuitry involving frontal/parietal/temporal regions and the thalamus) could lead to an altered consciousness of sensory experience that would be expressed as delusions or hallucinations. The model also explains the perseverative behaviour observed in studies using the Wisconsin Card Sorting Test and is consistent with the compromised blood flow to the prefrontal cortex in these patients. Overall, this model suggests a major role for prefrontal regions and their multiple distributed cortical, thalamic, and striatal connections in a fundamental cognitive function—representationally guided behaviour—that permits organisms to adapt flexibly to a changing environment and to achieve temporal and spatial continuity between past experiences and present and future actions.

Alternatively (or complementarily), the chapter author has used the clinical presentation of schizophrenia as a point of departure, postulating that the symptoms arise from 'cognitive dysmetria' [25, 26]. This refers to impaired connectivity between frontal, cerebellar, and thalamic regions as a consequence of a neurodevelopmental defect or perhaps a series of them. Motor dysmetria has been observed in schizophrenia since its original description by Kraepelin, and soft signs of poor co-ordination are reported in more contemporary studies [11].

More injurious, however, is the related 'cognitive dysmetria', which produces 'poor co-ordination' of mental activities. The word *metron* literally means 'measure'—a person with schizophrenia has a fundamental deficit in taking measure of time and space and in making inferences about interrelationships between him- or herself and others, or between the past, present, and future. He or she cannot accurately time input and output, and therefore cannot

co-ordinate the perception, prioritization, retrieval, and expression of experiences and ideas. This model has received extensive support from work with magnetic resonance imaging and positron emission tomography. (See Chapter 60 for more detail.)

The common thread in these observations is that schizophrenia reflects a disruption in a fundamental cognitive process that affects a specific circuitry in the brain [23, 24]. Various research teams may use different terminology and somewhat different concepts—meta-representations, representationally guided behaviour, information processing/attention, cognitive dysmetria—but they convey a common theme. Cognitive dysfunction in schizophrenia is an inefficient temporal and spatial referencing of information and experience as the person attempts to determine boundaries between self and non-self and to formulate effective decisions or plans that will guide him or her through the small-scale (speaking a sentence) or large-scale (finding a job) manoeuvres of daily living. This capacity is sometimes referred to as *consciousness*.

Investigators also converge on similar conclusions about the neuroanatomic substrates of the cognitive dysfunction. All agree that it must involve distributed circuits, rather than a single specific ‘localization’, and all suggest a key role for interrelationships among the prefrontal cortex, other interconnected cortical regions, and subcortical regions, particularly the thalamus and striatum (see Chapter 60).

Pathophysiology and aetiology

A consensus now exists among many clinicians and research investigators that schizophrenia is best conceptualized as a ‘multiple-hit’ illness similar to cancer. Individuals may carry a genetic predisposition, but this vulnerability is not ‘released’ unless other factors also intervene. Although the majority of these factors are considered environmental, in the sense that they are not encoded in DNA and could potentially produce mutations or influence gene expression, the majority are also biological, rather than psychological, and include factors such as birth injuries or nutrition [27]. Current studies of the neurobiology of schizophrenia examine a multiplicity of factors, including genetics, anatomy (primarily through structural neuroimaging), functional circuitry (through functional neuroimaging), neuropathology, electrophysiology, neurochemistry and neuropharmacology, and neurodevelopment.

Genetics

Evidence for a genetic contribution to schizophrenia is based on family studies, twin studies, studies of adoptees, and molecular genetic techniques. Summaries of individual family studies have shown siblings of schizophrenic patients to have about a 10% chance of developing schizophrenia, whereas children who have one parent with schizophrenia have a 5–6% chance. The risk of family members developing schizophrenia increases markedly when two or more family members have the illness. The risk of developing schizophrenia is 17% for persons with one sibling and one parent with schizophrenia, and 46% for children of two schizophrenic parents. Twin studies have been remarkably consistent in demonstrating high concordance rates for identical twins averaging 46%, compared to 14% concordance in non-identical twins. Adoption studies show that the risk for schizophrenia is greater in the biological relatives of

index adoptees who had schizophrenia than in the biological relatives of mentally healthy control adoptees.

Studies are now under way to illuminate the genetic underpinnings of schizophrenia at the molecular level (see Chapter 61 for more details). Researchers have implicated several different gene regions, but none has emerged as conclusive as yet. Because of implications for solving multiple key problems (diagnostic, prognostic, treatment choices), this is one of the central topics for schizophrenia research and it is likely to remain so for some time [28].

Neuropathology

A better understanding of neurodevelopment has helped shape contemporary post-mortem studies. During the second trimester, neurons in the fetal brain must migrate to the appropriate layers of the cortex, then connect with other groups of neurons to form functional networks. Other developmental processes include excessive proliferation of cells and dendrites, subsequently followed by pruning and programmed cell death (apoptosis) of subplate neurons; surviving cells remain as interstitial neurons (or ‘inter-neurons’) of the white matter. The resulting network of neurons and cytoplasmic processes is called the *neuropil*. Research suggests that schizophrenia could be related to disturbances in any of these phases of brain maturation, ranging from migration to apoptosis. Failure of the cells to migrate to their proper position may show up as ectopic grey matter or neuronal disarray in specific regions of the hippocampus.

Displacement of neurons and a paucity of neurons in the superficial layers in the rostral and intermediate portions of the entorhinal cortex of the parahippocampal gyrus have also been reported and have been attributed to faulty neuronal migration. More recently, researchers have observed displacement of interneurons in the frontal lobe cortex, including decreased cell density in the superficial white matter and increased cell density in the deeper white matter, findings also thought consistent with an alteration in the migration of subplate neurons or in the pattern of programmed cell death [29].

Neuropathology has also been used to explore whether abnormalities can be found in key candidate regions such as the thalamus or prefrontal cortex. Decreased cell density in the medial dorsal nucleus of the thalamus, a crucial nucleus that projects to the prefrontal cortex, thalamic abnormalities, and increased cell packing density in the prefrontal cortex have all been described. The latter finding is consistent with a loss of the surrounding neuropil and consequent shrinkage of the interneuronal space. A convergence of findings is beginning to emerge from the variable perspectives of structural and functional neuroimaging and neuropathology. These perspectives are all consistent with neurodevelopmental mechanisms and with abnormalities in frontal, temporal, and thalamic regions.

Neurodevelopmental influences

Several lines of evidence have supported speculation that schizophrenia is a neurodevelopmental disorder resulting from brain injury occurring early in life. For example, schizophrenic patients are more likely than non-schizophrenic control subjects to have a history of birth injury and perinatal complications, which could result in subtle brain injury, setting the stage for the development of schizophrenia [27]. Seasonality of birth in schizophrenic patients has also suggested to some a neurodevelopmental aetiology. Throughout the temperate northern latitudes, more people with schizophrenia are

born in winter months than at any other time. This suggests that some schizophrenic persons could have sustained central nervous system damage in the womb from a viral illness.

Evolutionary aspects

That schizophrenia persists in the human population despite the fact that the majority of people who develop it do not marry or procreate is fascinating. This observation should perhaps be coupled with another that has been less frequently noted and has not yet been systematically investigated—a substantial number of highly creative individuals have family members who are in the schizophrenia spectrum. The association between manic–depressive illness and creativity is well established, but most of this work has focused on literary or artistic creativity [30].

In the case of schizophrenia, there may be a link with scientific creativity, although the evidence at present is only anecdotal. However, an impressive number of Nobel laureates have an association with schizophrenia. Bertrand Russell had a son and a granddaughter who suffered from schizophrenia, as well as an aunt and an uncle who probably also suffered from this illness when it was simply called ‘insanity’. Albert Einstein had a son by his first wife who developed schizophrenia. John Nash, a recent Nobel laureate in economics, developed schizophrenia himself in his early 30s and also had a son who suffers from schizophrenia. James Joyce was emotionally aloof and cold and became increasingly disorganized artistically; his daughter Lucia suffered from hebephrenic schizophrenia. Isaac Newton was a solitary, chronically suspicious, and socially aloof man who had a variety of unusual interests and beliefs; he would probably be called schizotypal using modern nomenclature; however, he also had a psychotic break at age 40.

Coupled with the persistence of schizophrenia throughout history despite decreased fertility and procreation, this modest association between schizophrenia and ‘genius’ suggests that, perhaps like sickle-cell anemia, a predisposition to schizophrenia may convey a biological advantage in some situations.

Epidemiology and course of schizophrenia

Assen Jablensky

Introduction

Epidemiological research into schizophrenia aims to answer four essential questions:

- What is the 'true' frequency of the disorder in various populations, and how is it distributed across the various groups within populations?
- Do the incidence, manifestations, and course of schizophrenia vary in relation to factors of the physical and social environment?
- Who is at risk, and what forces determine or influence the risk of developing schizophrenia?
- Can the answers to these questions help explain what causes the disorder and how to prevent it?

Schizophrenia has been studied extensively from an epidemiological perspective since Kraepelin [1] introduced the concept of *dementia praecox* in 1896 [1–6]. In the first half of the twentieth century, epidemiological research into schizophrenia took two divergent paths. While European studies tended to focus on population distributions and genetic risks, North American researchers investigated the social ecology of the disorder. A variety of methods were explored and successfully applied by the pioneers of psychiatric epidemiology, and the contours of the epidemiological map of schizophrenia in Europe and North America were effectively laid down between the two World Wars. The early studies were carried out by dedicated researchers who often spent months or years collecting data 'door-to-door' in small communities. Close knowledge of the respondents, access to multigenerational records from local parish registers, and the co-operation of the community resulted in studies that remain landmarks of psychiatric epidemiology (Table 58.1).

During the last several decades, the scope of epidemiological studies of schizophrenia has expanded to include populations in Asia, Africa, and South America, about which little had been known previously. The World Health Organization (WHO) International Pilot Study of Schizophrenia [7] and its successor—the WHO 10-country epidemiological study [8]—were the first systematic investigations of the comparative incidence, clinical manifestations, and course of schizophrenia in both developing and developed countries. The WHO programme was an impetus for similar studies in India, China, the Caribbean, and Australia. Two major studies of psychiatric morbidity in the United States—the Epidemiological

Catchment Area project [9] and the National Comorbidity Survey [10]—generated data on the prevalence of DSM-III/IIIR schizophrenia and related disorders in representative population samples. In the 1980s and 1990s, epidemiological studies increasingly utilized existing large databases, such as cumulative case registers or birth cohorts, to test hypotheses about risk factors and began to include methods of genetic epidemiology. There is a current tendency towards integrating epidemiological approaches with other types of aetiological research in schizophrenia. This predicts an important role for epidemiology in the era of genetics and molecular biology of mental disorders.

Epidemiological methods in the study of schizophrenia

Measurement of the prevalence, incidence, and disease expectancy of schizophrenia depends critically on the sensitivity of the case-finding method (that is, its capacity to identify all affected persons in a given population) and the availability of a diagnostic instrument or procedure that selects 'true' cases (that is, those corresponding to an established clinical concept).

Case-finding

Case-finding designs fall into three broad groups: case detection in clinical populations, door-to-door surveys of population samples or whole communities, and birth cohort studies. Each method has its advantages and limitations.

While case-finding through the mental health services provides relatively easy access to a substantial proportion of all persons with schizophrenia, the cases in treatment may not be fully representative of all individuals with the disorder. Bias related to gender, marital status, socio-economic factors, culture, or ethnicity is known to affect the probability of being in treatment at a given time in a given setting, and generalizations about schizophrenia from hospital or clinic samples are liable to error. Some of the deficiencies of case-finding through service contacts are avoided in cumulative national or regional psychiatric case registers, which cover large, well-defined populations and can be linked to other population databases (for example, birth records). This makes registers efficient research instruments in low-incidence disorders such as schizophrenia.

Table 58.1 Historical landmarks in the epidemiology of psychoses

Author	Method	Target population	Case finding	Assessment
Koller (1895) [2]	The first case-control study of psychoses	Cases of psychosis and normal controls	Hospital and clinic records	Genealogical inquiry
Luxenburger (1928) [3]	Twin concordance analysis	Monozygotic and dizygotic twin pairs	Search of birth registers	Diagnosis: 'definite' and 'probable'
Brugger (1931) [4]	Census (door-to-door survey)	Area in Thuringia (population 37,561)	Hospital records and key informants	Personal examination of 'suspected' cases and controls
Klemperer (1933) [5]	Birth cohort study	Random sample ($n = 1000$) of all births in Munich, 1881–1890	Tracing of cohort members (44% successfully traced)	Personal examination or key informant interview (271 examined)
Essen-Möller <i>et al.</i> (1956) [6]	Census and follow-up surveys	Rural community ($n = 2550 + 1013$ new residents during follow-up)	Complete census; tracing of persons who had migrated out	Personal examination and re-examination of all residents

Surveys involve accounting for every person at risk within a defined community or a population sample in terms of either being or not being a case. Face-to-face interviews (and follow-up) of all residents in defined communities has been a feature of some high-quality research, especially in Scandinavian countries [6]. However, since the size of the populations surveyed in this way is limited, the number of detected cases of schizophrenia is usually too small to generate stable estimates of epidemiological parameters. Surveys of large populations involve two basic designs: a single-phase survey of a probability sample drawn from the general population; and a two-phase survey where a validated screening test is first applied to the entire population and only those scoring as screen-positive proceed to a full assessment. In the instance of schizophrenia, logistics dictates a choice between assessing large numbers less rigorously and investigating a smaller sample in greater depth. In the absence of a simple and valid screening procedure for schizophrenia, such as a biological or psychological test, the advantages of the two-phase survey may be offset by poor sensitivity or specificity of the screening device, which is usually a questionnaire or checklist.

The study of birth cohorts at ages when their members have passed through the greater part of the period of risk for onset of schizophrenia is usually done by face-to-face interviewing or by analysing available case register data. Well-characterized birth cohorts are among the best tools for the study of the incidence of schizophrenia and associated risk factors [11]. However, even in settings where the population is stable and mortality and morbidity are adequately monitored, the size of birth cohorts with prospectively collected data may not be sufficient for conclusive epidemiological inferences.

All this suggests that there is no single 'gold standard' of case-finding for schizophrenia that could be applied across all possible settings, and the assets and liabilities of particular case-finding procedures need to be evaluated in the context of each study. This makes the detailed reporting of case-finding methods a mandatory prerequisite for an 'evidence-based' epidemiology of schizophrenia.

Diagnosis

Variation in diagnostic concepts and practices always explains a proportion of the variation in the results of schizophrenia studies, especially if they involve different populations or different periods. In the late 1960s, the WHO International Pilot Study of Schizophrenia [7] examined diagnostic variation in schizophrenia across nine countries by comparing the diagnoses made by psychiatrists using

a clinical interview and diagnostic classification by a computer algorithm [12] utilizing the same interview data. The results demonstrated that in the majority of settings, psychiatrists were using comparable diagnostic concepts. The introduction of explicit diagnostic criteria and rules with the consecutive editions of DSM and the WHO's ICD-10 improved further the reliability of diagnosis but did not resolve all diagnostic issues, with implications for epidemiology. While ICD-10 and DSM-IV tended to agree well on the core cases of schizophrenia, they agree less well on the classification of atypical or milder cases. Such differences may be less important in clinical practice, but they present a problem for epidemiological and genetic studies. By providing more restrictive criteria for schizophrenia, both classifications aim to identify clinically similar cases and to minimize false-positive diagnoses. This is not an unequivocal advantage, since applying such criteria at case-finding may result in the rejection of potential cases which fail to meet the full set of criteria at initial assessment. Therefore, it is desirable to develop less restrictive screening versions of the DSM and ICD criteria for epidemiological research.

Instruments

The diagnostic instruments used in surveys which involve interviewing fall into two categories: fully structured interviews such as the Diagnostic Interview Schedule (DIS) [9] and the Composite International Diagnostic Interview (CIDI) [13], both written to match exactly the diagnostic criteria of DSM-III-R/IV and ICD-10; and semi-structured interview schedules, such as the Present State Examination (PSE) [12] and the Schedules for Clinical Assessment in Neuropsychiatry (SCAN) [14], which cover a broad range of psychopathology.

The DIS/CIDI type of instrument is reliable and capable of generating standard diagnoses of common mental disorders in a single-phase survey design. Its clinical validity in schizophrenia is less certain because symptoms may not be reported accurately or impairment may be underestimated by the respondent. In contrast, the PSE/SCAN allows a greater amount of psychopathological data to be elicited in a flexible clinical interview format, but its use in epidemiological studies presupposes the availability of clinically trained interviewers. While SCAN and other similar interviews are suitable as second-stage diagnostic instruments, there is still a need for a relatively simple and effective screening procedure for case-finding of schizophrenia in field surveys.

The epidemiological description of schizophrenia draws on extensive evidence available today on its frequency, age, and sex distribution in relatively large populations or geographical areas. Less than complete information is available on variations in its epidemiological characteristics that may be found in unusual or isolated populations.

Prevalence

Prevalence provides an estimate of the proportion of cases per 1000 persons at risk present in a population at a given time or over a defined period. Point prevalence refers to the 'active' (that is, symptomatic) cases on a given date or within a brief census period. Since asymptomatic cases (for example, persons in remission) will be missed in a point prevalence survey, it is useful to supplement the assessment of the present mental state with an enquiry about past episodes of the disorder to obtain a lifetime prevalence index. In schizophrenia, which tends to be a chronic course, estimates of point and lifetime prevalence will be closer to each other than in remitting illnesses.

An overview of selected prevalence studies of schizophrenia spanning over seven decades is presented in [Table 58.2](#) and in two systematic reviews of the literature [15, 16]. The studies differ in many aspects of methodology, but in the majority, they feature a high intensity of case-finding. Several studies are repeat surveys in which the original population was reassessed following an interval of 10 or more years (the resulting consecutive prevalence figures are indicated by arrows).

Most studies have produced point prevalence estimates in the range of 2.1–7.0 per 1000 population at risk and a lifetime prevalence of schizophrenia in the range of 15.0–19.0 per 1000. These figures should be considered with caution because of demographic differences between populations related to factors such as age-specific

mortality and migration. A systematic review of 188 studies in 46 countries, published between 1965 and 2002 [15], estimated the median value for point prevalence at 4.6 per 1000 persons and for a lifetime prevalence at 7.2 per 1000.

Certain populations and groups deviate markedly from the central tendency. A strikingly high prevalence of schizophrenia (2–3 times the national or regional average) has been found in geographically and genetically isolated populations, including small communities in northern Sweden and Finland [19, 25], while at the other extreme, virtual absence of schizophrenia and a high rate of depression have been claimed for the Hutterites of South Dakota, a Protestant sect whose members live in close-knit endogamous communities sheltered from the outside world [27]. Negative social selection for schizoid individuals who fail to adjust to the lifestyle of the majority and eventually migrate without leaving progeny has been suggested (but not definitively proven) as an explanation. Results of two surveys in Taiwan [28], separated by 15 years, pointed to a falling prevalence of schizophrenia (from 2.1 to 1.4 per 1000) in the context of major socio-economic change and an overall increase in total mental morbidity in the population.

The question about the extent of true variation in the prevalence of schizophrenia across populations has no simple answer. Methodological differences among studies, related to sampling, case-finding, and diagnostic assessment, are likely to account for a good deal of the observed variation [29].

Notwithstanding such caveats in the interpretation of survey findings, the prevalence rates are fairly similar in the majority of studies, though certain specific populations clearly deviate from the modal value. Even in those instances, however, the magnitude of the deviation is modest, compared with the 10- to 30-fold differences in prevalence observed in other multifactorial diseases (for example, diabetes, ischaemic heart disease, multiple sclerosis) across populations.

Table 58.2 Selected prevalence studies of schizophrenia

Author	Country	Population	Method	Prevalence per 1000 population at risk
Bøjholm and Strömberg (1983) [17]	Denmark	Island of Bornholm (n = 50,000)	Census interviews, repeat census	3.9 → 3.3
Böök (1953) [18] Böök <i>et al.</i> (1978) [19]	Sweden	Genetic isolate (n = 9000); age 15–50	Census interviews, repeat census	9.5 → 17.0
Crocetti <i>et al.</i> (1971) [20]	Croatia	Sample of 9201 households	Census of hospital records and interviews	5.9
Dube and Kumar (1972) [21]	India	Four areas in Agra (n = 29,468)	Census based on hospital and clinic records	2.6
Keith <i>et al.</i> (1991) [22]	United States	Aggregated population across five ECA sites	Sample survey; interviews	7.0 (point); 15.0 (lifetime)
Jeffreys <i>et al.</i> (1997) [23]	UK	London health district (n = 112,127)	Census; interview of sample (n = 172)	5.1
Jablensky <i>et al.</i> (2000) [24]	Australia	Four urban areas (n = 1,084,978)	Census, screen for psychosis; patient interviews	4.7 (point); 5.8 ^a (12 months)
Perälä <i>et al.</i> (2007) [25]	Finland	National sample (n = 8028)	Screen for psychosis, interviews, register and casenote data	10.0 (lifetime)
Morgan <i>et al.</i> (2014) [26]	Australia	Catchment areas with total population (n = 1,464,921)	Sample (n = 1642) of patients with psychoses in contact with mental health services	3.1 (point) 3.45 ^b (lifetime)

^a Schizophrenia and spectrum disorders.

^b All psychoses.

Incidence

While prevalence is a proportion, incidence is a rate (an estimate of the annual number of new cases in a defined population per 1000 persons at risk). Incidence is of greater interest for the study of risk factors than prevalence, since it represents the so-called force of morbidity (the probability of disease occurrence) in a given population and is closer in time to the action of antecedent or precipitating factors. The estimation of incidence depends critically on the ability to determine reliably the point of onset of the disorder. In the case of schizophrenia, the long prodromal period and the fuzzy boundary between the premorbid state and the onset of psychosis make this particularly difficult. In the absence of an objective biomarker of the disease, onset is usually defined as the point in time when clinical manifestations become recognizable and diagnosable according to specified criteria. The first hospital admission, which has been used as a proxy for disease onset in many studies, is not a robust indicator because of the variable time lag between the earliest appearance of symptoms and the first admission across treatment facilities and settings. A better approximation is provided by the first contact, that is, the point at which any psychiatric, general medical, or alternative 'helping' agency is accessed by symptomatic individuals for the first time. A limitation common to both first-admission and first-contact studies is that they produce rates of 'treated' incidence and miss symptomatic cases that do not present for assessment or treatment. This limitation can be overcome by periodically repeated door-to-door surveys of the same population or by longitudinal cohort studies.

Table 58.3 presents the essential features and findings of seven historical incidence studies of schizophrenia. Although these studies vary in details of their methodology, the variation of the reported rates in settings as different as Barbados and Dublin is relatively modest, in the range of 0.32 [38] to 0.57 [33] per 1000 population at risk. Studies using more stringent criteria, such as DSM-IIIR, DSM-IV, ICD-10, or *Catego* S+ [12], have reported incidence rates 2–3 times lower than those based on 'broad' criteria. A systematic review of data from some 160 studies from 33 countries, published between 1965 and 2001 [30] yielded a median value of 0.15 and mean value of 0.24 per 1000, with a 5-fold range of the rates and a tendency for more recent studies to report lower rates. Similar results have been reported in a systematic review and meta-analyses of schizophrenia incidence studies in England [31].

Considering the methodological differences among studies, generalizing about the incidence of schizophrenia from pooled data may be problematic [29]. To date, the only investigation that had applied a uniform design and common research tools to generate directly comparable incidence data for different populations was the WHO 10-country study [8]. Incidence counts in the WHO study were based on first-in-lifetime contacts with any 'helping agency' within defined areas (including traditional healers in the developing countries) which were monitored for new cases over a 2-year period. Potential cases and key informants were interviewed by clinicians using standardized instruments, and the timing of onset was ascertained for the majority of the patients. In 86% of the 1022 patients, the onset of diagnostic symptoms of schizophrenia was within the year preceding the first contact, and therefore, the first-contact incidence rate was adopted as a reasonable approximation to the 'true' onset rate. Two definitions of 'caseness' were used to determine incidence: a 'broad' clinical definition comprising ICD-9 schizophrenia and paranoid psychoses; and a more restrictive definition of PSE/*Catego* S + 'nuclear' schizophrenia manifesting with Schneiderian first-rank symptoms. The rates for eight of the catchment areas are shown in Table 58.4.

While the differences between the rates for 'broadly' defined schizophrenia (0.16–0.42 per 1000) were significant ($P < 0.001$), those for 'nuclear' schizophrenia were not, suggesting that the frequency of this diagnostic subgroup varies less across different populations. Replications of the design of the WHO 10-country study, including its research procedures and instruments, have been carried out, with similar results in India [36] and the Caribbean [38].

Disease expectancy (morbidity risk)

This is the probability that an individual born into a defined population will develop the disease if he or she survives the period of risk for that disease. In the instance of schizophrenia, the period of risk is usually defined as 15–54 years. If age- and sex-specific incidence rates are known, disease expectancy can be estimated directly by a summation of the age-specific rates within the period of risk. Alternatively, disease expectancy can be estimated indirectly from prevalence data (Table 58.5).

Table 58.3 Selected incidence studies of schizophrenia

Author	Country	Population	Method	Rate per 1000 population at risk
Ödegaard (1946) [32]	Cumulative national case register	Total population of Norway	All first admissions 1926–1935 ($n = 14,231$); statistical analysis	0.24 (hospital diagnoses)
Walsh (1969) [33]	Ireland	City of Dublin ($n = 720,000$)	First admissions	0.57 (males), 0.46 (females)
Murphy and Raman (1971) [34]	Mauritius	Total population ($n = 257,000$)	First admissions	0.24 (Africans); 0.14 Indian Hindus; 0.09 (Indian Moslems)
Helgason (1977) [35]	Iceland	Total population ($n = 221,799$)	First admissions (case register)	0.27
Rajkumar <i>et al.</i> (1993) [36]	India	Area in Chennai (Madras) ($n = 43,097$)	Key informants; door-to-door survey	0.41
Brewin <i>et al.</i> (1997) [37]	UK	City of Nottingham	Two cohorts of first contacts (1978–1980 and 1992–1994)	0.25 → 0.29 0.14 → 0.09
Mahy <i>et al.</i> (1999) [38]	Barbados	Total population ($n = 262,000$)	First contacts, interviews	0.32 (ICD-9)

Table 58.4 WHO ten-country study of schizophrenia

Country	Area	'Broad' definition (ICD-9)			'Narrow' definition (CATEGO S+)		
		Male	Female	All	Male	Female	All
Denmark	Aarhus	0.18	0.13	0.16	0.09	0.05	0.07
India	Chandigarh (rural area)	0.37	0.48	0.42	0.13	0.09	0.11
India	Chandigarh (urban area)	0.34	0.35	0.35	0.08	0.11	0.09
Ireland	Dublin	0.23	0.21	0.22	0.10	0.08	0.09
Japan	Nagasaki	0.23	0.18	0.20	0.11	0.09	0.10
Russia	Moscow	0.25	0.31	0.28	0.03	0.03	0.02
UK	Nottingham	0.28	0.15	0.22	0.17	0.12	0.14
United States	Honolulu	0.18	0.14	0.16	0.10	0.08	0.09

Reproduced from *Psychol Med Monogr Suppl.*, 20, Jablensky A, Sartorius N, Ernberg G, *et al.*, Schizophrenia: manifestations and course in different cultures. A World Health Organization ten-country study, pp. 1–97, Copy-right (1992), with permission from Cambridge University Press.

The estimates of disease expectancy produced by a number of studies are fairly consistent across populations and over time. Excluding outliers, such as the northern Swedish isolate [18, 19], they vary about 5-fold; in the WHO study [8], they range from 0.59% (Aarhus) to 1.8% (Chandigarh, rural area) for ICD-9 schizophrenia and from 0.26% (Honolulu) to 0.54% (Nottingham) for *Catego S* + 'nuclear' schizophrenia. The frequently cited modal estimate of lifetime disease expectancy for broadly defined schizophrenia at around 1% seems to be consistent with the evidence.

Associations with age and sex

Schizophrenia may have its onset at any age—in childhood as well as past middle age—although the vast majority of onsets fall within the 15–54 years of age interval. Onsets in men peak steeply in the age group of 20–24 years; thereafter, the rate of inception remains more or less constant at a lower level. In women, a less prominent peak in the age group of 20–24 years is followed by another increase in incidence in age groups older than 35. While the age-specific incidence up to the mid-thirties is significantly higher in men, the male-to-female ratio becomes inverted with age, reaching 1:1.9 for onsets after the age of 40 and 1:4, or even 1:6, for onsets after the age of 60. There seems to be no real 'point of rarity' between the symptomatology of late-onset schizophrenia and schizophrenia of early onset.

The sex differences in mean age at onset are unlikely to be an invariant biological characteristic of schizophrenia. For example,

within families carrying high genetic risk (two or more affected members), no significant differences in age at onset have been found between male and female siblings with schizophrenia. In some populations (for example, India and China), the male predominance in the frequency of onsets in the younger age groups is attenuated or even inverted [39, 40].

The question of whether the total lifetime risks for men and women are about the same, or different, has not been answered definitively. In the WHO 10-country study, the cumulated risks for males and females up to the age of 54 were found to be approximately equal [8]. Scandinavian studies which followed up population cohorts into very old age (over 80) reported a higher cumulated lifetime risk in women than in men [41].

Male–female differences have been described in relation to the premorbid history (better premorbid functioning in women), the occurrence of brain abnormalities (more frequent in men), course (a higher percentage of remitting illness episodes and shorter hospital stay in women), and outcome (higher survival rate in the community, less disability in women). However, there is no unequivocal evidence of consistent sex differences in the symptom profiles of schizophrenia, including the frequency of positive and negative symptoms. Generally, the sex differences described in schizophrenia are more likely to result from normal sexual dimorphism in brain development, as well as from gender-related social roles, rather than from sex-specific aetiological factors.

Table 58.5 Selected course and outcome studies of schizophrenia

Author	Country	Sample size	Follow-up years	Proportion of good outcome
Bleuler M (1978) [107]	Switzerland	208	23	20% complete remission; 33% 'mild defect'
Tsuang <i>et al.</i> (1979) [108]	United States	186	35	46% recovered or improved significantly
Ciampi (1980) [109]	Switzerland	289	37	20% recovered, 43% 'definitely improved'
Huber <i>et al.</i> (1980) [110]	Germany	502	22	26% recovered, 31% remission, 'mild defect'
Johnstone <i>et al.</i> (1990) [73]	UK	530	13	14% 'excellent'; 18.5% 'very good social adjustment'
WHO (2007) [74]	Developing countries	467	15–26	62.7% complete remissions; 55.5% never hospitalized during follow-up; 42.9% unimpaired social functioning during 75% of follow-up
WHO (2007) [74]	Developed countries	603	15–26	36.8% complete remissions; 8.1% never hospitalized during follow-up; 31.6% unimpaired social functioning during follow-up

Fertility, mortality, and comorbidity

Earlier studies reported low fertility in both men and women diagnosed with schizophrenia. The mean number of children fathered by men with schizophrenia in Sweden was 0.9, and the average number of live births over the entire reproductive period of women treated for schizophrenia in Norway between 1936 and 1975 was 1.8, compared with 2.2 for the general female population [42]. Yet this phenomenon is neither universal nor consistent over time. In the WHO 10-country study [8], the fertility of women with schizophrenia in India did not differ from that of women in the general population within the same age groups and geographic areas. Although men with schizophrenia continue to be reproductively disadvantaged, the fertility of women with schizophrenia has increased over the last decades, and this trend is likely to be sustained as a result of deinstitutionalization and the greater number of people with mental disorders being able to live in the community.

Excess mortality associated with schizophrenia has been well documented by studies on large cohorts. National case register data for Norway, 1926–1941 and 1950–1974, indicated that while the total mortality of psychiatric patients was decreasing, the relative mortality of patients with schizophrenia remained unchanged at a level higher than twice that of the general population [32]. A meta-analysis of 18 studies [43] estimated a crude mortality rate of 189 deaths per 10,000 population per year and a 10-year survival rate of 81%. Mortality among males was significantly higher than among females, and the difference was primarily due to an excess in suicides and accidents. Unnatural causes apart, the leading causes of death among schizophrenia patients are similar to those in the general population, with the exception of significantly lower-than-expected cancer morbidity and mortality, especially for tobacco-related malignancies in males with schizophrenia [44]. This puzzling phenomenon has been replicated by several case register and record linkage studies [45, 46] and does not appear to be an artefact. Its causes remain unknown, though protective effects of both genes and anti-psychotic pharmacological agents have been proposed.

The single most common cause of death among schizophrenia patients at present is suicide (aggregated standardized mortality ratios of 9.6 for males and 6.8 for females), which accounts for 28% of the excess mortality in schizophrenia [47]. The suicide rate in schizophrenia patients is at least equal to, or may indeed be higher than, the suicide rate in major depression. Several risk factors, relatively specific to schizophrenia, have been suggested: being young and male; experiencing multiple relapses and remissions; comorbid substance use; awareness of the deteriorating course of the condition; and loss of faith in treatment. Data from successive patient cohorts in Denmark [48], Scotland [49], and Western Australia [50] suggested an alarming trend of increasing mortality in first-admission patients with schizophrenia. Particularly striking was the standardized mortality ratio of 16.4 for males with schizophrenia in the first year after diagnosis. In the Australian study, suicide risk was highest in the first 7 days after discharge from inpatient care. These trends seem to parallel the significant reductions in the number of psychiatric beds and the concomitant pressure for early patient discharge. Whether the increases in suicide mortality are associated with the shift in the management of schizophrenia from hospital to community care remains to be established.

Comorbidity

There is significant comorbidity in schizophrenia, comprising: (1) common medical problems and diseases that affect schizophrenia patients more frequently than attributable to chance; and (2) certain rare conditions or abnormalities which tend to co-occur with the disorder.

Physical disease is common but tends to remain often undetected and underdiagnosed. Between 46% and 80% of inpatients with schizophrenia, and between 20% and 43% of outpatients, have been found in different surveys to have concurrent medical illnesses [51]. Persons with schizophrenia, and especially those who are homeless or injection drug users, are at increased risk for potentially life-threatening communicable disease, such as HIV/AIDS, hepatitis C, and tuberculosis [52]. Among the chronic non-communicable diseases, patients with schizophrenia have significantly higher-than-expected rates of diabetes, arteriosclerosis, and ischaemic heart disease, which are increasingly contributing to their high mortality rate [54–56]. Obesity and concomitant metabolic syndrome involving insulin resistance are at present common problems in schizophrenia patients. Although a high incidence of diabetes in schizophrenia patients had been described long before the introduction of neuroleptic treatment, a contributing role for some of the drugs with antagonist properties at histamine and serotonin receptors has not been ruled out.

Some rare genetic or idiopathic disorders, such as metachromatic leukodystrophy, acute intermittent porphyria, and coeliac disease, as well as dysmorphic features such as high-steeped palate, malformed ears, and other minor physical anomalies, have also been reported to co-occur with schizophrenia [57, 58]. On the other hand, several studies have found a lower-than-expected rate of rheumatoid arthritis in schizophrenia patients [59]. A recent joint study by the Psychiatric Genomic Consortium and the Rheumatoid Arthritis Consortium analysed a large sample of cases and controls for the two disorders and concluded that the negative relationship between them reflects, 'at least in part', genetic factors [60].

Substance abuse

Substance abuse is at present by far the most common associated health problem among patients with schizophrenia [61] and may involve any drug of abuse or a polydrug combination. It seems, however, that the addictive use of cannabis, stimulants, and nicotine is disproportionately high among schizophrenia patients and may be linked to the underlying neurobiology of the disorder. In a nationwide sample of patients with psychotic disorders in Australia [24], a lifetime diagnosis of comorbid drug abuse or dependence was made in 36.3% of males and 15.7% of females with schizophrenia (compared to 3.1% and 1.3%, respectively, in the general population). In addition to poor prognosis of schizophrenia in patients with heavy cannabis use, a systematic review of published data on cannabis exposure and the onset of schizophrenia [62] concluded that early use increased the risk of psychosis in a dose-related manner, especially in persons at high genetic risk of schizophrenia [63]. Similarly, stimulants tend to exacerbate acute psychotic symptoms in over 50% of schizophrenia patients [64]. The prevalence of cigarette smoking among schizophrenia patients is, on average, 2–3 times higher than in the general population [24], but the evidence regarding any effects

of nicotine use specifically on the onset and course of schizophrenia is equivocal.

Geographical and cultural variation

To date, no population or culture has been identified in which schizophrenic illnesses do not occur. There is also no strong evidence that the incidence of schizophrenia either is uniform or varies widely across populations, provided that the populations being compared are large enough to minimize the effects of small-area variation. The evidence that specific psychosocial or cultural factors play an aetiological role in schizophrenia is also inconsistent [65–67]. However, there are well-replicated findings of variations in the course and outcome of schizophrenia across populations and cultures that involve, above all, a higher rate of symptomatic recovery and a lower rate of social deterioration in traditional rural communities. Data supporting this conclusion were provided by the WHO studies [7, 8], which found a higher proportion of recovering or improving patients in developing countries such as India and Nigeria than in developed countries. Sampling bias (for example, a higher percentage of acute-onset schizophreniform illnesses of good prognosis among Third World patients) was not a likely explanation. A better outcome in developing countries was found in patients with various modes of onset, and the initial symptoms of the disorder did not distinguish good-outcome from poor-outcome cases. What causes such differences in the prognosis of schizophrenia remains largely unknown. The follow-up in the WHO studies demonstrated that the outcome of paranoid psychoses and affective disorders was also better in developing countries. Such a general effect on the outcome of psychiatric disorders may result from psychosocial factors such as availability of social support networks, non-stigmatizing beliefs about mental illness, and positive expectations during the early stages of psychotic illness, as well as from unknown genetic or ecological (including nutritional) factors influencing brain development.

Variations in the course and outcome of schizophrenia

The course of schizophrenia is as variable as its symptoms. Since the great majority of schizophrenic patients are today receiving pharmacological treatment, current and recent studies may not reflect the 'natural' course and outcome of the disorder.

The 'natural history' of schizophrenia before the neuroleptic era

Studies in urban communities in Scotland [68] and India [69] and a study in a rural community in China [70] estimated the proportions of never-hospitalized schizophrenic patients at 6.7%, 28.7%, and 30.6%, respectively. About half of the Scottish patients had been prescribed neuroleptics by their general practitioners, while the Indian and Chinese patients had been virtually untreated. In all three settings, the outcomes of these samples were heterogeneous, but they did not differ much from the outcomes in treated patients. In a historical study of 70 Swedish patients with first admissions in 1925, lifetime records were retrieved and re-diagnosed in accordance with DSM-III criteria [71]. The outcome was rated as 'good' in 33% (but no patient was considered as completely recovered), as 'profoundly deteriorated' in 43%, and as intermediate in 24%.

A long-term perspective on the course of schizophrenia over successive generations is provided by a meta-analysis of 320 outcome studies on schizophrenia or *dementia praecox* published between 1895 and 1992, including a total of 51,800 subjects [72]. Overall, about 40% of the patients were reported as improved after an average length of follow-up of 5.6 years. There was a significant increase in improvement during the period 1956–1985, compared to 1895–1955, clearly related to the introduction of neuroleptic treatment, but a secular trend towards better outcomes with every successive decade had been present for much longer. Coupled with the virtual disappearance of the most 'catastrophic' forms of schizophrenia (for example, *'lethal catatonia'*), these observations suggest that a transition to a less deteriorating course of the disorder had occurred prior to modern pharmacological treatment. Among the factors explaining this shift, one should consider improvements in general care and progressive changes in attitudes and hospital regime which occurred in a number of institutions on both sides of the Atlantic in the 1930s and 1940s, as well as heightened expectations that psychosocial measures, such as psychotherapy or rehabilitation, could result in a cure in some cases.

Patterns and stages in the course of schizophrenia

The marked heterogeneity in the course of schizophrenia can be reduced to a limited number of patterns into which cases tend to cluster over time. In earlier long-term follow-up studies, 8–12 different categories of course had been described. These classifications were derived from empirical observation, rather than statistical modelling. They conflated into single categories: the mode of onset, longitudinal aspects such as frequency and duration of psychotic episodes, remissions, and end states. Treating these various aspects of the longitudinal profile of the illness as independent dimensions is today recommended [73]. However, the complexity of statistical modelling of the course of schizophrenia is such that the development of a classification of course that would be both useful in clinical practice and rigorous in a statistical sense may not be easy to achieve. Therefore, a heuristic compromise between these two requirements should, as a minimum, define operationally and assess separately: (1) the number and duration of discrete episodes of illness; (2) the predominant clinical features of each episode (for example, psychotic or affective); and (3) the number and length of remissions and their quality (presence/absence of residual negative or deficit symptoms and signs). By combining these variables, several patterns of course have been derived that have found good empirical support in international follow-up studies: (1) single psychotic episode followed by complete remission; (2) single psychotic episode followed by incomplete remission; (3) two or more psychotic episodes, with complete remissions between episodes; (4) two or more psychotic episodes, with incomplete remissions between episodes; and (5) continuous (unremitting) psychotic illness. With some modifications, these longitudinal patterns have been incorporated into research tools such as the SCAN [14].

WHO studies on course and outcome of schizophrenia

A transcultural investigation co-ordinated by the WHO [74]—the International Study of Schizophrenia (ISOs)—which involved 18 research centres in 14 countries, achieved the tracing of 75% of cases that had been assessed in the earlier WHO studies and also included additional patient cohorts from mainland China, Hong Kong, and

India. Follow-up data were collected on a total of 1633 cases, and 890 patients were re-interviewed at either 15- or 25-year follow-up since their first assessment. The main results were as follows. Firstly, there was striking heterogeneity in the course of schizophrenia. Patients with similar baseline clinical characteristics developed a spectrum of outcomes, ranging from clinical and social recovery after a single psychotic episode to chronic unremitting psychosis and severe impairment. However, the overall rate of recovery was 48% at the 15-year follow-up and as high as 54% at the 25-year follow-up. Secondly, the frequency of both relapses and remissions increased over time. Regardless of this, the cumulative proportion of time during which patients had psychotic symptoms tended to remain stable or decrease. At 15- and 25-year follow-up, 42% and 41%, respectively, had been free of psychotic symptoms for the past 2 years. Thirdly, while the percentage of patients with continuous deteriorating illness was similar across the sites of the WHO studies, the outcome was generally better in the developing countries. This could not be attributed to any particular clinical subtype of the disorder, for example to cases of acute onset, since it applied equally to cases of slow, insidious onset. The main outcome difference across the study areas was in the average length of symptom-free remissions. No single factor accounting for this difference could be identified, but better integration of the mentally ill person in the domestic economy of traditional rural communities could be part of the explanation. It should be noted, however, that increasing social and economic stresses experienced by both urban and rural communities in many developing countries may have eroded the traditional support systems, resulting in worse outcomes, as suggested by several recent studies. Fourthly, whether the better outcome of schizophrenia in developing countries is 'transportable' following migration to other settings remains unclear. Data on immigrants treated for first episodes of schizophrenia in the UK suggest that while Asian patients have lower relapse and readmission rates than British-born whites, Afro-Caribbean immigrants show a higher rate. Marked social and family structure differences between the Asian and Afro-Caribbean immigrant communities suggest that the likelihood of a more benign course may depend on the degree to which the immigrant group has retained its traditional values and intra-group cohesion [75].

Factors maintaining the incidence of schizophrenia in populations

Coupled with the evidence that the lifetime risk of the disorder (about 1%) is similar across populations, the question about factors that sustain the incidence of schizophrenia despite reduced reproductive fitness remains open. Schizophrenia is a complex polygenic disorder, with incomplete or variable penetrance of the genotype and widespread locus and allelic heterogeneity. The polygenic model implies that loss of risk alleles resulting from the lower reproductive fitness of affected individuals would have a negligible effect on the overall gene pool in the population. Previous conjectures that *de novo* germ-line mutations inherited from an ageing father may be responsible for a substantial proportion of incident cases of schizophrenia [76] is difficult to reconcile with current knowledge that mutation rates for most human genes are within the range of 10^{-6} – 10^{-5} per generation, that is, their contribution to the maintenance of schizophrenia in the population would be insignificant. Considering

that both multiple genes and multiple exogenous factors are likely to be involved in the causation of schizophrenia, neither increased fertility in asymptomatic carriers of the risk genes nor paternal inheritance of germ-line mutations appear to be either necessary or sufficient for the persistence of the disorder.

Genetic risk: necessary and sufficient?

Family aggregation of schizophrenia is at present the only epidemiologically well-established risk factor for the disorder, with a relative risk for first-degree relatives of persons with schizophrenia in the range of 6–17% [78]. Allowing for diagnostic variation, the risk estimates generated by different studies are similar and suggest a general pattern of descending risk as the proportions of shared genes between any two individuals decrease. Although heritability of schizophrenia (commonly estimated at about 80%) provides the basis for the search of specific genes, gene networks, and regulatory polymorphisms involved in schizophrenia causation, the extent to which genetic vulnerability alone is necessary and sufficient to produce the disorder remains unclear. While an environmental contribution to the aetiology of schizophrenia is highly plausible, the evidence in support of it is inferential, typically proceeding from the early observation that the concordance for schizophrenia in monozygotic twins (sharing 100% of their genes) is only about 50%. The majority of investigators now agree that genes and environments should be studied jointly, and three models of conjunction have been proposed [79]: (1) the effects of predisposing genes and environmental factors are additive and increase the risk of disease in a linear fashion; (2) genes modulate the sensitivity of the brain to environmental insults; and (3) by fostering certain personality traits and associated behaviour, genes influence the likelihood of an individual's exposure to stressful environments.

Environmental insults during gestation and fetal development

A winter–spring excess of schizophrenic births was first described in 1929 [80] and since then reported by numerous studies, mostly in the northern hemisphere (southern hemisphere data are less consistent). Though some of these studies did not definitively prove or rule out a seasonal effect, winter–spring births were associated with a mild, but significant, increase in the relative risk (RR) for schizophrenia (RR = 1.11; CI 1.06–1.18) in a large population cohort from Denmark [81]. Thus, birth seasonality appears to be a robust finding, though few biologically testable hypotheses have been advanced to explain it. One of them is the seasonally increased risk of intrauterine exposure to viral infection *in utero*. Exposure to influenza has been implicated as a risk factor since a report that a significant proportion of adult schizophrenia in Helsinki was associated with presumed second-trimester *in utero* exposure to the 1957 A2 influenza epidemic [82]. Numerous studies, attempting to replicate the link between maternal influenza and schizophrenia, have since reached conflicting results, with negative findings reported from an increasing number of studies based on large population samples [83], as well as studies including data on schizophrenia risk in the offspring of women with prospectively recorded influenza infection during pregnancy [84]. However, positive associations between schizophrenia in the offspring and maternal infection during pregnancy has been reported for rubella [85] and toxoplasmosis [86], and the issue of prenatal infection contributing to schizophrenia

risk merits further study. Maternal obstetric complications, ranging from placental abnormalities in the first trimester of pregnancy to diabetes, pre-eclampsia, perinatal hypoxia, and low birthweight, are widely regarded to be risk factors in schizophrenia. Population-based studies [87] using prospectively recorded obstetric data tend to report conflicting or inconclusive results, with generally small effect sizes (odds ratio of <2) for any positive findings [88]. However, several birth cohort studies with long-term follow-up have found significantly increased risk of adult schizophrenia in individuals who had survived severe, mainly hypoxic perinatal brain damage [88]. Birthweight (adjusted for gestation) is another factor that may have a complex relationship with schizophrenia risk. A large cohort study in Sweden [89] found significant hazard ratios of 7.03 for males of low birthweight (<2500 g) and 3.37 for those of high birthweight (>4000 g). It remains unclear, however, if severe obstetric complications, such as perinatal hypoxia or low birthweight, are capable of raising substantially the risk of schizophrenia in an adult in the absence of increased genetic risk. Maternal schizophrenia is associated with a higher rate of pregnancy complications, including low birthweight [90], but it is not known if the effects of genetic liability and obstetric complications on schizophrenia risk in the offspring are additive or interactive. It is also possible that genetic predisposition sensitizes the developing brain to lesions resulting from randomly occurring, less severe obstetric complications. Such gaps in knowledge or inconsistencies among research findings point to the clarification of these issues as a priority for epidemiological research.

Early developmental antecedents of schizophrenia

Children at high genetic risk for schizophrenia (that is, having parents or other first-degree relatives with the disorder) tend to show early signs of aberrant neurodevelopment, including ventricular enlargement on computerized tomography [91] and decreased activation in the prefrontal and parietal regions of the heteromodal association cortex on functional magnetic resonance imaging [92]. The results of such imaging studies are limited by small sample size and may not be generalizable. However, population-based or cohort studies, such as the National Child Development Study in the UK, have demonstrated a higher incidence of abnormal motor and speech development before 2 years of age and of soft neurological signs (poor motor control, co-ordination, and balance), non-right-handedness, and speech defects between the ages of 2–15 [93]. Cognitive deficits involving verbal memory, sustained attention, and executive functions, as well as abnormalities in event-related brain potentials and oculomotor control [94–96], are common in patients with schizophrenia and antedate the onset of clinical symptoms. They also occur in a proportion of their clinically normal biological relatives but are rare in control subjects drawn from the general population. Their specificity to schizophrenia needs to be investigated in larger population samples. Should such *endophenotypes* be validated as biological markers of schizophrenia, the power of risk prediction at the level of the individual is likely to increase substantially. In a Swedish cohort study [97] involving a 15-year follow-up of 109,643 men conscripted into the army at the age of 18–20, the individuals who subsequently developed schizophrenia were compared with the rest of the cohort on the performance of IQ-related tests and tasks at the time of conscription. Controlling for potential confounders, the risk of schizophrenia was found to increase linearly with the

decrement of IQ. The effect was mainly attributable to poor performance on verbal tasks and tests of reasoning.

Premorbid social impairment

Individuals who develop schizophrenia as adults are more likely to manifest difficulties in social interaction during childhood and adolescence than individuals who do not develop schizophrenia. Population-based evidence of early socialization difficulties (school problems, social anxiety, and preference for solitary play) in children who develop schizophrenia as adults is provided by the prospective study of a national birth cohort in the UK [93]. It should be noted, however, that the early behavioural traits that tend to be associated with schizophrenia in adult life have low specificity and their predictive value is limited.

Early rearing environment

Support for an effect of the early rearing family environment on the risk of developing schizophrenia is provided by a study of a Finnish sample of adopted children born to mothers with schizophrenia (a high-risk group) and a control sample of adoptees at no increased genetic risk [98]. Though the rates of adult psychosis or severe personality disorder were significantly higher in the high-risk group, compared with the control group, the difference was entirely attributable to a subset of the high-risk children who grew up in dysfunctional or otherwise disturbed adoptive families—a result consistent with the gene–environment model of genetic influence on a person's sensitivity to psychosocial adversity.

The urban environment

Earlier hypotheses that urban environments increase the risk of psychosis, either by contributing to causation (the breeder effect) or by attracting vulnerable individuals (the drift effect), have been more recently revived in the light of epidemiological findings suggesting that urban birth is associated with a moderate, but statistically significant, increase in the incidence of schizophrenia, affective psychoses, and other non-affective psychoses [99]. It remains unclear whether the effect is linked to a factor operating pre- or perinatally, or a factor influencing postnatal development.

Socio-economic disadvantage

Since the 1930s, numerous studies in North America and Europe have consistently found that the economically disadvantaged social groups contribute disproportionately to the first-admission rate for schizophrenia. Two explanatory hypotheses of social causation ('breeder') and of social selection ('drift') were originally proposed [100]. According to the social causation theory, greater socio-economic adversity, characteristic of lower-class living conditions, could precipitate psychosis in genetically vulnerable individuals who have a restricted capacity to cope with complex or stressful situations. However, another study [101] found that the social class distribution of fathers of schizophrenic patients did not deviate from that of the general population, and that the excess of low socio-economic status among schizophrenic patients was mainly attributable to individuals who had drifted down the occupational and social scale prior to the onset of psychosis. As a result, aetiological research in schizophrenia in recent decades has tended to ignore such 'macrosocial' variables. However, the possibility remains that

social stratification, socio-economic status, and acculturation stress are contributing factors in the causation of schizophrenia.

Migrants and ethnic minorities

An exceptionally high incidence rate of schizophrenia (about 6.0 per 1000) has been reported to be found in the African-Caribbean population in the UK [102, 103]. The excess morbidity is not restricted to recent immigrants and is higher in the British-born second generation of migrants. Similar findings of nearly 4-fold excess over the general population rate have been reported for the Dutch Antillean and Surinamese immigrants in Holland [104]. The causes of this phenomenon remain obscure. Incidence studies in the Caribbean do not indicate any excess morbidity in the indigenous populations from which migrants are recruited. Explanations in terms of biological risk factors have found little support. A finding in need of replication is the significant increase of schizophrenia among the siblings of second-generation African-Caribbean schizophrenia patients, compared with the incidence of schizophrenia in the siblings of white patients [105]. Such 'horizontal' increase in the morbid risk suggests that an environmental factor may be modifying the penetrance of the genetic predisposition to schizophrenia carried by a proportion of the African-Caribbean population. Psychosocial hypotheses involving acculturation stress, demoralization due to racial discrimination, and blocked opportunities for upward social mobility have been suggested but not yet definitively tested.

Can schizophrenia be prevented?

Increasing investment in early diagnosis and treatment of schizophrenia raises important questions of whether people likely to develop schizophrenia can be reliably recognized at the prodromal stage, prior to the onset of symptoms, or even earlier, with a view to pharmacological, cognitive, or social interventions aiming to primary prevention of the disorder [111]. Early diagnosis and treatment of symptomatic cases can have an effect on the short- or medium-term outcome, but the population-wide detection of people at risk is problematic. Screening young age groups in the population for predictors, such as family history of psychosis, obstetric complications, or abnormal eye tracking, is likely to end up in multiple false-positive and false-negative results and a generally low positive predictive value. Problems of reliability of measurement apart, population-based screening will pose huge practical and ethical problems of having to treat a large number of individuals who do not have the disorder and missing many others who eventually will develop the disorder. While pre-symptomatic detection and preventative intervention in schizophrenia do not, at present, appear to be feasible, secondary prevention, aiming at optimizing the treatment of early symptomatic cases and supporting their social, educational, or occupational functioning, has the potential for improving the prognosis and outcome of the disorder.

Summary and conclusions

After many decades of epidemiological research, essential questions about the nature and causes of schizophrenia still await answers [106]. However, two major conclusions stand out.

- Schizophrenia is characterized by phenotypic variability and likely genetic heterogeneity. While the clinical concept of schizophrenia as a broad syndrome with some internal cohesion and characteristic patterns of course over time is well supported by epidemiological evidence, its dissection into modular subtypes with specific neurocognitive and neurophysiological underpinnings is beginning to be perceived as a promising approach in schizophrenia genetics. The study of endophenotypes cutting across the conventional diagnostic boundaries may reveal unexpected patterns of associations with symptoms, personality traits, or behaviours, as well as genetic polymorphisms, providing epidemiology with rich material for future hypothesis testing at the population level.
- No single environmental risk factor of major effect on the incidence of schizophrenia has yet been established. Further studies using large samples are required to evaluate potential risk factors, antecedents, and predictors for which the present evidence is inconclusive. Assuming that multiple environmental risk factors of small to moderate effect will eventually be identified, the results will complement those of genetic research.

Genetics of schizophrenia

Kimberley M. Kendall, James T.R. Walters, and Michael C. O'Donovan

Genetic epidemiology

The main focus of this chapter is the progress that has occurred over the past 10 years in identifying molecular genetic risk factors for schizophrenia. The recent successes have required persistence in the face of considerable adversity. Some of the barriers to progress reflect difficulties inherent in genetic studies of almost any complex disorder, medical or psychiatric. Others reflect the particular challenges of studying heterogeneous psychiatric disorders where the diagnostic categories are, at best, of uncertain validity (see Chapters 7 and 8). That molecular genetic research in schizophrenia has been allowed to continue, and ultimately flourish, owes much to the work of genetic epidemiologists who, over many decades, have consistently documented a substantial heritable component to variation in liability to schizophrenia. This section provides a brief consideration of that essential underpinning work; readers with a particular interest in this work, much of it historical, are directed to authoritative reviews elsewhere [1–3].

Family studies

Family studies spanning much of the 1900s demonstrated that first-degree relatives of index cases with schizophrenia (probands) had a higher risk, about 10-fold, of developing the disorder than the population at large [1]. The validity of these early studies was often questioned, given methodological shortcomings, for example lack of control groups, biased ascertainment, diagnoses that were not blind to family relationships, and diagnoses which were unreliable in the absence of operational diagnostic criteria. However, from the 1980s onwards, a wave of more sophisticated studies addressed these deficiencies; overall, they consistently supported the earlier work [1, 3]. For example, the risk for siblings of probands with schizophrenia is around 8–10% (Fig. 59.1). At first inspection, the lifetime risk of schizophrenia among parents of an affected individual (6%) seems low, compared with other first-degree relatives (siblings and offspring). However, due to low fecundity associated with schizophrenia [4], parents as a general class have a low risk of the disorder, and when risk is expressed relative to population baseline rates, the relative risk is similar (around 9–10) for parents, siblings, and children of an affected individual [5].

Compared with earlier plots of morbid risk [1], the inclusion of newer data in Fig. 59.1 results in two major differences. One concerns

the risk in twins (see Twin studies, p. 587). The other concerns the risk to offspring of two affected parents, which was previously estimated to be around 48%, based on a small number of observations, but a more recent (large) study puts this at around 28%, increasing to 39% when schizophrenia-related disorders are included [6].

Twin studies

The principles underlying the many twin studies conducted in psychiatric disorders are the same. Monozygotic (MZ) twins are perfectly correlated for all genetic loci that show variation in the population, whereas dizygotic (DZ) twins are, on average, 50% correlated. Assuming that the extent to which MZ and DZ twins share their environment is roughly equal, higher concordance in MZ twins suggests the disorder is, at least partly, genetic. Concordance of less than 100% in MZ twins suggests environmental factors or chance (including *de novo* mutation) also play a role. Early twin studies showed higher concordance in MZ twins, compared to DZ twins, but as with family studies, methodological concerns left these open to criticism. However, the most recent wave of studies have addressed earlier methodological limitations.

In a pooled sample analysis of four modern-era twin studies, proband-wise concordance rates for (strict and probable) DSM-III-R schizophrenia were 50% in MZ twins and 4.1% in DZ twins [7]. Modelling suggested that variance in population risk was best attributed to additive genetic factors acting together with specific (in the sense of exposures affecting only one twin) environmental factors. Heritability, the component attributable to genes, was 88%, although a more recent meta-analysis of a larger number of twins provided a lower estimate of around 81% [8]. Surprisingly, the lifetime risk for schizophrenia among DZ co-twins of affected probands seems considerably lower than that for non-twin siblings for reasons that are not fully established. The substantial difference in concordance between MZ and DZ twins is suggestive of influences from gene–environment correlation and/or non-additive genetic inheritance [9].

Adoption studies

As both the genetic and environmental backgrounds of family member twins are, at least in part, correlated, it is difficult to separate definitively the contributions of genetic and environmental factors through family and twin study designs alone. Moreover, the

Fig. 59.1 Lifetime risk of schizophrenia according to the relationship to an affected individual.

Source: data from Gottesman II, *Schizophrenia Genesis: The Origins of Madness*, Copyright (1991), WH Freeman; *Am J Med Genet*, 97(1), Cardno AG, Gottesman II, Twin studies of schizophrenia: from bow-and-arrow concordances to star wars Mx and functional genomics, pp. 12–17, Copyright (2000), John Wiley and Sons; *Arch Gen Psychiatry*, 67(3), Gottesman II, Laursen TM, Bertelsen A, et al., Severe mental disorders in offspring with 2 psychiatrically ill parents, pp. 252–7, Copyright (2010), American Medical Association.

validity of twin studies has repeatedly been criticized, based on the possibility of greater correlations between the prenatal and postnatal environments of MZ than DZ twins. Thus, a third design based on adoption studies has formed an important foundation for the hypothesis of an important role for genes in the aetiology of schizophrenia. The premise underpinning the adoption design is that if genes play a role in a phenotype, adoptees should show evidence for phenotypic correlation with their biological relatives, despite being removed from a correlated environment.

Detailed discussion of the early adoption literature is given elsewhere [1, 10]. Briefly, adoptee studies have shown that the adopted-away children of people with schizophrenia have higher rates of schizophrenia and schizophrenia spectrum disorder than adoptees of controls. Adoptive family studies have shown that the biological relatives of affected adoptees have higher rates of the disorder than either their adoptive relatives or the relatives of unaffected adoptees. And one cross-fostering study showed that adoptees of control parents raised by a parent with schizophrenia had a lower risk of the disorder than the biological offspring of a person with schizophrenia raised by adoptive parents without the disorder.

Most adoption studies were conducted prior to the use of modern operational diagnostic criteria, so particularly notable is a study based on the Finnish national register, which used such criteria from the outset. Narrowly defined schizophrenia only showed a trend level difference in the adopted-away children of mothers with the disorder, compared with those of controls (5.3% vs 1.7%, respectively). However, the risk for schizophrenia spectrum disorders (22.46%) among adoptees whose mothers had schizophrenia spectrum disorder was much higher than the adoptees of controls (4.36%), supporting the hypothesis of a genetic contribution to a broader schizophrenia-related phenotype [11]. In the most recent study incorporating adoption data, adoptees with an affected

biological parent had an elevated relative risk (13.7) of developing schizophrenia [12] in the range expected for first-degree relatives of an affected proband.

Overall, the findings from adoption studies of multiple designs are consistent with those from other genetic epidemiological approaches; while the validity of the assumptions underpinning each study design can be debated, this consistency provides a strong and coherent body of evidence for an important contribution of genetic inheritance to the aetiology of schizophrenia.

Genetic epidemiology and risk across disorders

The challenges of psychiatric diagnosis, and the evidence for the validity or otherwise of the boundaries that separate diagnostic categories or that delineate subtypes, are discussed in Chapters 7 and 8. However, to appreciate the context of recent genomic findings, this topic requires brief consideration. Genetic research has generally treated schizophrenia as a fully distinct entity from major mood disorders, based on both Kraepelinian tradition and also evidence from family studies that suggested the disorders breed true (that is, they segregate in different families). The status of schizoaffective disorder has historically been unclear. Some have considered it to be a categorical error, others a form of bipolar disorder, of schizophrenia, a distinct entity, or a state of comorbidity [13]. Moreover, although schizophrenia is now widely considered to be a neurodevelopmental disorder, it has been regarded as completely distinct from other neurodevelopmental categories such as intellectual disability (ID), autism spectrum disorder (ASD), and attention-deficit/hyperactivity disorder (ADHD). However, the idea that the disorders, in particular schizophrenia and mood disorders, breed true is not fully supported by historical family studies [3] and recent genetic epidemiology now offers substantial challenges to this view.

One study that has been particularly influential was based on over 2 million families from Sweden [12]. As expected, first-degree relatives of probands with schizophrenia had around a 9- to 10-fold increase in the risk for the disorder. However, they also had a substantially increased risk (3- to 6-fold, depending on the class of relative) of bipolar disorder, as did the adopted-away biological children of parents with schizophrenia. Modelling suggested around half of the heritability of schizophrenia comes from genetic effects that also contribute to bipolar disorder. Strong evidence for overlaps in the genetics of schizophrenia, schizoaffective disorder, and bipolar disorder were also found in an innovative twin study [14] in which individuals were allowed to have multiple diagnoses (that is, symptoms of one disorder were not used to exclude another disorder), and similar conclusions can be drawn from a study showing that the heritability of narrowly defined schizophrenia is essentially unchanged when other psychotic disorders are included [9].

Regarding possible overlaps among neurodevelopmental disorders, a study of three different data sets supported an earlier Danish study in finding that first-degree relatives of people with schizophrenia had more than twice the expected risk for ASD [15]. The parents and sibs of probands with bipolar disorder also had an increased risk for ASD, albeit to a lesser degree. Extending the findings to ID, an Australian study found the children of mothers with schizophrenia, bipolar affective disorder, and unipolar depression to be at an increased risk of ID [odds ratio (OR) 2.9–3.1] [16]. As we have discussed, familial clustering does not imply shared genes, but the findings are consistent with the hypothesis of genetic overlap, a theme we consider later when discussing the molecular genetics data.

Paternal age and fecundity

People with schizophrenia have fewer children than the general population, an effect that is quite substantial, with men and women with the disorder reproducing at rates of 75% and 50%, respectively, lower than expected [4]. Low fecundity associated with schizophrenia has led to speculation about how risk alleles, and therefore the disorder, remain apparently impervious to removal from the population by natural selection [4]. It has also been established that children of older fathers are at increased risk of developing schizophrenia, a recent study estimating the risk to be 1.5-fold higher than expected in children of fathers over the age of 45 [17]. A hypothesis that has tried to link these two observations and has become a topic of sufficient interest to deserve special mention is that the answer to the persistence of the disorder lies in *de novo* or new mutation. The hypothesis is largely founded upon the fact that, like the risk of schizophrenia, the rate of *de novo* point mutation also increases with paternal age [18]. It is clear that *de novo* mutation does indeed contribute to schizophrenia (discussed later), but this contribution is minor and is unlikely to explain either the persistence of the disorder in the population or the effect of paternal age. The true explanations for the paternal age effect are not fully resolved, but a credible alternative may be that unaffected men who have a higher genetic loading (and therefore whose children are at higher genetic risk) may also tend to have children later, perhaps as a result of subclinical behavioural or personality traits [19]. This is of more than theoretical interest, given the potential to give incorrect advice about the risks that might accompany delayed fatherhood,

based upon a model where the directions of cause and effect are incorrectly specified.

Molecular genetics

Linkage, association, and genetic architecture

Linkage performs best when applied to genetic disorders with simple (dominant, recessive, sex-linked) patterns of inheritance but rapidly loses power in the face of marked locus heterogeneity (that is, there are large numbers of distinct genomic regions with pathogenic variants). This is particularly true if the heterogeneity cannot be constrained by selecting families with particular phenotypic features. It is also not suited to disorders where the risk alleles are numerous and common and have small effects because even in a single family, the risk is likely to be due to multiple alleles, none of which is required to be co-transmitted with the phenotype. Under that scenario, association studies offer a more powerful approach.

Linkage allows researchers to survey the whole genome for disease-causing variants, using only a few hundreds of genetic markers, whereas hundreds of thousands of markers are required to screen the whole genome by association. In the late twentieth century, technological limitations in the speed and cost of genome analysis meant that linkage was perceived to have a huge advantage since researchers trying to apply association methodologies were forced to select specific candidate genes. Candidates were selected on the basis of being located within a region of putative linkage (positional candidates) or because they were postulated to be involved on the basis of their role in biological processes (functional candidates).

Linkage

While linkage studies routinely delivered hundreds of pathogenic genes for single-gene disorders, they did not deliver replicable findings in schizophrenia, or indeed many other common medical disorders. Even a meta-analysis of over 3200 separate pedigrees [20] failed to identify high-confidence linked loci. With the benefit of hindsight, it is now clear that the genetic and phenotypic architectures of schizophrenia are probably as unfavourable for linkage as it is possible to be.

It is true that large numbers of statistically significant linkages were observed in individual pedigrees or groups of pedigrees (for an example, see [21]) and that genuine linkages are difficult to replicate in the face of extensive locus heterogeneity. These two factors mean we cannot be certain whether the failures to replicate initial linkages reflect the greater-than-expected locus heterogeneity of the disorder or whether they were simply false positives. For now, what we can say with certainty is that no Mendelian forms of schizophrenia have yet been identified. Interest in applying (modified) principles of linkage is likely to be rekindled by the new genome-wide sequencing methods which, at single base, rather than mega-base, resolution, may deal better with heterogeneity.

Candidate gene association

In the 1990s and early 2000s, large numbers of candidate genes and variants were tested in schizophrenia. In [Table 59.1](#), we present the findings for some of the most widely discussed genes from the candidate gene literature [22], based upon results from the largest

Table 59.1 Associations to the most widely discussed genes from the candidate literature (p values represent the best association within, or close to, the gene)

published genome-wide association study (GWAS) [23] of schizophrenia, which included most of the data sets that were considered supportive of the earlier associations, and the findings can therefore be considered to largely supersede the earlier evidence. In the vast majority of cases, the candidate genes are not supported at what is now considered an appropriately stringent threshold ($p < 5 \times 10^{-8}$). However, there are caveats to this conclusion. In some cases (*DTNBP1*, *NRG1*, *RGS4*), the strongest findings depended on marker combinations (haplotypes), which are not specifically evaluated in GWAS data. Whether this is an important caveat is unclear, since the high-density coverage of markers in the GWAS is likely to have covered the markers presumed to drive the haplotype associations. Secondly, for one locus—*DRD2* encoding the dopamine D2 receptor, there is now strong evidence for an association in the vicinity of this gene, although not to an allele that was identified in the candidate gene literature. For those particularly interested in candidate genes, and the differences in approach that systematic coverage of candidate genes has enabled, we recommend two papers: one pre-GWAS [22] and one post-GWAS [24]. As the latter concludes, the current evidence suggests that the historical candidate gene literature did not yield clear insights into the genetic basis of schizophrenia.

With hindsight, there are several reasons why this phase of genetic study did not deliver. Major limitations in our understanding of schizophrenia meant the choice of candidates did not constrain the enormous variation of the genome to a substantially smaller number of genes with a high prior probability of being associated. Moreover, how small the association effect sizes were likely to be, and therefore what constitutes adequate sample sizes, was not widely appreciated until the landmark work of the Wellcome Trust Case Control Consortium [25]. Together, small effect sizes and the low prior probability for any candidate variant meant the studies were substantially underpowered to detect true associations at the stringent levels of significance necessary to control for type I errors. For example, a candidate gene study of 2000 subjects (a large study for most of the candidate gene era) has power of only 0.001 to detect an effect size at the upper end of the range (OR 1.2) that has subsequently been

shown to operate for schizophrenia, at genome-wide significance. Moreover, even if some of the candidate associations were true, subsequent replication studies would have been underpowered to confirm them.

Genome-wide association studies

Human variant mapping studies, such as The HapMap Project, have documented the nature and genomic location of a high fraction of all common DNA sequence variation that is present in the human population. This knowledge, coupled with novel genomic technology and statistical methodology, made it possible around 15 years ago to undertake the so-called GWAS, in which millions of SNPs are comprehensively assayed in an individual in a single experiment. In contrast to earlier association approaches, the GWAS design does not rely on prior knowledge of the most likely candidate genes or candidate genes, making GWAS seem an ideal tool for disorders of unknown pathophysiology such as schizophrenia.

The first GWAS studies of schizophrenia, based on small samples, failed to identify associations, leading some to suggest that the class of genetic variant accessible to this study design, that is, common alleles, plays no role in the disorder. However, an alternative view, informed by similar developments in complex genetics as a whole, was that the early studies were underpowered; other than suggesting that no common risk alleles operate in the disorder with large effect sizes (ORs >2 ; equivalent to *APOE* in Alzheimer's disease), the main message was that success would require extremely large samples that could realistically only be obtained by collaboration. How large GWAS studies might have to be was shown by the study of O'Donovan and colleagues (2008) [26]. Like those that preceded it, this study was based on what would now be considered a very small-discovery GWAS sample, but the top findings were pursued sequentially in large replication cohorts into a final meta-analysis, which included 7308 schizophrenia cases and 12,834 controls. This led to highly suggestive evidence for association to a locus containing the gene *ZNF804A*, but genome-wide significant evidence was only obtained when the affected phenotype was broadened to include bipolar disorder, allowing an analysis of 9173 cases and 12,834 controls. Association to schizophrenia on its own at genome-wide significance was not obtained for a further 3 years, by which time the analysis was based on almost 60,000 subjects [27].

In terms of gene discovery, the early work was disappointing, but it did point to some of the key features that have emerged from much larger GWAS. Firstly, the effect size of the associated common variant at *ZNF804A* was small, with an OR of 1.1, an effect size typical of the findings that have followed. Secondly, while it was difficult to obtain genome-wide significance, the study demonstrated an excess of nominally significant replications when the top GWAS associations were tested in large independent samples. This suggested that large numbers of true associations lay among the markers showing moderate evidence of association in GWAS that even large meta-analyses were underpowered to unequivocally implicate. And thirdly, the enhanced evidence for association between a variant at the gene *ZNF804A* and a combined schizophrenia–bipolar phenotype tends to support the findings from epidemiology for genetic overlaps between these two disorders.

A major insight into the role of common variants in schizophrenia came not from specific associations, but from patterns of data from large groups of markers. Seminal here was the work of

the International Schizophrenia Consortium [28] that proposed large numbers of common risk alleles exist for schizophrenia, but in the GWAS sample they had available (about 3000 cases and 4000 controls), these could not be identified at the required levels of significance due to small effect sizes. To test this, the ISC considered all alleles in their study to be possible risk alleles if they were associated with schizophrenia at a very loose threshold of significance (for example, $p < 0.5$). The ISC postulated that under a highly polygenic model, although most such associated alleles will be false, there would also be large numbers of true risk alleles captured at this threshold. They further postulated that if the disorder were polygenic enough, in independent data sets, individuals with the disorder would, on average, carry a larger burden of the presumed risk alleles than those without the disorder. In their landmark study, not only did the ISC confirm this to be true, they also showed by testing a range of models of genetic architecture that it was likely that the component of risk conferred by common risk alleles was distributed across at least 1000 alleles, and quite possibly many more than this. Modelling also suggested that the common polygenic SNP component to the disorder contributed around a third of the genetic risk to the disorder. The approach developed by the ISC, variously known as polygenic risk scoring (PRS), risk profile scoring (RPS), and genetic risk scoring (GRS), has, as we shall discuss later, become an important tool in psychiatric research extending beyond discovery genetics.

Since these early studies, approximately 20 risk alleles were identified from studies conducted by informal groupings of investigators and structured consortia (see [29]). However, the main breakthrough in detecting common alleles for the disorder required the international community to pool their resources into a super-consortium, which is now known as the Schizophrenia Working Group of the Psychiatric Genomics Consortium. The effect of this has been dramatic; in its first paper in 2011, the PGC reported ten associations using a sample of 9394 cases, but only 3 years later, based on a discovery GWAS sample of approximately 35,500 cases and 45,000 controls and with additional follow-up in another sample of 1513 cases and 66,236 controls, 128 independent genetic associations spanning 108 physically distinct genomic loci were identified [23].

Associations were particularly enriched for genes expressed in the brain, confirming schizophrenia is primarily a CNS disorder, rather than a manifestation of peripheral dysfunction, although the findings do not exclude a role for the latter. Some of the associations appear to give support to classical neurotransmission hypotheses of schizophrenia, including associations to loci containing *DRD2* (encoding the dopamine receptor D2) and genes involved in glutamatergic neurotransmission (for example, *GRM3* encoding metabotropic glutamate receptor type 3, *GRIN2A* encoding subunit 2A of the ionotropic NMDA receptor, and *GRIA1* encoding subunit 1 of the ionotropic AMPA receptor). The finding of associations to the locus encoding *DRD2*, the only known effective therapeutic target in schizophrenia, also holds out the possibility that other associations highlight drug treatment targets. However, the vast majority of the findings are not so plausibly interpreted and likely hold clues to novel aspects of pathophysiology. In particular, multiple associations to genes (*CACNA1C*, *CACNB2*, and *CACNA1I*) encoding calcium channels point to the likely importance of this family of proteins in the disorder.

As is characteristic of GWAS, the vast majority of the associations (including those to the loci containing the candidate genes discussed) could not be credibly ascribed to DNA variants that are predicted to change the amino acid sequences of proteins, and it seems most likely that the majority of susceptibility alleles exert their effects by altering gene expression. This makes interpreting the functional significance of the associations a challenging task and researchers are still mining the findings, aiming to develop a deeper understanding of their implications for pathophysiology.

A recent example of the sort of work required was recently reported by Sekar and colleagues (2016) [30], who dissected the source of an association at the extended MHC region of chromosome 6. This region spans about 8 million bases, contains hundreds of genes, and represents the most robustly associated locus in the PGC study and the locus with the largest (though still modest) effect size ($OR = 1.2$) [23]. The authors showed that much of the association at this locus was driven by a complex chromosomal structural rearrangement, which affects expression of the gene complement component *C4A*. How this finding potentially fits with emerging insights into the biological basis of schizophrenia is discussed later.

Despite the undoubted successes of the PGC study, only a small fraction of all common variation has been identified, representing 3–4% of the variance for the disorder. However, the PGC and GWAS that preceded it do provide a clear strategy for success; notwithstanding the enhanced heterogeneity that most investigators assume comes from pooling samples from a diverse range of ancestries (the PGC study was based on individuals of European and Asian ancestry from over 30 countries), diagnostic methods, and ascertainment strategies, large samples clearly deliver. It is a certainty that in the next few years, the number of associated loci will increase considerably. Developing methods and resources that accelerate the rate by which those findings can be converted to biological insights into the aetiology will be critical if the wealth of findings are to be translated into benefits for patients.

Genomic copy number variants

CNVs are deletions and duplications of chromosomal segments of at least 1000 bases (1 kb); they are highly relevant to autism and other forms of ID, as discussed in Chapter 28. Prior to the GWAS era, a deletion CNV at chromosome 22q11.2 (22q11.2del) was the only DNA variant, common or rare, that was indisputably pathogenic for schizophrenia [22]. This deletion is also known to cause a congenital syndrome variously called velo-cardio-facial syndrome (VCFS), di George syndrome, or Shprintzen syndrome. The fact that carriers of this CNV usually have recognizable clinical and dysmorphic features was critical to the early discovery of its involvement in schizophrenia, since it was possible to demonstrate an elevated rate of psychosis in those with the clinical features of VCFS.

Although few doubted that the rate of psychosis was elevated in those with VCFS, it was not uncommon for it to be argued that the associated psychiatric phenotype represented a symptomatic form of psychosis secondary to ID, rather than a disorder that should be considered true schizophrenia. However, it has now become more widely accepted that those with VCFS have schizophrenia for reasons that we touch on here, as they are relevant more generally to any discussion of rare variants in schizophrenia. Firstly, studies using research diagnoses showed that the psychosis that occurs in VCFS meets operational diagnostic criteria for schizophrenia, the only

criterion for schizophrenia that we currently have. Secondly, studies of ‘routine’ clinical cases of schizophrenia have demonstrated that those with operationally diagnosed schizophrenia also have a greatly elevated rate (about 40- to 60-fold) of 22q11.2del [31]. Thirdly, the elevated risk of schizophrenia in VCFS is not restricted to those with obvious ID. Fourthly, cognitive impairment is increasingly accepted as a core feature of schizophrenia, rather than a primary cause of the disorder (see Chapter 57). Finally, as the number of CNVs associated with both cognitive impairment and schizophrenia has increased, so the idea that the psychosis in 22q11.2del is distinct from the rest of schizophrenia seems less tenable, and more so since it has been recently shown that people with CNVs and schizophrenia also have elevated burdens of the sorts of common schizophrenia risk alleles derived from GWAS in general (that is, non-CNV carrier) patient populations [32].

Beyond 22q11.2del, the recognition of a wider role for CNVs in schizophrenia had to await the development of genome-wide technologies that allow a genotype-, rather than a phenotype-led, approach. Evidence for a role of CNVs in schizophrenia comes from three main sources.

Firstly, as we already discussed, risk alleles such as CNVs that confer large effects on risk of the disorder are likely to be under strong negative (natural) selection, leading some to the hypothesis that risk alleles of large effect might be maintained by new or *de novo* mutations. Consistent with this prediction, CNVs have been observed to occur as new or *de novo* mutations more frequently in cases (about 5% at the current resolution for detecting CNVs) relative to controls (about 1–2%) [33]. Secondly, at a genome-wide level, large studies have consistently shown that the total burden of large (>100 kb) and rare (frequency <1%) CNVs (both deletions and duplications) is increased around 1.15-fold in patients with schizophrenia in comparison with controls [34]. Finally, and most conclusively, there is now strong evidence implicating multiple specific loci in the disorder.

The earliest genotype-led study to suggest the role of a CNV in schizophrenia was a small study of parent–proband trios in which the aim was to discover *de novo* mutations [35]. Two candidate CNVs were identified—one a *de novo* duplication spanning a number of genes, including *APBA2*, and the other was a transmitted deletion at *NRXN1*. Both CNVs had been previously implicated in neurodevelopmental phenotypes, suggesting they may be pathogenic. Moreover, *APBA2* and neurexin 1 are members of a complex, which mediates interactions between pre- and post-synaptic structures in the brain. Promising though these findings were, they were no more than suggestive, and it took a larger case-control study to convincingly implicate deletions at the neurexin 1 locus in the disorder, with a substantial OR of around 9 [36].

The most robust early evidence implicating specific CNVs, however, came from simultaneous publications from two consortia—the SGENE+ consortium [37] and the International Schizophrenia Consortium [34]. Hitherto unprecedented in psychiatric genetics, the two studies had almost identical results. Both implicated deletions at 15q13.3 and 1q21.1, while the SGENE+ study additionally reported evidence supporting deletions at 15q11.2 that the ISC study had excluded for technical reasons. Since this early work, a number of additional, strongly supported schizophrenia-associated CNVs have been identified (Fig. 59.2). All the CNV loci implicated

so far are rare (population frequency usually <0.1%), each occurring in fewer than 1% of cases, and those that have been discovered have considerably larger effect sizes than SNPs, with ORs ranging between about 2 and 60 [38]. It should be noted that power considerations imply that rare variants can only be convincingly associated if they have large effect sizes, and therefore, the profile of effect sizes documented to date may be more a feature of the current sample sizes than an intrinsic property of CNVs as a mutation class.

One of the most notable features of schizophrenia risk CNVs is that they are also risk factors for other neurodevelopmental disorders, including ID, ASD, epilepsy, and ADHD, and a range of congenital malformations, that is, they are often pleiotropic. Indeed, every CNV known to increase the risk of schizophrenia also does so for ID [39]. The theme of shared risk factors across disorders is taken up further under Sequencing studies, p. 592 and Applications of polygenic methodology, p. 594.

Sequencing studies

For the present purposes, although CNVs and other chromosomal arrangements are detectable by sequencing, the primary aim of sequencing studies is to identify variants similar in structure to those detected by GWAS (that is, single nucleotide and small insertion/deletion variants), but which are too rare to be captured by GWAS. Cost implications have led researchers to focus on the coding exome, so we will refer to these as rare coding variants (RCVs) that change the DNA sequence at single or a few nucleotides. As for studies of CNVs, exome sequencing studies have been prosecuted along two main designs: family-based seeking a contribution from *de novo* RCVs and case-control. Even though the largest of the first wave of studies were grossly underpowered to detect individual pathogenic single nucleotide variants (SNVs), they did show that groups of genes that had previously been identified as likely related to the disorder were enriched for very rare, non-synonymous RCVs in cases, compared with controls, and among mutations occurring as *de novo* mutations [40, 41]. Just as elevated burdens of rare CNVs [34] and common risk alleles [28] heralded the identification of specific risk alleles of those classes, this burden of RCVs provided for optimism that the same would be true for this class of alleles when sample sizes are adequate.

Sample sizes are still too small to expect large-scale discovery, but nevertheless, this optimism has already been shown to be well founded. A meta-analysis of 4264 cases, 9343 controls, and 1077 parent–proband trios obtained strong evidence for a single gene enriched for very damaging (so-called loss of function, or LoF) mutations in schizophrenia [42]. The gene *SETD1A* encodes a protein that methylates histone proteins, a process believed to be important in regulating gene expression. Identifying which genes are regulated by *SETD1A* is the next step in understanding how loss of activity of this protein leads to disease.

Sequencing studies have also recapitulated the findings from CNVs of overlaps between neurodevelopmental disorders. As a group, genes impacted by LoF *de novo* mutations in schizophrenia are enriched for those affected by this same class of mutation in people with ASD and ID [40], while at an even finer level of resolution, the same LoF mutation in *SETD1A* that contributes high risk to schizophrenia also does so for severe ID and developmental delay [42].

Fig. 59.2 Penetrance of schizophrenia-associated CNVs for schizophrenia and other developmental disorders [38]. DD, developmental delay; ASD, autism spectrum disorders; CM, congenital malformation.

Glimpses of the biological basis of schizophrenia

Most of the genetic risk for schizophrenia is not yet linked to specific DNA variants, and even the majority of robust associations do not implicate individual genes at high levels of certainty. This is because GWAS implicates chromosomal regions, rather than definitively pointing to only a single gene, and CNVs usually span multiple genes. Nevertheless, there is already strong evidence that many of the findings converge onto plausible pathophysiological processes. System genomics studies (analyses that determine if certain types of mutations are overrepresented in groups of genes that have related functions) show that in people with schizophrenia, rare mutations of all classes (CNVs and RCVs, transmitted and *de novo*) tend to cluster in genes encoding post-synaptic components of excitatory synapses. In particular, an excess of mutations have been found repeatedly in genes encoding proteins affiliated with the *N*-methyl-*D*-aspartate receptor (NMDAR) and those affiliated with the neuronal activity-regulated cytoskeleton-associated (ARC) protein which regulates post-synaptic strength at glutamatergic synapses [40, 41, 43, 44]. Studies have also documented that rare mutations and, to a lesser extent, common variant associations are enriched among

genes encoding proteins whose synthesis is inhibited by fragile X mental retardation protein (FMRP) [23, 40, 41]. Genes encoding voltage-gated calcium channels are similarly implicated both by GWAS and by one study of rare genetic variation [23, 41, 45], and more recently, evidence has emerged for enrichment of case CNVs in genes encoding GABA_A receptor affiliated proteins [44], which has strong functional links with the glutamatergic system. All these sets of genes are important components or regulators of synaptic plasticity, a set of processes that are known to be critical for a range of cognitive processes, including learning, memory, and, it now seems highly likely, schizophrenia [44, 46].

These convergent findings point to some general biological hypotheses, but they do not capture the totality of the association signal. There is evidence from the association between schizophrenia and rare variants at *SETD1A*, as well as from common GWAS signals [47] that chromatin modification is also implicated, while the identification of complement C4A as a susceptibility factor highlights the involvement of immune mechanisms. It is unclear if the findings discussed here also converge on the general area of synaptic plasticity, but it is notable that in the brain, much of C4 protein

co-localizes with glutamatergic markers. There is also evidence that mice lacking C4 show abnormalities of plasticity in visual pathways, perhaps through synaptic pruning. It is therefore possible that these apparently disparate biological pathways converge onto a coherent, and yet broad, set of pathogenic processes.

Genetic prediction and testing

Here we briefly consider the implications of the findings discussed previously. In people with schizophrenia entering genetic studies (which are biased towards chronicity and severity), the rate of known pathogenic CNVs is around 2.5%, implying low sensitivity for prediction. In the general population, the penetrance for schizophrenia in carriers (the proportion of carriers developing the disorder) is between 2% and 18% (Fig. 59.2) [38], implying low specificity for prediction. While the screening value of CNVs for prediction is therefore low for the proportion of cases who are carriers, that knowledge may have value for patients who often are desperate for an explanation for their illness. Moreover, as we have seen, schizophrenia is not the only possible outcome in CNV carriers; considering developmental delay, ASD, and congenital malformations, the average penetrance for any of these disorders is around 40% (Fig. 59.2). So for the 50% of the offspring of CNV carriers who themselves are carriers, the risk for a range of neurodevelopmental outcomes is high. CNVs may also lead to comorbidity for medical phenotypes, which may be overlooked in people with psychosis who often do not gain good access to physical health care but that are treatable if detected (for example, cardiac defects, epilepsy, cataracts). Considerations such as these have led to calls for CNV testing to be offered to people with schizophrenia [48], although at the time of writing, as far as we are aware, this is not routine practice in any part of the world.

The principles of PRS are discussed previously. This method provides researchers with a tool that allows an unaffected individual's liability to the disorder to be estimated. While this has many research applications, currently, the degree of liability captured by PRS is not of clinical value; its sensitivity and specificity for predicting affected status are inadequate, and the predictive power as depicted by area under the curve (AUC) analysis is only 0.62 [23].

Applications of polygenic methodology

As perhaps the first valid biomarker for liability to the disorder, PRS is opening up interesting areas for research [49]. In the first paper to exploit this, the ISC (2009) [28] showed the burden of common schizophrenia-associated alleles, as measured by PRS, was not just increased in people with schizophrenia, but it was also increased in people with bipolar disorder. This finding points to a shared genetic contribution between the two disorders and is consistent with some of the newer genetic epidemiology discussed earlier in the chapter [12]. Subsequently, RPS and other polygenic approaches [49] have documented substantial sharing of risk alleles between schizophrenia and major depression, as well as significant, and perhaps more unexpected, overlaps with autism, ADHD, anorexia nervosa, obsessive-compulsive disorder, and neuroticism. More controversially, polygenic risk for schizophrenia (in unaffected people) has been linked to poor cognitive performance yet, simultaneously, to higher educational performance and creativity [50]. Given the large number of risk alleles involved in schizophrenia, and the likelihood that these, in turn, influence multiple domains of brain function, it is perhaps not surprising that overlaps exist for common alleles

across multiple psychiatric, behavioural, and cognitive phenotypes. Nevertheless, considered alongside results of studies showing overlap between neurodevelopmental disorders with respect to rare genetic variation [51], these findings pose challenges to the validity of current classification systems.

The ability to measure, imperfectly, genetic liability in unaffected people also offers new opportunities for patient stratification. In the earliest such application, it was shown that in people with bipolar disorder, loading for schizophrenia polygenic risk was higher in people with psychotic features and in those who met criteria for schizoaffective disorder [52]. Conversely, in people with schizophrenia, the polygenic burden of bipolar risk alleles is higher in those who have co-occurrence of manic symptoms [53]. Findings such as these suggest a biological structure of psychosis corresponding, in part, to symptom domains, rather than categories, although much more work is required to establish this unequivocally. Many other approaches to stratification based on risk alleles are being investigated, including treatment response, outcome after first episode, and predicting functional impairment, but none of the findings yet have the robustness of those documenting phenotype overlaps.

PRS also offers the potential for looking in unaffected people for phenotypes that correspond to increased liability, for studying the developmental trajectory of individuals at elevated risk, and perhaps for identifying modifiable environmental factors or psychological cognitive traits that alter trajectories to illness. Again, these findings generally are not yet entirely robust, but it has been shown that elevated PRS relates to negative, rather than positive, symptom dimensions, suggesting the former may be better markers for detecting those at risk of the disorder [54].

Finally, PRS also offers the possibility of evaluating putative intermediate phenotypes that might mediate the link between genes and disorder. In schizophrenia, clear positive findings have yet to emerge, and for now, perhaps the most interesting of this type of study concerns negative studies. A particularly notable example of this, given the size and power of the study, was one that found no overlap between genes that influence the size of subcortical brain structures and those that influence schizophrenia [55], implying that the volume of those brain structures (for example, striatum, hippocampus) is not an important mediating factor of genetic risk for schizophrenia.

Conclusions

After a lengthy period of apparent advances and retreats, molecular genetic studies of schizophrenia have recently delivered robust findings in large number. These, in turn, are beginning to provide insights into general areas of pathophysiology, challenge the validity of psychiatric nosology, and provide novel tools for research more widely. Thus far, there has been limited clinical translation of these results, though some of the findings implicating rare genetic variants may be of direct relevance in the clinic. On a cautionary note, the current findings represent only a fraction of the total genetic contribution to schizophrenia. While there are grounds to believe that much more will be uncovered and that the process of doing so will accelerate, there remains much to be done to convert the genetic findings to a deep mechanistic understanding that will be required

if genetics is to fulfil its promise of driving the development of novel treatments.

Structural and functional neuroimaging of schizophrenia

Andreea O. Diaconescu, Sandra Iglesias, and Klaas E. Stephan

Historical origins of neuroimaging in schizophrenia

Neuroimaging has played a pivotal role in the scientific investigation of schizophrenia. In particular, imaging provided empirical evidence that the brain of patients with schizophrenia exhibits structural and functional differences, compared to both controls and patients with other diseases. This evidence was crucial for the long-standing debate of whether schizophrenia has biological roots or is purely social and psychological in origin (for example, as hypothesized by theories of ‘double-bind’ [1] or the concept of the ‘schizophrenogenic mother’ [2]). This introductory section provides a brief overview of seminal neuroimaging studies of schizophrenia across different modalities.

Historically, an early and extremely influential *in vivo* demonstration of structural brain changes in schizophrenia was provided by a computed tomography (CT) study by Johnstone and colleagues (1976). This study demonstrated significant enlargement of ventricles in patients with schizophrenia, compared to matched healthy controls; furthermore, ventricular size correlated significantly with cognitive impairment [3]. One concern was that these structural changes might have arisen from the long-term institutionalization of these particular patients and the often invasive treatments they had received (including insulin coma therapy). However, the finding of enlarged ventricles was subsequently replicated in multiple CT and magnetic resonance imaging (MRI) studies (Fig. 60.1) [4–6] and confirmed by meta-analyses [7].

Early functional neuroimaging studies of schizophrenia examined basic physiology, using radioactive measurements of cerebral perfusion and metabolism, respectively, as provided by single-photon emission computed tomography (SPECT) and positron emission tomography (PET). A seminal SPECT study found that older (but not younger) patients with chronic schizophrenia had decreased perfusion in their frontal lobes, compared to a control group of alcoholic patients [8]. This ‘hypofrontality’ was also detected using PET and was related to poor performance in cognitive tests [5]. Together with increased metabolic activity in the basal ganglia, hypofrontality

offered an explanation for the ‘[...] simultaneous generation of positive and negative symptoms [...]’ [9]. However, subsequent PET studies failed to find hypofrontality [10, 11]; this discrepancy may have arisen from several factors, including performance differences between patients and controls in particular, but also differences in whether studies examined ‘resting’ conditions or cognitive tasks and differences in statistical analysis techniques (for discussions of hypofrontality, see [12, 13]).

Electroencephalography (EEG) played an important role in early brain activity investigations of schizophrenia, providing high temporal resolution of normal and pathological brain processes. Early studies reported multiple abnormalities in the electrical brain activity of patients with schizophrenia, for example epileptic-like potentials, reduced alpha activity, and/or enhanced fast-wave activity [14]. The investigation of evoked EEG responses to sensory events [event-related potentials (ERPs)] received particular interest. Notable findings in schizophrenia patients included reductions in N100 [15, 16] and P300 amplitudes [17], irrespective of the sensory modality. Since the early 1990s, the auditory mismatch negativity (MMN) has been widely investigated in schizophrenia. The MMN is the difference potential between responses to unpredictable stimuli (‘deviants’) and predictable stimuli (‘standards’). In the first study of MMN in schizophrenia, Shelley *et al.* (1991) found an attenuation of the auditory MMN amplitude in schizophrenia patients, as compared to controls [18]. This finding has since been replicated by a large number of studies (for a meta-analysis, see [19]) and continues to play a major role in contemporary schizophrenia research.

Prior to the advent of functional MRI (fMRI), PET played a critical role in assessing regional activation changes in schizophrenia during cognitive tasks *in vivo* [20–24]. Given the long-standing notions of schizophrenia as resulting from abnormal connectivity [25] (see The dysconnection theory of schizophrenia, p. 602), particular attempts were made to link aberrant activity in neural networks to symptoms of schizophrenia [23, 26–28]. For instance, the concept of ‘cognitive dysmetria’—‘the difficulty in prioritizing, processing, coordinating, and responding to information’ [29]—was linked to alterations of a prefrontal–thalamic–cerebellar circuit measured with PET in schizophrenia patients [30].

Finally, the development of fMRI in the 1990s led to a breakthrough in neurophysiological research on schizophrenia *in vivo*. While the non-quantitative nature of the blood–oxygen level-dependent (BOLD) signal and the complexities of data analysis induced an initial delay in the uptake of fMRI, its considerably higher temporal and spatial resolution, compared to PET, as well as its radioactive-free nature, radically increased the utility and availability of functional neuroimaging for schizophrenia research. The earliest fMRI applications to schizophrenia included neurological soft signs, as probed by simple motor tasks [31], auditory hallucinations [32], and working memory [33]. Since then, the vast majority of functional imaging studies on schizophrenia have used fMRI, as reflected by the literature covered in the following sections.

Following the early milestone neuroimaging studies described previously, the neuroimaging research in schizophrenia has virtually exploded, resulting in a vast body of literature that is impossible to cover in a single chapter. In the following, we partition the neuroimaging literature on schizophrenia into two broad classes: discovery-oriented and theory-driven approaches. With regard to the latter, we use four major contemporary pathophysiological theories in order to structure the imaging literature on schizophrenia and focus on studies with a direct connection to proposed disease mechanisms. We conclude with an outlook on computational neuroimaging approaches that strive for mechanistic interpretability, as opposed to descriptive accounts of neuroimaging data [34].

Discovery-oriented neuroimaging approaches

The introduction of non-invasive neuroimaging with MRI enabled the systematic search for structural and functional differences in the brain of patients with schizophrenia. Most of the initial work, beginning in the early 1980s [35, 36], used structural MRI to identify neuroanatomical abnormalities. Two main approaches have been used: region of interest (ROI) analyses, which are based on a priori chosen regions delineated by atlases or manual tracing, and whole-brain approaches such as voxel-based morphometry (VBM) [37].

Some of the most notable replicated findings include: ventricular enlargement [38], cerebral atrophy [39], grey matter reductions in the amygdala, hippocampus, parahippocampal gyrus, and anterior cingulate gyrus [40, 41], and frontal lobe abnormalities, particularly in prefrontal and orbitofrontal subregions [42]. Whole-brain approaches, such as VBM, that are not biased to one particular region, have pointed to grey matter decreases in patients with schizophrenia, compared to healthy controls, in several regions, including the thalamus, insula, superior temporal gyrus (in particular, in the left hemisphere, which is associated with auditory information processing and language), anterior and posterior cingulate, and medial frontal gyrus [43, 44].

Longitudinal studies addressed the question of whether these volumetric abnormalities were present before the onset of the illness or materialized only after its onset. A particular focus has been on individuals at risk for schizophrenia; here, longitudinal studies found volumetric reductions of the temporal, cingulate, insular, prefrontal, and parahippocampal cortices in those individuals who later developed first-episode psychosis symptoms [45]. In a large multi-site early prevention study of at-risk mental state (ARMS) individuals, larger reductions in grey matter volume of the parahippocampal gyrus were detected in ARMS individuals who transitioned to psychosis, compared to those who maintained a subclinical symptom level [46]. Grey matter abnormalities also progressed after the onset of schizophrenia. Longitudinal studies in chronically ill patients suggest that progressive brain changes continue for up to 20 years after the first symptoms [7, 47]. These changes include lateral ventricle volume increases and grey matter density decreases in specific brain regions, including the superior frontal gyrus, superior temporal gyrus (particularly in the left hemisphere), right caudate nucleus, and right thalamus [7, 47].

The development of diffusion-weighted imaging (DWI) has made it possible to investigate white matter *in vivo* and derive estimates of connectivity by tractography. Meta-analyses of DWI studies in schizophrenia suggested that white matter abnormalities are apparent in two main regions—the left frontal deep white matter tract linking the frontal lobe, thalamus, and cingulate gyrus, and the left temporal deep white matter tract linking the frontal lobe, hippocampus, amygdala, and temporal and occipital lobes [48, 49]. DWI-derived connectivity matrices have fuelled the emerging field of connectomics, which uses graph-theoretical methods to examine the topology of networks. Applications of the graph theory to DWI data from patients with schizophrenia suggested reduced network capacity for integration, as reflected by longer path lengths [50], reduced network efficiency [51], and reduced ‘rich club’ organization [52].

A parallel line of research has assessed these putative functional integration abnormalities in schizophrenia by corresponding

analyses of functional connectivity. While reduced functional connectivity—in particular fronto-temporal connectivity [27]—has featured prominently in the literature [52, 53], enhanced functional connectivity has also been reported [54, 55], even in the presence of reduced structural connectivity in patients [56]. However, this diversity may, at least in part, also result from methodological differences across studies. For example, Yang *et al.* (2014) showed that global signal regression strongly affected coupling estimates (see [56] for discussion).

Graph-theoretical investigations of functional connectivity matrices have provided important insights into network alterations in schizophrenia [56]. Notable findings include reductions in clustering, small worldness, and the probability of high-degree hubs [53]. Interestingly, meta-analyses of fMRI activity in schizophrenia have shown that abnormal activations are concentrated in hubs of a 'normative connectome' such as the thalamus, middle cingulate gyrus, and the dorsolateral prefrontal cortex (PFC) [57].

An alternative approach to examining large-scale functional connectivity without a priori parcellation is independent component analysis (ICA). This method identifies networks as spatially distinct maps of voxels which share a common time course. This approach has shown across both 'resting state' conditions and cognitive paradigms that schizophrenia is characterized by altered global connectivity patterns [58, 59].

Theory-driven neuroimaging approaches

The short summary of discovery-oriented analyses of structural and functional neuroimaging data in the previous section outlined alterations of global brain organization that are largely descriptive and do not specify a specific disease mechanism. We now turn to imaging studies that were motivated by a particular pathophysiological theory. These include: (1) the neurodevelopmental theory; (2) the dopamine theory; (3) GABAergic and glutamatergic theories; and (4) the dysconnection theory of schizophrenia.

The neurodevelopmental theory of schizophrenia

The *neurodevelopmental theory of schizophrenia* postulates an aberrant development of the central nervous system as the cause of the disorder [60, 61]. In brief, this theory assumes that a disruption occurs during early (pre-/perinatal) or late (puberty and adolescence) neurodevelopmental processes that impacts on the biochemistry, function, and structure (including connectivity) of the brain. Possible environmental factors include (social) stressors that result in endocrine and metabolic changes and/or infections, presumably interacting with specific genetic predispositions [62].

One starting point for the neurodevelopmental theory was the finding, from the early neuroimaging studies described previously, of structural brain differences in schizophrenia, especially increased lateral ventricles (Fig. 60.1). For example, intrigued by the finding that enlarged ventricles were already present at the earliest stage of schizophrenia, Murray and Lewis (1987) speculated that these changes represented possible consequences of earlier developmental disturbances [60]. Furthermore, this structural abnormality was initially thought not to be associated with the duration of the disease or type of therapy [63]. (Later studies showed, however, that the enlargement of ventricles continues during the course of schizophrenia;

for a meta-analysis and review, see [7, 64], respectively). These structural findings were hypothesized to result from the interaction between genetic predisposition and environmental insults. One model suggested that disruptions in normal neurodevelopment may take place in the pre- or perinatal period, through infections or obstetric complications which impact globally on the normal development of the nervous system, including proliferation and migration of neurons, and the growth and pruning of axonal connections [60, 62, 63]. This was supported by studies showing that individuals who developed schizophrenia were more likely to have experienced pre- or perinatal adverse events, compared to healthy subjects (for review, see [65]); mixed evidence (reviewed in [66]) exists for a similar risk role of perinatal infections.

An alternative to a more 'global lesion' is that the early damage of circumscribed brain regions may affect the development of other regions such as the PFC [61]. One particular candidate for such an initial lesion is the hippocampus, which contributes to regulating the activity of midbrain dopamine neurons; indeed, animal models with prenatal hippocampal lesions found increased activity of dopaminergic neurons in the midbrain [67]. The ensuing change in neuromodulatory projections might impact on the development of prefrontal (and other) regions.

A non-trivial challenge for the neurodevelopmental account of schizophrenia is to explain why morphological changes are not confined to the time of the hypothetical insult but continue to unfold in time. As noted by Kempton *et al.* (2010), the finding of continuously accelerated enlargements of the lateral ventricles '[...] challenges an exclusively neurodevelopmental model of schizophrenia' [64]. Beyond simple volumetric changes, several longitudinal structural MRI studies have demonstrated that schizophrenia has a progressive nature, with pronounced grey matter changes occurring over at least 20 years after disease onset; comprehensive reviews and meta-analyses can be found in [7, 68–70]. For example, an early study by Thompson and colleagues (2001) observed accelerated grey matter loss over 5 years in very early-onset schizophrenia, compared to healthy controls, starting in parietal brain regions and motor and supplementary motor cortices, and progressing later to the superior frontal gyri, dorsolateral PFC, and temporal cortices, including the superior temporal gyrus (Fig. 60.2) [71]. This progressive grey matter loss was correlated with an overall decrease in global functioning in the patient group. In particular, faster loss rates of grey matter in temporal regions were associated with more severe positive symptoms, and faster loss rates of frontal grey matter loss with negative symptoms.

Consistent with these results, a more rapid grey matter reduction relative to age-related loss in healthy controls was found in subsequent longitudinal MRI studies across different clinical stages and medication status. This included first-episode schizophrenia patients [72], medicated patients [73], and, to a lesser extent, drug-naïve patients [74] (Fig. 60.2). Generally, medication appears to modulate, but not explain, accelerated grey matter loss in patients with schizophrenia [68, 75].

The dopamine theory of schizophrenia

The *dopamine (DA) theory of schizophrenia* was initially based upon the thesis that the efficacy of neuroleptic drugs to attenuate psychosis symptoms depended on striatal D2 antagonism [76]. Since then, a substantial number of PET and SPECT studies have provided

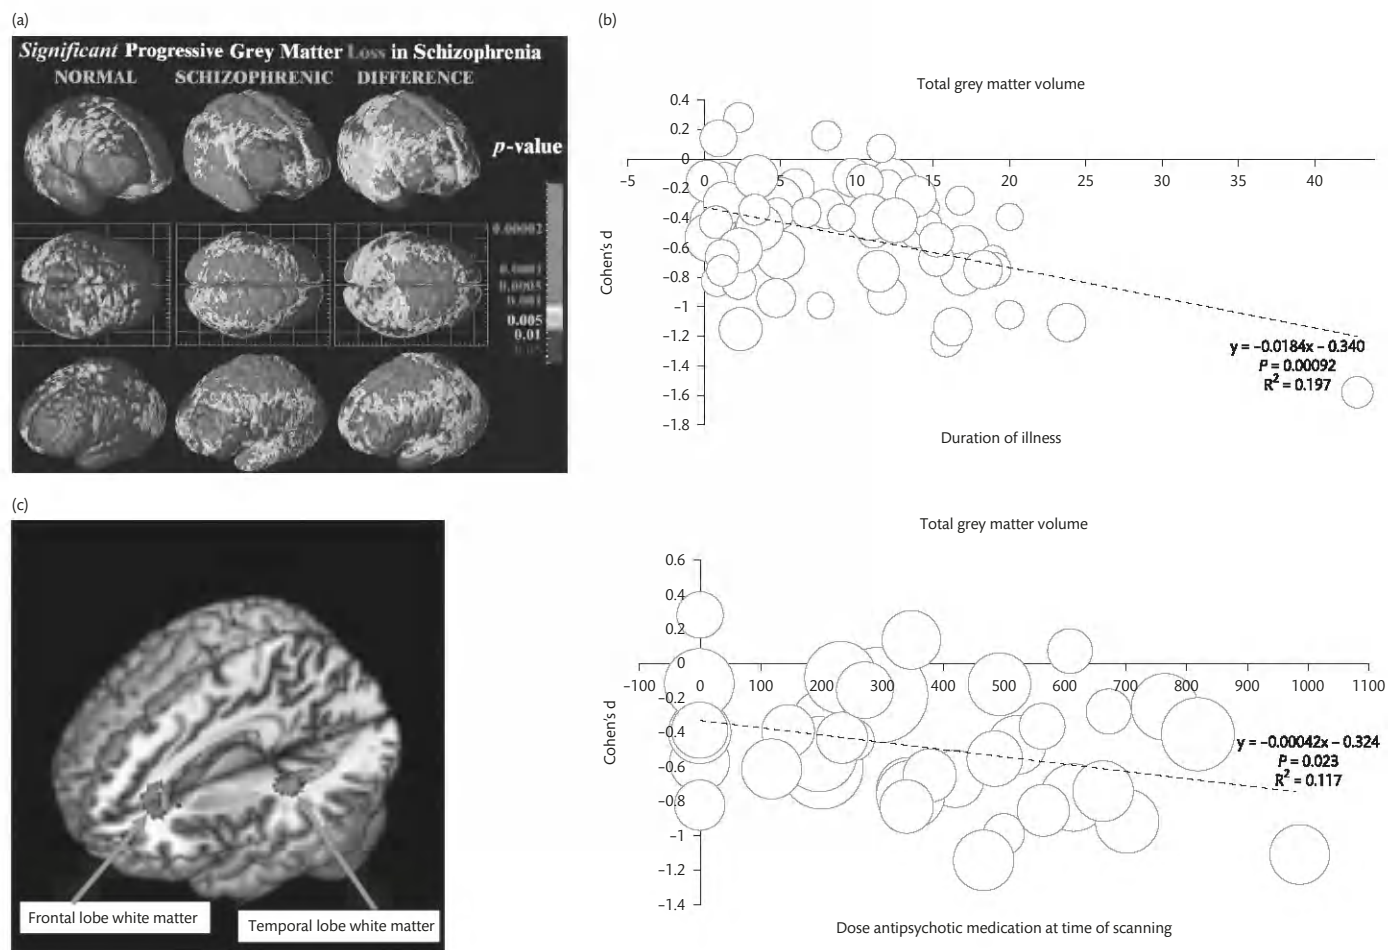

Fig. 60.2 Progressive grey and white matter loss in schizophrenia.

(a) Significant grey matter loss in normal adolescents and schizophrenia (see Colour Plate section).

compelling evidence of elevated presynaptic DA levels in the striatum (for example, [77]). Presynaptic DA can be investigated using tracers like ^{18}F -dihydroxyphenyl-*L*-alanine (^{18}F -DOPA), which are taken up by dopaminergic terminals and probe DA synthesis capacity. Beyond individual studies, evidence of elevated DA synthesis capacity in the striatum was provided by meta-analyses of patients with schizophrenia [78, 79]. This elevation was also found in individuals at risk for psychosis [80, 81], including medication-naïve prodromal individuals [82]. When followed longitudinally, a subset of the ultra-high-risk subjects who transitioned from the prodromal stage to frank psychosis showed a progressive increase in DA synthesis [83]. In addition to the striatum, corresponding findings were also recently made for the midbrain [84].

Another argument in favour of a central role of DA relates to the role of the DA system in learning and plasticity. DA modulates

glutamatergic plasticity in several ways; for example, activation of D1 receptors enhances, and of D2 receptors diminishes, NMDA receptor-mediated long-term potentiation [85]. Referring to the importance of DA in learning and plasticity, one theory of psychosis holds that individuals with schizophrenia attribute aberrant salience to irrelevant information due to inappropriate, 'chaotic' phasic firing of DA neurons [86–89]. This theory posits a key role of the DA system in mediating the misattribution of salience [90] and is supported by a host of fMRI studies in patients with schizophrenia. Firstly, empirical support for this theory comes from Pavlovian conditioning experiments where neutral cues were associated with appetitive or aversive events [91–93]. Behaviourally and autonomically, schizophrenia patients exhibited reduced differences in responding to paired cues (that is, cues that predict reinforcement) relative to unpaired ones. These behavioural effects were related to increased activity in the

dopaminergic midbrain and dopaminoceptive regions, including the ventral striatum, across both aversive and appetitive contexts [91, 92]. Secondly, in the context of instrumental learning, BOLD activation in the ventral striatum in response to reward-predicting cues was shown to be blunted in medicated patients [94], medication-free patients [95–97], unaffected patient siblings [98], and healthy controls with subclinical psychosis-like symptoms [99]. In some studies (for example, [94]), attenuated responses to reward prediction error, but increased responses to prediction error, on neutral trials were also found in the dopaminergic midbrain.

Blunted striatal activations in response to task-relevant stimuli may be specifically linked to negative symptoms [100], even in unmedicated patients [95], whereas enhanced midbrain and striatal response to task-irrelevant stimuli appear to be related to positive symptoms in both unmedicated [94, 101] and medicated patients [93]. fMRI studies that specifically tested salience attributions [102] provide further support for aberrant signals in the midbrain and ventral striatum, as accounting for positive symptoms in schizophrenia [103].

The GABAergic and glutamatergic theories of schizophrenia

The *NMDA* (*N*-methyl-*D*-aspartate) and *GABA* (gamma aminobutyric acid) *receptor hypofunction theory of schizophrenia* was based on the finding that dissociative anaesthetics, including ketamine, an NMDA receptor (NMDAR) antagonist [104], can induce a transient psychosis-like state in healthy volunteers that is characterized by perceptual alterations, delusion-like ideas, thought disorder, and blunted affect [105]. Ketamine can also aggravate psychosis in patients with schizophrenia [106].

A single dose of ketamine leads to a significant reduction in the auditory MMN, an electrophysiological response to rule violations. This was first shown using invasive recordings in monkeys [107], followed by multiple demonstrations in humans, based on EEG (for example, [108–110]). Importantly, the auditory MMN is also significantly reduced in patients with schizophrenia, in a comparable manner as under ketamine application [111], and represents one of the most robust group-level physiological indices of the clinical diagnosis of schizophrenia. Reduced auditory MMN amplitude in schizophrenia was first described by Shelley *et al.* (1991), a finding that has since been replicated by dozens of studies (for a meta-analysis, see [19]).

The auditory MMN is reduced not only in schizophrenia patients, but also among ARMS individuals with subclinical symptoms, and substantially more reduced in those who transition to psychosis [112]. A recent fMRI study also demonstrated auditory mismatch impairments in schizophrenia patients, as reflected by reduced BOLD responses to mismatch blocks in auditory regions (primary auditory cortex and superior temporal gyrus), anterior cingulate, and medial prefrontal gyri [113] (Fig. 60.3).

In addition to NMDARs, GABAergic receptors have been implicated in the pathophysiology of schizophrenia [114–116]. Both processes may be closely connected—given that NMDARs provide a major source of excitatory input to inhibitory interneurons [117, 118], NMDAR antagonism may lead to disinhibition of their post-synaptic target neurons, with less coherent pyramidal cell firing as a possible consequence (for review, see [119]). Indirect empirical evidence for this process in schizophrenia is provided by studies examining neuronal oscillations with EEG/MEG recordings [120]. For example, gamma-band oscillations in the dorsolateral PFC,

Fig. 60.3 (see Colour Plate section) Haemodynamic response to mismatch blocks ($P < 0.05$). A corrected cluster size threshold was based on a Monte Carlo simulation. First row: healthy controls; second row: schizophrenia patients; third row: difference between healthy controls and schizophrenia patients for the contrast mismatch > standard (baseline) condition. Schizophrenia patients exhibited less activity in the auditory cortex and prefrontal and salience network (bilateral ACC, medial frontal gyrus, and right insula). Enhanced activity was found in schizophrenia patients in the pre- and post-central gyri, compared to the control group. *z*-co-ordinates refer to the Talairach system.

Reproduced from *Brain*, 138(Pt 5), Gaebler AJ, Mathiak K, Koten JW, *et al.*, Auditory mismatch impairments are characterized by core neural dysfunctions in schizophrenia, pp. 1410–23, Copyright (2015), with permission from Oxford University Press.

which are in the 30- to 80-Hz range and scale with working memory load [121], are significantly reduced in schizophrenia patients, compared to controls [122].

A more direct, but static, readout of GABA levels can be obtained by magnetic resonance spectroscopy (MRS) (for review, see [123]). MRS can be implemented in different ways; most commonly, it focuses on hydrogen nuclear spins (^1H MRS). These hydrogen nuclear spins are reflected by specific radiofrequency signals that are determined by the chemical environment of the hydrogen spins. This allows, in principle, for the detection of certain endogenous metabolites, including GABA and glutamate.

MRS is increasingly being applied to schizophrenia. For example, Yoon *et al.* (2010) found reduced GABA levels in the visual cortex of patients with schizophrenia [124]. This reduction correlated with orientation-specific surround suppression, a psychophysical measure that is believed to reflect cortical inhibition. Kegeles *et al.* (2012) employed MRS to measure GABA and glutamate levels in the dorsolateral and medial PFC, respectively, contrasting both medicated and non-medicated patients with schizophrenia to healthy controls. They found a significant increase of both GABA and glutamate levels in the medial prefrontal region in unmedicated, but not medicated, patients. By contrast, there were no group differences in the dorsolateral PFC for either transmitter [125].

The practical application of MRS to schizophrenia, however, is aggravated by various methodological challenges [126]. One of the most obvious practical limitations is that most presently used MRS techniques are limited spatially to a small ROI (although alternatives are emerging such as chemical exchange saturation transfer (CEST) techniques; see, for example, [127]). Variations in the ROIs across reports may provide one partial explanation for why the MRS literature on alterations of GABA levels in schizophrenia is diverse and difficult to reconcile. Put differently, 'MRS assays of GABA concentration have yielded equivocal evidence of large-scale alteration in GABA concentration' in schizophrenia [126]. The most comprehensive review to date that we are aware of (that is, [128]) failed to find significant alterations in GABA levels in schizophrenia, as assessed by MRS.

The dysconnection theory of schizophrenia

The proposition that schizophrenia represents a mental condition characterized by cognitive disintegration dates back to Wernicke, who proposed that the disorder arises due to a disruption of association fibre tracts, and later to Bleuler (1911) who described the 'splitting' of mental functions [129]. The dysconnection theory of schizophrenia follows this tradition. It arose from the initial thesis that positive symptoms in schizophrenia might be explained as a consequence of disrupted temporo-prefrontal functional connectivity, as had been observed in early PET studies [130]. This led to conceptualizing schizophrenia initially as a disconnection syndrome [27, 131].

However, although most structural and functional connectivity analyses in schizophrenia tend to report a decrease in connectivity, especially with the frontal cortex [132], enhanced connectivity is also a frequent finding, as discussed previously. This motivated a replacement of the Latin prefix 'dis' (apart) by the Greek prefix 'dys' (bad or ill) [133] and led to a more concrete specification of the pathophysiology that underlies aberrant functional coupling of schizophrenia. Specifically, the dysconnection hypothesis postulates

that the central disease mechanism in schizophrenia is an aberrant neuromodulatory regulation (dopaminergic and/or cholinergic) of NMDAR-dependent synaptic plasticity [131]. This explains both functional and structural connectivity in schizophrenia as the consequences of disturbances in 'NMDAR-neuromodulator interactions' (NNI) [133, 134].

Abnormal NNI is consistent with the other pathophysiological theories described previously and may offer a unifying theme for their integration (for details, see [134]). For example, NMDAR hypofunction due to aberrant neuromodulatory regulation can explain progressive grey matter loss (as NMDARs provide a potent neurotrophic signal); it naturally incorporates the NMDAR hypofunction and DA theories and it relates to GABAergic dysfunction, given the role of the latter in post-synaptic gain control, and thus the encoding of precision. Equally importantly, NNI is affected by both genetic [135] and environmental (hormonal, immunological, and metabolic) risk factors for schizophrenia. This makes NNI a key target of gene-environmental interactions and could help explain the clinical heterogeneity across patients [134].

What distinguishes the dysconnection theory from other theories of schizophrenia, however, is that it proposes a specific computational patho-mechanism—an abnormal hierarchical Bayesian inference in the cortex, as a result of aberrant NNI [133, 136]. In hierarchical Bayesian theories of brain function, such as predictive coding [137, 138], the brain is assumed to construct a hierarchical model of the world in order to infer the environmental causes of its sensory inputs. In this predictive coding framework, hierarchically related levels of cortical processing streams exchange predictions and prediction errors in order to estimate states of the world given sensory input (perceptual inference) and adjust the model's predictions (learning). Critically, prediction errors are weighted by how uncertain or precise both predictions and sensory inputs are. This ensures that perception and learning are influenced by the relative reliability of sensory information and prior beliefs.

Importantly, in addition to physiological studies in animals (for example, [139]), human pharmacological neuroimaging studies have disclosed likely relations between the computational quantities in predictive coding and physiological processes (for reviews, see [34, 136, 140]). In brief, prediction errors are thought to be conveyed by ascending connections via both AMPA (α -amino-3-hydroxyl-5-methyl-4-isoxazole propionate) and NMDA receptors, while predictions are signalled via NMDARs by descending connections. Finally, precision weighting is likely implemented by neuromodulatory, as well as GABAergic, influences, both of which regulate the gain of glutamatergic post-synaptic responses.

The physiological-computational links suggested by the dysconnection theory are important for at least two reasons. Firstly, they suggest that the heterogeneous spectrum nature of schizophrenia could be resolved by tools that infer subject-specific abnormalities of NNI from measured brain activity and behaviour [133]. Secondly, they highlight the connections of the dysconnection hypothesis to the other theories of schizophrenia discussed previously. In particular, precision provides an important bridge to the theory of DA-induced 'aberrant salience' in schizophrenia [87]. Put differently, precision offers a formal definition of salience that can help explain prominent symptoms such as hallucinations and delusions [136, 141, 142].

Neuroimaging studies have provided several lines of empirical evidence for the physiological (NNI) and computational (hierarchical Bayesian inference) aspects of the dysconnection theory. Reviews can be found elsewhere [134, 136, 143]; here, for lack of space, we focus on three particular aspects from the recent literature.

Firstly, according to the dysconnection hypothesis, the empirically observed reduction in the auditory MMN should be understood as resulting from abnormal NNI and reflecting impaired hierarchical Bayesian inference [133]. This has been corroborated by recent studies. For example, computational modelling of empirical EEG data demonstrated that a Bayesian inference process [144] provides a better explanation of trial-by-trial changes in the auditory MMN than conventional theories such as change detection or adaptation. Physiologically, reduced MMN in schizophrenia patients is reflected by abnormal connectivity in auditory hierarchies, as shown by a dynamic causal model (DCM) of EEG data that revealed both abnormal ascending and descending connection strengths at the time when surprising stimuli (deviants) were presented [145].

Secondly, from the perspective of the dysconnection hypotheses, hallucinations would arise naturally when prior expectations (about the occurrence of human voices) in higher areas of the auditory hierarchy become abnormally tight (for example, due to a cholinergic abnormality; cf. [137]). One consequence of such overly precise priors would be a down-weighting of prediction errors computed in lower areas. This is precisely what was found in a recent fMRI study on schizophrenia patients with auditory hallucinations that showed a reduced prediction error signal in the auditory cortex [146]. Interestingly, the putative hyper-precision of auditory priors could reflect a compensatory response to initially abnormally high sensory precision.

Thirdly, an imbalance in the precision weighting of bottom-up signals and top-down predictions—in this case, reduced precision of predictions relative to sensory precision—would also explain the empirically observed reduced sensitivity of patients with schizophrenia to visual illusions [147]. This has been studied in patients with schizophrenia, using an identical ‘hollow mask’ illusion paradigm for both fMRI and EEG. In both modalities, DCM demonstrated that, consistent with reduced precision of predictions (in this case about facial stimuli), the patients’ pronounced lack of susceptibility to the ‘hollow mask’ illusion could be explained by increased strengths of bottom-up connections, combined with reduced strengths of top-down connections, compared to healthy controls [148, 149].

Outlook

Neuroimaging studies have provided invaluable insights into the structural and functional changes associated with schizophrenia. In spite of their scientific success, neuroimaging and electrophysiological techniques have not provided concrete diagnostic tools for psychiatry so far [150]. One explanation for this lack of translation is that conventional analysis methods have remained mostly descriptive—they describe patterns of activations, connections, or changes in brain structure, but they do not allow for quantifying the probability that a particular disease mechanism is present. This, however, is the basis for differential diagnosis and targeted treatment.

In the following, we briefly outline two complementary strategies for addressing this problem. A first possibility is to invest in

the development of neuroimaging techniques that provide more direct physiological interpretability than the available structural or functional contrasts in MRI. A prime candidate for this purpose is MRS. Despite its potential, it has, somewhat surprisingly, not made decisive contributions to schizophrenia research so far. Reasons include variability in ROIs across studies, as discussed previously, but also technical limitations since at lower field strengths, the separation of different peaks in the spectrum is difficult. Advances in high-field MRI and the development of CEST techniques—which make MRI sensitive to concentrations of a host of endogenous metabolites [151, 152] and provide whole-brain coverage of neurotransmitter systems—are beginning to change the clinical utility of MRS, as illustrated by recent applications to epilepsy [127].

A second option is to pursue a neuromodelling strategy. This usually takes one of two forms: biophysical network models (BNMs) and generative models (for review, see [34]). The former consist of regional circuit models that are connected by long-range connections, typically informed by DWI data (for review, see [153]). While BNMs have found application for schizophrenia (for example, [54]), their complexity makes parameter estimation from fMRI or EEG data difficult; often, only a single global scaling parameter of connection strengths is estimated. This has restricted the potential of BNMs to provide clinical tests. ‘Generative models’ (Fig. 60.4) [163] represent an alternative. These describe potential neural mechanisms that could have generated the measured neuroimaging data (EEG or fMRI), including noise. Put differently, generative models embody a probabilistic mapping from the (hidden) neural states to the measured data; this mapping can, in principle, be inverted to uncover disease mechanisms in individual patients [154]. One example of such an approach is DCM, which describes the dynamics of neuronal populations using differential equations [155]. DCMs explain measured brain activity as arising circuit dynamics that is a function of: (1) intrinsic connectivity; (2) experimentally induced perturbations; and (3) modulatory inputs that invoke contextual changes in synaptic strengths (that is, short-term plasticity during learning or neuromodulatory influences). In conjunction with suitably defined observation models, DCMs can be applied to either fMRI or electrophysiological data. Importantly, such models require a prior distribution, indicating the possible range of parameter values. Techniques such as DWI or MRS can be used to provide anatomical or physiological constraints on the variance of these prior distributions in individual patients (for proof of concept, see [156]). As has been demonstrated in various validation studies in humans and animals (for example, [109, 157–159]), DCM can potentially detect alterations in glutamatergic, GABAergic, and neuromodulatory (for example, dopaminergic and cholinergic) synaptic transmission and thus provide a considerably more detailed assessment of pathophysiology than a phenomenological account of changes in function coupling.

A complementary approach within a computational approach to neuroimaging-based differential diagnosis is provided by generative models of behaviour. These can be fitted to individual behavioural responses in order to infer on trajectories of computational quantities such as prediction errors. While this approach has featured prominently in the investigation of dopaminergic abnormalities in schizophrenia, as discussed previously, recent results based on hierarchical Bayesian models have suggested the possibility of assessing trial-wise activity in both dopaminergic and cholinergic regions

Fig. 60.4 (see Colour Plate section) Generative models for neuroimaging data.

Generative models applied to neuroimaging data propose that we can infer on neural activity (for example, firing rate) from the measured signal. Constrained by priors that define neuroanatomical connectivity obtained by DWI techniques, generative models comprise neural state equations, which describe the hidden dynamics in terms of differential equations that are parameterized, and a forward model that describes a mapping from the neural state to the measured signal. To estimate how neural states translate into the measured signal, the model is inverted, that is, fitted to the neuroimaging data and the connectivity parameters that generated the observed data are estimated. DWI, diffusion-weighted imaging; M/EEG, magneto-/electroencephalography.

under the same paradigm [160, 161]. This may provide a powerful approach for classifying patients with schizophrenia into different NNI subgroups.

The utility of generative models for detecting physiologically defined subgroups within schizophrenia has been demonstrated previously. For example, Brodersen and colleagues (2014) applied a simple DCM of interactions between visual, parietal, and prefrontal regions to fMRI data from 41 patients with schizophrenia who performed a working memory task [162]. Using a variational Gaussian mixture model, they found that three clusters provided an optimal explanation of variability in connectivity estimates across patients. Remarkably, these subgroups, defined in an entirely unsupervised way, exhibited significant differences in negative symptoms, thus establishing a link between physiology and clinical symptoms. While this finding did not constitute a clinically relevant solution, as it only predicted symptoms that were already known to the clinician, it illustrates the potential of a ‘generative embedding’ approach. The hope is that more sophisticated models, such as DCMs capable of inferring transmitter-specific synaptic properties from electrophysiological data [157], could convey real clinical utility such as predictions about treatment responses [34].

While generative modelling approaches open up exciting opportunities for neuroimaging research on schizophrenia, validation studies are needed to determine their clinical utility. In other words, regardless of how well a model may capture a putative pathophysiology, it needs to support differential diagnosis or predict treatment response with sufficient accuracy and in individual patients. This can only be tested in prospective studies where patients are followed up after a clinical intervention and which target clinically relevant questions such as predicting the response to specific drugs for psychosis.

Schizoaffective and schizotypal disorders/acute and transient psychotic disorders

William S. Stone, Stephen V. Faraone, and Ming T. Tsuang

Introduction

This chapter focuses on several disorders that show similarities to schizophrenia, including schizoaffective disorder, schizotypal personality disorder, and brief psychotic states. Areas of emphasis include the clinical features, classification, diagnosis, epidemiology, course, and prognosis for each disorder. Some aspects will be underscored to reflect critical issues such as levels of heterogeneity, reliability, and validity. These issues are related to the accurate classification of the disorders, which are important for at least three related reasons. Firstly, it is essential to develop reliable and valid diagnostic criteria in order to study the aetiology of the disorders and then utilize that knowledge to develop rational and testable intervention strategies. Heterogeneity adds variance to the process that reduces both the reliability of diagnosis and also the statistical power of experimental designs to detect intervention/treatment effects.

Secondly, the development of newer generations of psychopharmacological treatments holds the promise of matching more appropriate and efficacious medications with specific syndromes or types of symptoms. This trend underscores the importance of differential diagnosis in determining what treatment a patient will receive. Heterogeneity within a diagnostic category complicates the achievement of this goal. Thirdly, as psychiatry inches closer to the inclusion of dimensional and trans-diagnostic models in the conceptualization, assessment, and treatment of psychopathology, diagnostic reliability and validity are increasingly critical components of translational efforts to integrate clinical, behavioural, cognitive, biological, and genetic markers/phenotypes across psychiatric disorders [1, 2]. Each disorder will be considered separately, starting with a review of schizoaffective disorder, the most severe of the three conditions.

Schizoaffective disorder

Clinical features

Each edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) described a version of a disorder that afflicts

patients with both schizophrenic and affective symptoms. The term 'schizoaffective disorder' first appeared in DSM, third edition (DSM-III) in 1980 [3], but without operational diagnostic criteria. DSM-III-Revised (DSM-III-R) introduced four diagnostic criteria and depressive and bipolar subtypes [4]. DSM-IV retained the diagnostic criteria and added a mixed subtype [5] that did not change in the DSM-IV 'Text Revision' (DSM-IV-TR). Criterion A in DSM-IV required an uninterrupted mood episode that could be major depressive (and must include depressed mood), manic, or mixed in nature. During the same period, Criterion B required a period of at least 2 weeks with hallucinations or delusions that were not associated with prominent mood disturbances. Criterion C specified that the symptoms comprising the mood disturbance persisted for significant portions of the active and residual stages of the disorder. Criterion D required that symptoms of the disorder were not attributable to substance use/abuse or to general medical conditions.

Schizoaffective disorder in DSM-5 does not differ radically from its conception in DSM-IV [6, 7] but is defined more stringently. Criterion C, in particular, now requires that symptoms of a major mood episode must be present for over half of the total duration of the active and residual phases of the illness (that is, the entire course of illness). This change is also significant because DSM-IV did not define the required duration of the mood disturbance. Moreover, DSM-5 requires the mood disturbance to meet diagnostic criteria for a major mood episode for a majority of the illness. Affective disorders that do not meet full criteria for a major mood episode do not meet the criterion. One effect of the change in Criterion C may be to reduce an apparent bias in clinical diagnosis towards less severe diagnoses, as shown, for example, by a study that compared clinical diagnoses with research diagnoses of hospitalized psychiatric inpatients [8]. In that study, treating clinicians diagnosed 36% of the sample ($n = 134$) with schizophrenia, 37% with schizoaffective disorder, and 27% with psychotic bipolar disorder. By contrast, diagnoses made by trained research personnel using the Structured Clinical Interview of DSM-IV-TR included 48% with schizophrenia, 28% with schizoaffective disorder, and 24% with psychotic bipolar disorder.

Like schizophrenia, Criterion A in DSM-5 schizophrenia must be met at some point in schizoaffective disorder. Unlike schizophrenia,

Criterion B, which involves functional declines in social, interpersonal relations, or work, and Criterion F, which involves the exclusion of autistic spectrum disorder or communication disorder in childhood, are not required in DSM-5 schizoaffective disorder. At any point in time, affective and non-affective symptoms may or may not occur simultaneously, which underscores the importance of considering the course of the illness longitudinally, in addition to its cross-sectional presentation. Symptom clusters that are primarily affective, schizophrenic, or mixed predominate at different times.

Compared to patients with schizophrenia, patients with schizoaffective disorder often (though not always) demonstrate relatively high levels of premorbid function [9, 10]. This trend partly reflects the absence of a required functional decline in schizoaffective disorder. Nevertheless, premorbid vulnerabilities in multiple cognitive and clinical functions are common [11]. Patients with schizoaffective disorder also tend to show more identifiable precipitating events. The nature of the precipitating stressor may vary widely; for example, it may be physical (for example, recently giving birth or experiencing a head injury) or interpersonal (for example, a change in an important relationship). The clinical course of the disorder is often characterized by a periodic, rapid onset of symptoms that shows a relatively high degree of remission after several weeks or months. As Vaillant pointed out in the 1960s, many of these patients 'recover' completely after an episode and resume their lives at premorbid levels of function [12]. As will be further noted later in this chapter, the clinical features of some cases of schizoaffective disorder mainly resemble those of schizophrenia, while the features of other cases are more similar to those of bipolar disorder. Regardless of the subtype or variant of the disorder, however, the mortality rate is of special concern. Rates of death due mainly to suicide or accident show elevations in this disorder that are similar to those observed in schizophrenia and major affective disorders [13]. A recent study showed, however, that even when schizophrenia and schizoaffective disorder subjects were matched for age, gender, and race, schizoaffective subjects showed higher rates of suicide attempts, were hospitalized for suicidality more frequently, and showed higher rates of anxiety disorders, compared to schizophrenia subjects [14].

Schizoaffective disorder is more common in females than in males [6, 9]. The age of onset varies but tends to be younger than that of unipolar or bipolar disorder. Tsuang *et al.* found the median age of onset for schizoaffective disorder was 29 years, which was significantly lower than groups with bipolar or unipolar affective disorder, but similar to a group with schizophrenia. Marneros *et al.* [10] also reported that a median age of onset of 29 years for schizoaffective disorder was lower than the median age for groups with affective disorders (35 years), but reported that it was higher than a group with schizophrenia (24 years). In contrast, Reichenberg *et al.* [11] reported no differences in the age of first hospitalization between patients with schizophrenia, schizoaffective disorder, or non-psychotic bipolar disorder. These differences between studies reflect differences in both the diagnostic criteria employed and the heterogeneity of the disorder.

Classification

The classification of schizoaffective disorder has always been controversial. Kraepelin reported in 1919 that patients with both affective and schizophrenic symptoms complicated the differential diagnosis

due to the 'mingling of morbid symptoms of both psychoses'. Kasanin first employed the term 'acute schizophrenic psychoses' in 1933 to describe a group of patients who experienced a rapid onset of emotional turmoil and psychotic symptoms but who recovered after several weeks or months [9, 15]. These symptoms appeared similar to schizophrenia during periods of exacerbation, but unlike schizophrenia, they showed a greater tendency to remit between episodes. Kasanin's view of schizoaffective disorder as a (chronic) schizophrenia-like condition with a better outcome was not adopted by DSM-5 or earlier editions [7], though it is more consistent generally with the notion of acute and transient psychotic disorders described later in this chapter. Nevertheless, ongoing debates about the nature of schizoaffective disorder have persisted since Kraepelin's division of psychoses into affective and schizophrenia types, with most conceptualizations focusing on the following possibilities: (1) it is a type of schizophrenia; (2) it is a type of affective disorder; (3) it is a unique disorder that is separate from both schizophrenia and bipolar disorder; (4) it reflects an arbitrary categorization of clinical symptoms that masks a continuum of pathology between schizophrenia and affective illness; and (5) it contained a heterogeneous collection of 'interforms' between schizophrenia and affective disorder (that is, symptoms of both disorders).

The last possibility is not mutually exclusive of the first four; for example, one or more variants of schizoaffective disorder may be related closely to schizophrenia, while another may be related more closely to an affective disorder. The issue has yet to be resolved. Classification problems reflect conceptual difficulties about the nature of schizoaffective disorder, its diagnosis, and its reliability and validity. Compared to schizophrenia, bipolar disorder, and unipolar depression, both test-retest reliability and inter-rater reliability are low [16, 17]. It is too soon to know whether DSM-5 attempts to tighten diagnostic criteria will improve inter-rater reliability, especially in clinical settings [8]. Different conceptual assumptions and research strategies also lead to different conclusions about the nature of the disorder. Several meta-analyses by Baethge and colleagues showed, for example, that subjects with schizoaffective disorder showed clinical and demographic characteristics that fell between schizophrenia and bipolar disorder [18] and between schizophrenia and unipolar depression [19]. Levels of heterogeneity were also intermediate between schizophrenia and both bipolar disorder and unipolar depression [19, 20]. These findings were interpreted as consistent with the Kraepelinian dichotomy.

Family and outcome studies provide useful ways of assessing the relative merits of each of the possibilities outlined previously. These approaches are informative and will be reviewed later in this chapter, although interpretations of such studies are complicated at times by the use of different diagnostic criteria across investigations.

Family studies

Family studies employ a behavioural genetic method that assumes that related disorders co-aggregate more frequently in biologically related individuals than they do in the general population. Thus, a disorder more likely belongs in the schizophrenia spectrum if it occurs more frequently in biological relatives of schizophrenia patients, compared with appropriate controls. Similarly, a disorder more likely belongs in the affective spectrum if it occurs more frequently among the relatives of patients with affective disorders. Consideration of evidence directly pertinent to the

question of where schizoaffective disorder belongs in the schizophrenia spectrum, which includes a growing number of genetic studies, is beyond the scope of the current discussion. Instead, only representative findings pertinent to the present discussion about the clinical classification of schizoaffective disorder will be summarized here.

Bertelsen and Gottesman [21] summarized a series of seven family studies published between 1979 and 1993, using structured diagnostic criteria. Analyses of risk to the development of schizophrenia, schizoaffective disorder, and affective disorder in the first-degree relatives of patients with schizoaffective disorder were included. In all seven studies, the relatives showed a higher risk of developing an affective disorder than of developing schizophrenia. In five of the seven studies, the risks of developing schizophrenia was equal to, or greater than, the risk of developing schizoaffective disorder. Thus, the relatives of schizoaffective patients showed generally higher risks of developing disorders other than the one with which their ill relatives were diagnosed. These findings were consistent with a heterogenous view of schizoaffective disorder, in which individual cases represented subtypes of either schizophrenia or affective disorder. The findings were also consistent with the possibility that schizoaffective disorder represents a chance collection of 'interforms' between schizophrenia and affective disorder.

This latter view also found a measure of support in a more recent report that utilized the Danish National Register [22] where the relative risk of schizoaffective disorder was elevated significantly (relative risk = 2.76) if a first-degree relative had any history of mental illness. The relative risk increased further if the disorder demonstrated by the first-degree relative included schizophrenia (2.57), bipolar disorder (3.23), or schizoaffective disorder itself (1.92). Notably, the relative risk for schizophrenia was highest when a first-degree relative had schizophrenia (3.22), and the relative risk for bipolar disorder was highest when a first-degree relative had bipolar disorder (5.19). These findings show further that schizoaffective disorder may be related genetically to both schizophrenia and bipolar disorder, either as a subtype or as an interform.

These findings were not consistent with the view that schizoaffective disorder represented a continuum between the other two disorders, because in that case, the rate of schizoaffective disorder in first-degree relatives would have been higher, compared with the rates at which these relatives developed schizophrenia or affective disorder. The findings were also inconsistent with the possibility that schizoaffective disorder represented a unique disorder that was independent of either schizophrenia or an affective disorder. In that case, the first-degree relatives of patients with schizoaffective disorder should show relatively high rates of schizoaffective disorder itself, but relatively low rates of the other disorders. In a series of studies reviewed by Bertelsen and Gottesman [21], the morbid risk for schizoaffective disorder itself ranged from 1.8% to 6.1% in first-degree relatives of patients with schizoaffective disorder, which was still higher than the rate observed in the general population (see Epidemiology, p. 612). These results, taken together with the higher risks for both schizophrenia and affective disorder, suggest that schizoaffective disorder is a heterogenous condition. Recent reviews of family studies, including those that considered depressed (that is, unipolar) and bipolar subtypes, have also underscored both the heterogeneity of schizoaffective disorder and the controversial nature of its classification [23, 24].

Outcome studies

A majority of outcome studies show that schizoaffective disorder has a better course than schizophrenia, but a poorer course than affective disorder [25–27]. Other researchers reported similar findings. Kendler *et al.*, for example, showed intermediate levels of clinical impairment for schizoaffective disorder in an epidemiological family study. Marneros *et al.* reported on outcomes as part of the Cologne Longitudinal Study, using modified DSM-III-R diagnoses [28]. The outcomes were measured by symptoms in five dimensions (psychotic symptoms, reduction of energetic potential, qualitative and quantitative disturbances of affect, and other disturbances of behaviour) that persisted for at least 3 years. Consistent with the pattern described thus far, poor outcomes in the schizoaffective group occurred at a rate (49.5% of the sample) that was intermediate between those observed in the schizophrenic (93.2%) and affective groups (35.8%), and differed significantly from both of them. In a more recent study, Jäger *et al.* studied 241 patients at the time of their first hospitalization, and then again 15 years later [29, 30]. Again, schizoaffective subjects presented a less impaired clinical picture than the one shown by schizophrenic subjects, but more impaired than the one shown by affective subjects.

While these studies show schizoaffective disorder to have intermediate outcomes generally, there are categories in which it resembles schizophrenia or affective disorder more closely. For example, Samson *et al.* [25] and Reinares *et al.* [27] noted that outcomes for schizoaffective disorder were equivalent to those for affective disorder in several dimensions. Marneros *et al.* showed that 70% of a schizoaffective group were rated as good or excellent on a measure of social adjustment, which did not differ significantly from 84% of an affective group who received the same rating (reviewed in [27]). Both groups differed significantly from a schizophrenic group, however, in which only 44% of the group demonstrated good or excellent outcomes. Moreover, the schizoaffective and affective disorder groups did not differ on a rating scale of psychological impairments (for example, body language, affect display, conversation skills, and co-operation), although both were rated as significantly less impaired than the schizophrenic group.

Other studies, however, such as Kendler *et al.* [28], reported similarities between some types of psychotic symptoms in schizoaffective disorder and schizophrenia, including the severity of delusions and positive thought disorder and the frequency of hallucinations. Each of these groups showed higher levels of these symptoms than an affective disorder group. Hizdon *et al.* reported recently that individuals with schizoaffective disorder did not differ from individuals with schizophrenia on basic cognitive measures of executive function, memory, and processing speed, although the schizoaffective group did perform better on measures of social cognition [31]. Reichenberg *et al.* showed that individuals with schizophrenia and schizoaffective disorder who were assessed premorbidly performed similar to each other, but lower than individuals who later developed non-psychotic bipolar disorder, on selected tests of intellectual and academic functions [11].

These overall differences in outcome serve to validate the classification of schizoaffective disorder as a separate syndrome further. Its heterogeneity, however, raises the issue of whether such intermediate outcomes might reflect the mean of a combination of mainly good and mainly poor outcomes. This, in turn, leads to the question of whether schizoaffective disorder can be subtyped in a

useful and valid manner. If so, are better and worse outcomes associated with different variants of the syndrome?

Vaillant suggested in the 1960s that prognostic indicators, including a good premorbid level of adjustment, the presence of precipitating factors, an acute onset, confusion, the presence of affective symptoms, and a family history of affective disorder (or the absence of a schizophrenic history), could predict remission in approximately 80% of cases of 'remitting schizophrenia' [31]. The inclusion of affective symptoms and a positive family history for affective illness on the list contributed (later) to hypotheses that variants of schizoaffective disorder were related to affective illness and to better outcomes. In contrast, variants associated more with schizophrenic symptoms or family histories were associated more with schizophrenia and relatively poor outcomes. [32].

There have been a variety of attempts to subtype schizoaffective disorders, based on whether affective or schizophrenic symptoms predominate. The validity of many of these attempts, however, is inconclusive [21, 28]. Conversely, a latent class analysis of psychotic patients from the Roscommon Study showed that most cases of DSM-III-R schizoaffective disorder were categorized in either a bipolar schizomania class ($n = 19$) or a schizodepression class ($n = 13$), rather than in schizophrenia ($n = 1$), major depression ($n = 0$), schizophreniform ($n = 3$), or hebephrenia ($n = 3$) classes [33]. Moreover, Reinares *et al.* reviewed evidence showing that bipolar and depressive subtypes differed from each other in ways consistent with differences between bipolar and unipolar affective disorders [27]. For example, the bipolar schizoaffective subtype was associated with more total episodes, more episodes with shorter periods and cycles, and higher frequency of cycles. Higher numbers of cycles were associated with poorer long-term outcomes. Taken together, these studies show at least some recent support for the subtyping of schizoaffective disorder into mainly affective and mainly schizophrenic variants.

Other factors associated with poor outcomes include poor inter-episode recoveries [28], persistent psychotic symptoms in the absence of affective features, poor premorbid social adjustment, chronicity, a higher number of schizophrenia-like symptoms [34], and the presence of schizoaffective mixed states [27].

Differential diagnosis

The major feature of DSM-5 schizoaffective disorder [6] involves a mood disorder occurring concurrently with Criterion A of schizophrenia for a continuous period of time. Many other disorders that present with psychotic or mood symptoms should be considered in the differential diagnosis of schizoaffective disorder, including, for example, other psychiatric or neurological disorders involving psychotic symptoms, acquired substance or toxin-induced psychotic conditions, cognitive disorders, prodromal syndromes, personality disorders, anxiety disorders, neurodevelopmental disorders, and states of delirium. Particular concern involves the differential diagnosis between schizoaffective disorder and schizophrenia, and between schizoaffective disorder and either bipolar disorder or a depressive disorder with psychotic symptoms. In DSM-5, Criterion C distinguishes schizoaffective disorder from schizophrenia by requiring that the prominent mood disorder in schizoaffective disorder characterizes over half the period spanning the active and residual phases of the disorder. Criterion B distinguishes schizoaffective

disorder from other mood disorders involving psychosis by requiring the presence of delusions or hallucinations for at least 2 weeks in the absence of prominent depressive or manic symptoms. Notably, these diagnostic criteria may be met during some phases of the disorder, but not others. Thus, the presence of a prominent mood disturbance occurring over half the time could shift, for example, to occur less than half the time during the course of the disorder, which might necessitate a valid change in diagnosis from schizoaffective disorder to schizophrenia.

Epidemiology

Incidence

Earlier studies showed that new cases of 'schizomaniac' patients (that is, manic patients who also demonstrated schizophrenic or paranoid symptoms) numbered approximately 1.7 per 100,000 per year [35]. This was less than the 4 per 100,000 per year shown by 'schizodepressive' patients. The number of schizoaffective cases in this study exceeded the number of manic patients and made up half of the number of schizophrenia cases. Since then, Tien and Eaton analysed data from the Epidemiologic Catchment Area Study for three non-overlapping groups with psychotic symptoms [36]. One of these groups comprised individuals with 'psychotic affective syndrome', which was similar to schizoaffective disorder, except that most members of the group (59%) demonstrated psychotic symptoms only in conjunction with a mood disturbance (essentially DSM-III-R mood disturbance with psychotic symptoms). The incidence of this disorder was 1.7 per 1000 per year, which was approximately equal to the rate for schizophrenia (2.0 per 1000 per year). Even if the 59% of the group who met the criteria for a mood disorder with psychotic features were excluded, the remaining 41% would still comprise a higher incidence rate than that detected by earlier studies. Differences in sampling procedures (treated vs non-treated samples) may have contributed to the differences observed in the rates. More importantly, however, these studies showed that schizoaffective disorder occurred at 50–85% of the rate of schizophrenia, thus confirming that patients with this disorder comprise a clinically significant population. One current, but long-standing, issue involves questions about the temporal stability of incidence rates in schizophrenia-related disorders, as reflected by reports of both increases and decreases.

Prevalence

Until recently, prevalence estimates for schizoaffective disorder relied mainly on samples that were treated in clinics or other psychiatric settings. Because a variety of factors influence the decision to enter and remain in treatment, the estimates varied substantially. For example, Okasha reviewed studies that reported rates varying between 2% and 29% [23]. A recent epidemiological study in Finland using 8028 people who were at least 30 years old showed a lifetime prevalence rate of 0.32% for schizoaffective disorder (compared to 0.87% for schizophrenia), which accounted for 10.5% of all psychotic disorders [37]. This is a lower estimate than many earlier studies reported and likely results from a combination of factors (including a narrowing of diagnostic criteria and increased utilization of multiple sources of information such as case notes and registers, in addition to interview data) that together have improved diagnostic accuracy.

Review of evidence

Treatments for schizoaffective disorder are the same as those for schizophrenia and affective disorders alone. As the nature and efficacy of those treatments are discussed elsewhere, they will not be considered here. Rather, this section will focus on management issues related to the need to treat symptoms of both disorders simultaneously or sequentially.

Management

Psychopharmacological treatments may be viewed in terms of DSM-5 schizoaffective disorder subtypes, including the bipolar type and the depressive type. Treatment of the bipolar type will include dopamine antagonist medication (for example, clozapine, risperidone, quetiapine, ziprasidone, or olanzapine), particularly if psychotic symptoms are present. In addition, drugs for unipolar depression, mood stabilizers (for example, lithium), or anticonvulsants (for example, valproate or carbamazepine) may be useful with this group. It will be necessary in such cases to weigh the potential risks of such medications, such as elevated toxicity and metabolic abnormalities, against the potential benefits.

In the depressive subtype, combination treatments may also be more effective than a single treatment. Dopamine antagonist treatments alone may be more efficient, however, if affective symptoms (that is, depression) are largely secondary to the experience of having a psychotic condition and its attendant interpersonal, social, and financial difficulties. In these cases, remediation of the psychotic symptoms may also ameliorate the affective problems. For other cases, which include more of a treatment-refractory depression, drugs for psychosis may be augmented with a mood stabilizer or antidepressant medication. Moreover, electroconvulsive therapy may reduce mortality rates in schizoaffective patients.

As was true in earlier versions of DSM, the bipolar subtype (including a manic episode and possibly major depressive episodes) may be difficult to distinguish from the depressive subtype (including major depressive episodes in the absence of manic episodes), especially in the presence of psychotic symptoms. In these cases, treatment decisions may rest on the presenting symptoms of the patient. At any point, treatment is partly dependent on the presence or absence of psychotic symptoms. As noted previously, psychotic episodes in this period are associated with relatively poorer outcomes and are likely to require chronic drug therapy.

Schizotypal personality disorder

Clinical features

Like schizoaffective disorder, schizotypal personality disorder (PD) is a complex and chronic condition that includes some, but not all, of the features of schizoaffective disorder and schizophrenia. Changes from DSM-IV to DSM-5 reflect a growing recognition that, while this disorder should still be viewed as a personality disorder, it should also be classified as a schizophrenia spectrum condition [6, 38]. Most notably, persistent psychosis is not part of the syndrome in individuals with schizotypal PD, although milder forms of thought disorder may occur such as magical thinking or ideas

of reference (as opposed to delusions of reference, which indicate psychosis). Moreover, brief episodes of psychosis may occur in times of stress but will not persist.

Schizotypal patients show pervasive deficits in social and interpersonal traits. They often demonstrate aloofness, poor eye contact, affective constriction, and suspiciousness. Consequently, close interpersonal relationships either are avoided or cause discomfort and anxiety. This social anxiety persists despite familiarity and is often related to suspiciousness or attenuated psychotic paranoia, rather than to fears of negative evaluations by others. Individuals with schizotypal PD usually have few friends and demonstrate deficiencies in social cognition such as problems in sensing social cues or affective signals accurately from others. These problems in social cognition exacerbate suspiciousness or paranoia and contribute to the persistence of anxiety over time.

Schizotypal patients may show magical thinking, ideas of reference, unusual perceptions (for example, sensing the presence of another person or that people are talking about them), and/or perceptual illusions (for example, often perceiving a dimly lit lamp post as a person). Both their social deficits and these cognitive-perceptual problems contribute to an overall impression of oddness. However, this feature may occur independently of other clinical symptoms [39] and manifest itself in odd speech or unusual appearance. The oddness or eccentricities evident in these patients are often ego-syntonic (that is, they are not experienced as problems). Moreover, schizotypal patients show deficits in attention, long-term verbal memory, and executive functions. These cognitive deficits are qualitatively similar to those seen in schizophrenia (and schizoaffective disorder), but like many other clinical manifestations of this disorder, they are quantitatively milder [40, 41].

Like schizophrenia, schizotypal PD is often evident by early adulthood, but schizotypal traits may be evident in late childhood or adolescence. Once it appears, the disorder tends to show a chronic course, but one that includes periodic exacerbations and attenuations of symptoms. A study that followed individuals with schizotypal PD for 2 years showed that paranoid thoughts and unusual perceptual experiences were among the most stable and least malleable DSM-IV symptoms, while the most changeable were odd behaviours and restricted affect [40]. The former symptoms were thus more trait-like, and the latter were more intermittent. The same group also showed that in the course of 2 years (with treatment), 61% of schizotypal patients no longer met DSM-IV diagnostic criteria for the disorder [42]. With a more stringent definition of improvement (12 months with two or fewer symptoms meeting criteria), the rate of remission dropped to 23%. These studies show that both the severity and the expression of the disorder vary over time and probably as a function of treatment. A recent study that assessed twins with either schizotypal or paranoid PD over a 10-year period showed much of the observed stability of the disorders (about 67%) was attributable to shared genetic factors between early and middle adulthood, while the effects of environmental risk factors were more transient [43]. Consistent with previous studies, subjects with schizotypal PD also showed moderate declines in symptom levels over time [44, 45].

Classification

In contrast to the controversy surrounding the classification of schizoaffective disorder, family, twin, and adoption studies clearly support the view that schizotypal PD is best classified in the

schizophrenia spectrum [38, 46, 47]. Nevertheless, it is a complex and chronic disorder that, in all likelihood, is also heterogeneous. Kendler pointed out that this heterogeneity was at least partly related to the two primary methods used to study the disorder [48]. One of these involves the 'clinical method', which identifies patients with mild forms of schizophrenic or psychotic-like symptoms. This type of patient, for example, is often characterized by relatively high levels of positive psychiatric symptoms (for example, magical thinking and perceptual distortions). Patients identified in this manner often comprise a heterogeneous group themselves, however, involving patients with schizotypal symptoms, together with patients with other types of severe personality problems such as borderline personality disorder [47].

In contrast, the 'family research method' identifies relatives of patients with schizophrenia who have subtle schizophrenia-like symptoms. Features associated more with familial than with clinical schizotypal PD include a predominance of negative symptoms (for example, social withdrawal and impairment, and higher levels of anxiety and poor rapport), cognitive or electrophysiological impairments (for example, impaired language comprehension, eye-tracking, and attentional dysfunctions, though all of these also occur in clinical PD), and elevated rates of schizophrenia and related disorders in family members [46]. Thaker *et al.* reported that familial and clinical schizotypal PDs were similar on measures of physical or social anhedonia [49].

The concept of familial schizotypal disorder is particularly important because it may share a common genetic basis with schizophrenia. Paul Meehl first proposed the term 'schizotaxia' to describe the genetic vulnerability to schizophrenia and suggested that individuals with schizotaxia would eventually develop either schizotypal PD or schizophrenia, depending on the protection or liability afforded by environmental circumstances [50]. As the concept evolved, Meehl reformulated it to allow for the possibility that some people with schizotaxia would develop neither schizophrenia nor schizotypal PD. In fact, evidence now shows that the clinical symptoms observed in many non-psychotic first-degree relatives of people with schizophrenia are similar to those observed in familial schizotypal PD [46, 51]. Psychiatric features in such relatives frequently include an aggregation of negative symptoms that are qualitatively similar to, but milder than, those often cited in schizophrenia. Positive symptoms, however, are usually less evident in these relatives than they are in schizophrenia or schizotypal PD. Neuropsychological impairments in biological relatives of people with schizophrenia are also qualitatively similar to, but milder than, those seen in people with schizophrenia [41].

Faraone *et al.* suggested a reformulation of Meehl's concept of schizotaxia that focuses on these features of negative symptoms and neuropsychological deficits [46]. Unlike schizotypal PD, which occurs in less than 10% of adult relatives of patients diagnosed with schizophrenia, the basic symptoms of schizotaxia occur in 20–50% of adult relatives, suggesting further that the genetic liability to schizophrenia does not lead inevitably to schizophrenia, schizotypal PD, or schizoid PD. More recent studies showed that operational definitions of schizotaxia in non-psychotic adult relatives, based on neuropsychological deficits and negative symptoms, were supported by cluster analyses and were partially amenable to pharmacological intervention [41].

Diagnosis and differential diagnosis

The DSM-5 diagnostic criteria for schizotypal PD do not differ substantially from the criteria used in DSM-IV. While an alternative, more dimensional model of PDs is included in the DSM-5 manual that structures these symptoms somewhat differently, the categorical system of previous versions remains in place [6]. In this context, DSM-5 Criterion A includes deficits in personality that involves ideas (but not delusions) of reference (A1), unusual ideas or types of thought such as magical thinking (unrelated to cultural norms) or beliefs in special powers such as clairvoyance (A2), unusual perceptual experiences such as illusions or transitory hallucinations (A3), unusual forms of thinking or speech (such as frequent use of vague, tangential, metaphorical, or stereotyped language) (A4), frequent suspiciousness or paranoid thoughts (A5), constricted or inappropriate affect (A6), odd or unusual behaviours, manners of dress or other aspects of appearance (A7), constricted interpersonal relationships that often include few, if any, close friends or other non-familial relationships (A8), and acute anxiety in social situations that does not decline with familiarity and is related primarily to suspiciousness of others, rather than to self-consciousness or fear of negative evaluations by others (as is typical in social anxiety) (A9).

As in DSM-IV, five out of the nine symptoms are required to meet Criterion A. These symptoms emerge by early adulthood and occur in a variety of contexts. Criterion B requires that symptoms in Criterion A do not occur only during the periods of disorders involving sustained psychosis, such as schizophrenia, bipolar disorder, or depression with psychotic features, or autism spectrum disorder (ASD).

The differential diagnosis includes a variety of other disorders. A key difference between schizotypal PD and schizophrenia, psychotic mood disorders, or presentations of psychosis in ASD involves the transient nature of psychotic symptoms in schizotypal PD. It may be distinguished from ASD (though sometimes with difficulty) by the relatively greater deficits in social awareness, lack of emotional reciprocity, or frequent presence of stereotyped behaviours or interests in ASD. Schizotypal PD may be distinguished from neurodevelopmental disorders involving language or other forms of communication by the presence of relatively more specific problems in language reception or production that are usually identified by specialized testing. Such problems are not typically present in schizotypal PD. It also differs from communication disorders by its oddness of its content, rather than by the deficiencies of its form.

Schizotypal PD may be confused with several other PDs but can be distinguished from them. It differs from schizoid and from paranoid PD, for example, by its pattern of cognitive and perceptual distortions and by the eccentricities in appearance, language, or behaviour shown frequently by schizotypal patients. Schizotypal individuals who show transient psychotic symptoms may resemble individuals with borderline PD, but the pattern differs in that psychotic-like symptoms and social isolation in schizotypal PD are more likely to persist in the absence of affective turmoil, and schizotypal individuals are less likely to display the impulsive and manipulative traits that are often associated with borderline PD. Some individuals with narcissistic PD may demonstrate suspiciousness or social alienation, but, unlike in schizotypal PD, these symptoms/traits are related to underlying fears of exposing imperfections or flaws. Individuals with avoidant PD may be aversive to, or anxious in, social interactions,

but it reflects a fear of rejection in the context of a desire for such relationships in avoidant PD, whereas it reflects suspicion and a lack of desire for such relationships in schizotypal PD.

Epidemiology

Incidence

A literature search did not identify incidence studies for schizotypal PD.

Prevalence

A review by Tsuang *et al.* showed prevalence rates in non-clinical samples ranged from 0.7% to 5.1%, with a median nearing 3.0% [52]. Higher rates occurred in clinical samples—2.0–64.0%, with a median of 17.5%. More recently, Torgersen *et al.* reported a rate of 0.6% for DSM-III-R in a community sample, which is lower than the rates in studies reviewed by Tsuang *et al.* [53]. In contrast to non-clinical samples, the prevalence of schizotypal PD among the relatives of schizophrenic individuals is as high as 10%. More recently, the life-time prevalence of schizotypal PD in the United States was reported to be near 4.0%, with modestly higher rates for men (4.2%) than women (3.7%) [54].

Treatment

There is unfortunately a continuing dearth of outcome studies involving psychotherapy, psychosocial, or psychopharmacological treatments for schizotypal PD [47]. Older published studies often show methodological limitations (for example, small samples, subjects with mixed diagnoses, inadequate controls, and problems with internal validity) or provide outcome data on only limited aspects of the disorder. Despite these caveats, it is clear that few treatment gains are evident in earlier studies [55]. Recent evidence for the efficacy of psychotherapy for PDs is more promising but is limited mainly to other PDs [56].

Several earlier studies investigated the usefulness of medications in treating schizotypal PD, although they typically employed small numbers of subjects, combined samples of schizotypal and borderline PDs, and showed little clinical improvement. Dopamine antagonist drugs were proposed to reduce positive symptoms or depressed mood in times of acute stress, but the high incidence of adverse side effects discouraged their widespread use at other times, including the more chronic stable (that is, non-crisis) phases of the disorder. Other types of medication, including fluoxetine, have shown generally non-specific effects of treatment.

Hymowitz *et al.* administered a low dose of haloperidol to 17 outpatients with DSM-III diagnoses of schizotypal PD for 6 weeks [57]. The initial dose of 2.0 mg was intended to rise to 12.0 mg, but side effects prevented increases beyond a mean dose of 3.6 mg. Even with lower doses, 50% of the sample withdrew from the study because of side effects. The 17 subjects who completed 2 weeks of the protocol improved somewhat in ratings of ideas of reference, odd communications, social isolation, and overall functioning.

More recently, Koenigsberg *et al.* employed a double-blind protocol to administer low doses of risperidone (0.25–2.0 mg/day), a medication with serotonin antagonist properties, to 25 patients with DSM-IV schizotypal PD, for 9 weeks [58]. Compared to a placebo control group, patients who received risperidone demonstrated significant reductions in positive and negative symptoms, with

no difference in dropout rates between groups. These findings are encouraging and consistent with evidence described previously that schizotypal symptoms are amenable to change [40, 42]. Hopefully, findings like these will stimulate additional research into pharmacological treatments for this disorder.

Management

Though trust and rapport with a therapist are often difficult to establish in schizotypal PD, the therapeutic relationship may be used to mitigate the marked deficits in interpersonal relationships that characterize this syndrome [58]. The frequent occurrence of paranoia and suspiciousness, together with social aloofness and constricted affect, may make exploratory psychotherapeutic approaches less effective than supportive cognitive behavioural therapies. In fact, these patients may only seek treatment to alleviate circumscribed problems like anxiety or somatic complaints. Approaches that emphasize concrete interim goals and stipulate explicit means of attaining them thus have the best chances of success. Because individuals with this disorder are vulnerable to decompensation during times of stress and may experience transient episodes of psychosis, they may also benefit from techniques to facilitate stress reduction (for example, relaxation techniques, exercise, yoga, and meditation). Fortunately, some people with schizotypal features are likely to seek treatment in times of stress [59, 60]. In the short term, brief courses of dopamine antagonist treatment may be useful if symptoms of psychosis appear. It is important to note, however, that individuals with schizotypal PD may receive unwarranted diagnoses of schizophrenia and receive longer-term treatment [47].

Cognitive problems are also frequently amenable to concrete goal-oriented approaches to treatment. Patients benefit from understanding their cognitive strengths and weaknesses because it helps them confront and cope with long-standing difficulties in their lives. For example, problems in attention, verbal memory, or organizational skills contribute to failures in educational, occupational, and social endeavours, while reinforcing negative self-images and increasing performance anxiety. Knowledge of circumscribed cognitive problems allows patients to reframe their difficulties in a more positive manner and facilitate the selection of realistic personal, educational, and occupational goals. While cognitive deficits in schizotypal PD are well established [47], there have been few trials of medications to improve cognition, though the administration of guanfacine and dopamine agonists may show promise.

Brief psychotic disorder

Clinical features

Brief psychotic episodes have long been a source of interest [61] but have defied simple classifications. Consequently, different versions of this condition have been proposed and utilized. Brief psychotic disorder in DSM-5 involves at least one symptom from a group that includes delusions, hallucinations, disorganized speech, and/or grossly disorganized or catatonic behaviour [6]. The onset of these symptoms is rapid, with the transition from a non-psychotic state to a psychotic one occurring within 2 weeks. Typically, a prodromal period is not present. The duration of symptoms lasts from 1 day to 1 month. This diagnosis does not require associated social

or occupational dysfunction. Symptoms may not be attributable to substance abuse or therapeutic medications or to other medical conditions, nor can they be explained better by other psychiatric disorders that involve psychotic symptoms such as schizophrenia or bipolar disorder. Specifiers may be added that note that the episode followed a stressful incident (that is, with marked stressors) or did not (that is, without marked stressors). The episode may also be specified as post-partum, meaning it occurred during pregnancy or within a month of giving birth, and it may be specified as involving catatonia. The severity of the episode may be recorded on a 5-point scale that ranges from 0 (absent) to 4 for the previous 7 days. At the conclusion of the episode, individuals return to premorbid levels of function.

The International Classification of Diseases, tenth edition (ICD-10) defines a similar diagnostic category—the acute and transient psychotic disorders (ATPDs), with six subtypes [62]. One difference involves a longer period, compared to the DSM-5 version (3 months, compared to 1 month). ATPDs should also show a fully developed episode within 2 weeks.

In addition to classifications as psychotic disorders, brief psychotic episodes are also classified as clinical high-risk states. The Structured Interview for Prodromal Syndromes (SIPS) operationalizes a syndrome [Brief Intermittent Psychotic Symptoms (BIPS)] which may last up to 3 months and include at least one symptom of psychosis (at least one of the scales P1–P5 is rated a 6) in that period. The symptom(s) must last at least several minutes per day at least once per month, but less than 1 hour per day for at least 4 days per week for the last month [63, 64]. No decline in social or occupational functioning is required to meet the diagnostic criteria for this syndrome. The Comprehensive Assessment of At-Risk Mental State (CAARMS) defines a similar clinical high-risk syndrome [Brief Limited Intermittent Psychotic Symptoms (BLIPS)] that also requires at least one symptom of psychosis (at least one of the scales P1, P2, or P4 is rated 6 or P3 is rated ≥ 5) [65–67]. CAARMS BLIPS symptoms differ from those in the SIPS BIPS syndrome in that symptoms should have been evident in the previous 12 months, though not for more than 5 years. They occur 3–4 times per week when they persist for at least an hour, or they occur daily when they persist for less than an hour. Unlike BIPS, CAARMS symptoms are associated with at least a 30% drop in functioning on the Social and Occupational Functioning Assessment Scale (SOFAS), lasting at least 1 month in the previous year, or show a low score for over a year.

The risk of recurrent psychotic features in individuals who meet criteria for either the disorders described previously or the clinical high-risk syndromes is significant, though not as high as individuals who demonstrate first-episode schizophrenia [61, 68]. Differences between rates of recurrence in these different brief conditions are small.

Differential diagnosis

Brief psychotic disorders may be differentiated from chronic disorders with psychotic features, such as schizophrenia, bipolar disorder, and depression with psychotic features, both by the persistence of the symptoms and the loss of function in multiple domains and by the failure to resolve fully, even with treatment. It is important to note, however, that some individuals, despite the

generally favourable outcomes associated with brief psychotic symptoms, may develop a chronic psychotic disorder subsequently (especially those with longer symptom durations such as BLIPS cases). Problems involving substance abuse, traumatic brain injury, delirium, and other medical conditions should be considered and assessed. If forensic circumstances exist, the possibility of malingering or other forms of symptom magnification should be considered. Some PDs may also present with brief psychotic symptoms that may be distinguished (for example, borderline PD) by their chronicity and symptom history.

Management

In line with the brief course of these symptoms/disorders, crisis management is a first line of response and may include short-term hospitalization and treatments with dopamine antagonist medications. Behavioural treatments, such as cognitive behavioural therapy, may be useful to reduce or minimize stress and emotional dysregulation and thereby reduce the likelihood of future episodes. Nevertheless, it will be important to monitor individuals who have demonstrated brief psychotic disorders or episodes to assess their stability of clinical functions and the possible emergence of additional brief or chronic psychotic disorders.

Possibilities for prevention

Current early intervention programmes involve secondary prevention, which includes early identification and treatment of clinical (usually psychotic or psychotic-like) symptoms. While intervention is necessary to alleviate clinical symptoms at any point during the disorder, it is particularly important early on because it might alter the trajectory of illness. Patients treated with drugs for psychosis during their first or second hospital admission, for example, show better outcomes than those who are not treated until later.

Primary prevention, which involves treatment before the disorder manifests itself clinically, is not yet available for schizophrenia, schizoaffective disorder, schizotypal PD, brief psychotic disorder, or other disorders in the schizophrenia spectrum. To develop such treatments, it will be necessary to predict first who is most likely to develop a disorder and who is not. There are a few encouraging approaches, including ongoing genetic ‘high-risk’ studies that follow the offspring of schizophrenic parents longitudinally. Such studies help to identify traits early in life that predict which individuals are most likely to experience emergent clinical symptoms in adulthood. This type of study is particularly important because it can facilitate the formation of homogenous high-risk groups, which, in turn, can facilitate the development of focused prevention strategies. Similarly, longitudinal studies of clinical high-risk patients also provide critical information about the nature of ‘conversion’ to psychosis.

With our current knowledge, however, it is difficult to justify preventive treatments—especially medication—for people without symptoms. The authors have argued elsewhere, however, that if people in high-risk groups (like first-degree biological relatives of patients with schizophrenia, or clinical high-risk patients) show clinically meaningful symptoms that can be organized into valid liability syndromes, then intervention attempts may become appropriate [46, 51]. The authors proposed this course of action for people with ‘schizotaxia’ and suggested preliminary research guidelines [69].

Delusional disorders

Andreas Marneros

Definition

Delusional disorder is a psychotic disorder, characterized by well-systematized and long-lasting delusions, whereas other mental and personality domains usually remain intact.

Although modern diagnostic systems (DSM-5 297.1, ICD-10 F22, and presumably also ICD-11) [1–3] categorize it in a spectrum with schizophrenia and other psychotic disorders, it is autochthonous and autonomous, that is, a disorder by its own and independent with its specific clinical features and rules. A shift to schizophrenia in the course of the disease is rare [4, 5].

A very short history

There is a plethora of literature dealing with delusional disorders and paranoia, most of which is historical or in the form of case reports. It is beyond the scope of this chapter to deal with it in its entirety, so the basic conclusions drawn from it are included. Many of these original papers are quoted within references provided in this chapter [4–6]. The concept we nowadays call delusional disorder has a long history, as long as psychiatry itself. The term delusional disorder presents a new name for the old concept of paranoia and was ‘officially’ introduced with DSM-III-R in 1987, but it was created by George Winokur as early as in 1977 [7]. Delusional disorder, in fact, is nothing else than the latest successor, or the new name, of paranoia as defined in their final version by Emil Kraepelin in 1915, which was the successor of concepts like ‘monomania’ in French psychiatry and ‘primary insanity’ in German psychiatry [4]. The concept of paranoia has a long history which is closely connected with the development of psychiatry itself. Nevertheless, the debate on, and the interest in, paranoia lost its vim and vigour after the first decades of the twentieth century and came to a near standstill in the middle of that century. A wave of overdiagnosing schizophrenia was one of the main reasons of its marginalization, as well as the beginning of operationalized diagnostics and the introduction of new treatments, which are mostly refused by patients with paranoia. As mentioned previously, George Winokur introduced the term delusional disorder in 1977, aiming to bring clarity to the equivocal and diffuse use of the term paranoia, especially in the anglophone literature.

Winokur’s term covers, in fact, the same as Emil Kraepelin’s concept of paranoia.

Diagnosis

The ICD-10 category ‘persistent delusional disorder’ is likely to change into ‘delusional disorder’ in ICD-11 [3]. However, the major diagnostic criteria, according to ICD-11 Beta Draft, will probably remain unchanged, with the addition of a specifier for the present state of the condition (symptomatic—partial remission—full remission) (see [Box 62.1](#)).

The diagnostic criteria of DSM-5 are very similar to that of ICD. The most important difference regards the duration of delusions (ICD at least 3 months; DSM-5 at least 1 month).

Prevalence and demography

Prevalence and demography of delusional disorder within the general population are not exactly known. The base rate of delusional disorder is unclear. The most important reasons why this psychotic condition is difficult to uncover and little is known so far about treatment, prognosis, etc. are patients with delusional disorder do not feel ill or disabled and many other psychosocial abilities usually remain intact, so they do not seek medical or psychological help. In addition, the disorder is usually monosymptomatic and monothematic, so distinction between delusions, overvalued ideas, and reality is difficult, sometimes even impossible. The impairments in psychosocial functioning can be more circumscribed, as seen in other psychotic disorders; behaviour is not obviously bizarre or odd, and patients often show sufficient integration in relevant domains of social life, so there is no necessity for their families or authorities to initiate contact with mental services. However, boundaries between delusional disorder, other psychotic disorders, and paranoid personality are often elusive. The fact that delusions are common in a number of different mental disorders makes it difficult to estimate the prevalence of pure delusional disorder. Epidemiological investigations reporting on ‘paranoid’ symptoms in the general population refer to a great spectrum of phenomena, which are rarely symptoms of delusional disorder [4].

Box 62.1 Persistent delusional disorder in ICD-10 (F22)
(presumably delusional disorder in ICD-11)

- A. A delusion or a set of related delusions, other than those listed as typically schizophrenic in criterion G1(1)b or d for F20.0–F20.3 (that is, other than completely impossible or culturally inappropriate), must be present. The most common examples are persecutory, grandiose, hypochondriacal, jealous (zelotypic), or erotic delusions.
- B. The delusion(s) in criterion A must be present for at least 3 months.
- C. The general criteria for schizophrenia (F20.0–F20.3) are not fulfilled.
- D. There must be no persistent hallucinations in any modality (but there may be transitory or occasional auditory hallucinations that are not in the third person or giving a running commentary).
- E. Depressive symptoms (or even a depressive episode (F32) may be present intermittently, provided that the delusions persist at times when there is no disturbance of mood.
- F. *Most commonly used exclusion clause.* There must be no evidence of primary or secondary organic mental disorder, as listed under F00–F09, or of a psychotic disorder due to psychoactive substance use (F1x.5).

Reproduced from World Health Organization, *The ICD-10 Classification of Mental and Behavioural Disorders*, Copyright (1996), with permission from World Health Organization.

Nevertheless, based on available findings, the *lifetime prevalence* of delusional disorder in the general population may be estimated to be somewhat between 0.03% and 0.2%, while their prevalence in a clinical population is approximately 0.5–1% of all admissions (older investigations reported up to 4%) and approximately 2–3% of all psychotic disorders. Reported *gender* differences are not significant. *Age at onset* is usually middle to late adult life, with a peak between ages 35 and 50. Concerning *sociodemographic characteristics*, the majority of patients are married or in a stable partnership and they represent all social classes and levels of education, though lower socio-educational levels and, among these patients, immigrants, are more frequently represented. Similar to other psychotic disorders, many patients come from a broken home [4, 8–11].

Aetiopathogenesis

Various efforts are made to explain how delusional disorder arises, yet all are mainly speculative. The main approaches include the following:

1. The *phenomenological approach* describes preconditions and pre-delusional states, as well as formation, consolidation, and recovery or chronicity of delusional states [4, 12].
2. The *psychodynamic approach* tries to explain delusional disorders (paranoia) as a defence against awareness of vulnerability, having projection as the main mechanism. Libidinous allocations being connected to homosexuality, anality, etc. play an important role [4].

3. The *neuropsychological approach* uses cognitive deficit theories, involving cognitions, attributions, and emotions as an explanatory model [4].
4. Other *psychological approaches* assume that interactions of special personality features, stressful life events, and the social environment are essential for the development of delusional disorder. The many findings regarding *personality features* in patients with delusional disorder are inconsistent. According to psychological approaches, patients with delusional disorder often show strong introversion and anancastic features, little openness to experience, lack of concern for others, and lability of self-esteem and of self-concepts [4].
5. The *genetic approach* contributes only marginally, mainly because of very small samples [13].
6. The same applies to other *biological approaches*. Some investigations provide evidence of brain abnormality in the medial frontal/anterior cingulate cortex and insula [14]. But it is not certain whether such findings are specific for delusional disorder. Some delusional types can be present in brain damages, but that is an exclusion criterion for the autochthonous disorder [4].

Symptoms and differential diagnosis

The disorder, as already pointed out, is usually *monosymptomatic*, having as main symptom autochthonous, *monothematic delusions* of long duration. This means that: (1) the delusions are not associated, derivable, or embedded into a net of other psychopathological symptoms; some other symptoms, like hallucinations, can occur, although very rarely, but they are transient, not intensive, and derivable from the delusions—actually they are delusional misinterpretations, and not real hallucinations; (2) the delusions usually deal exclusively or predominantly with only one theme, that is, they are monothematic; only seldom—in a mixed type—more than one topic is evident with equal presence and intensity, none of which predominating over the others; the most common theme is persecution and related ideas; (3) their duration is long—months, years, or even decades, sometimes lifelong; (4) the consciousness is always clear and signs of dementia or of any other central nervous system disease are not present; and (5) they are not due to medical conditions or substances.

The first and second of these aspects differentiate delusional disorder from *schizophrenia*, *schizoaffective disorder*, *psychotic bipolar or depressive disorders* and (together with the third aspect) the *polymorphous type of brief psychotic disorder* [4, 6]. If occasionally mood episodes occur, the delusions are of longer duration and not derivable from the mood symptoms. In cases of *obsessive-compulsive disorder* with lack of insight respectively with delusional beliefs, the obsessive-compulsive behaviour is the differentiating feature. But one has to be aware that some types of delusional disorder, especially the querulous-litigious form, can be associated with obsessive behaviour. In *paranoid personality disorder*—in contrast to delusional disorder—paranoid thinking is usually diffuse and affects many areas of life; it does not have a priori evidence and is accompanied by a general suspiciousness during the lifespan [4]. The fourth and fifth aspects differentiate delusional disorder from organic psychosis.

Subtypes

The DSM-5 identifies seven *subtypes* of delusional disorder—erotomantic, grandiose, jealous, persecutory, somatic, mixed, and unspecified type, while ICD-10 also names a litigious and a self-referential type. But according to other views, the litigious form belongs to the persecutory type, whereas the self-referential aspect is associated with all types [4, 5]. However, all subtypes basically focus on the following three ‘arche-themes’, that is, existential, essential, and universal groups of concerns, fears, and desires of human beings:

- Sexuality and mating: focusing on Eros.
- Fears or desires regarding one’s own body as carrier of health, image, performance, and reproduction: focusing on Soma.
- Survival and safety: focusing on Security.

Delusional disorder can be therefore divided, according to their ‘arche-theme’, into three groups [4]:

- Erotocentric (erotomania, jealousy),
- Securocentric (persecutory and related delusions, Capgras syndrome, etc.), and
- Somatocentric (delusions of health threat, parasitosis, dysmorphia, own odour, pregnancy, Cotard’s syndrome, etc.).

Erotocentric group

Erotomantic type

Patients with delusions of erotomantic type are imperturbably convinced of being loved by someone, mostly by a celebrity or someone of higher social standing. That person usually is completely unaware and out of reach for the erotomantic, which may cause intense stalking behaviour from the patient [4, 5].

Although this syndrome has been known since the ancient Greek period, it found its first scientific reference as an autonomous syndrome by the German psychiatrist Ernst Kretschmer in 1918 [4]. The detailed descriptions of the French psychiatrist de Clérambault, however, contributed to connecting erotomania to his name (*‘de Clérambault syndrome’*), although he mainly described patients with delusions of being loved as a symptom of schizophrenia [15]. Erotomantic and jealous types can occur together, creating a common erotocentric group [4].

The *epidemiology* of the erotomantic type is unknown but seems to be rare. Delusions of being loved, however, can be found as symptoms in other psychotic conditions. The ‘Halle study on Delusional Disorders’ [4, 10, 11] found that out of 9969 inpatients at the Halle Psychiatric University Clinic in Germany between 1994 and 2007, and among 4753 non-organic psychotic disorders, only two patients had an erotomantic subtype of delusional disorder, both of whom were men. Although an earlier study [16] identified 15 patients with erotomantic delusions in a catchment area of approximately 400,000 people within a year, only three of these patients had an erotomantic delusional disorder.

Summarizing the data available, it can be concluded that the erotomantic type of delusional disorder is rare, more frequently—but not exclusively—occurring in unmarried females, with the first manifestation usually after the age of 30. But young men, even when married, may also be affected. The object of love usually is heterosexual, sometimes also homosexual. Stalking behaviour is not

unusual. The delusion may occur suddenly or develop gradually, and although the course and outcome are uncertain, they are usually long-lasting; sometimes the disorder may last several decades [4, 5, 17].

Jealous type

The jealous type is characterized by the delusion that the patient’s own sexual partner is being unfaithful. Delusional jealousy can also be a symptom of other psychotic disorders. As already mentioned, it can co-occur with the erotomantic type, building a common erotocentric group [4].

A synonym of the disorder is *Othello syndrome*, after the character in Shakespeare’s drama Othello who murdered his wife, based on his false belief that she had been disloyal. However, it is wrong to name delusional jealousy Othello syndrome. Othello’s belief that his wife was not faithful to him was not delusional, but based on false facts deliberately arranged by others, especially by Jago [4]. Othello never had delusions of jealousy.

Patients’ beliefs are sometimes bizarre or obscure; for example, even a high age of 80 or even higher is not an obstacle. Patients change their usual behaviour, become irritable, and show rough, aggressive, or even violent behaviour towards the partner. Their conviction cannot be disproven by any counter-argument or counter-evidence.

The prevalence of the jealous type is hard to be estimated for the same reasons as for other delusional disorders. Presumably it is approximately less than 10% within the group of delusional disorder. It remains unclear if there is a gender imbalance; some studies found more females, others more males. Previous assumptions that delusional jealousy is exclusively or predominantly an alcoholic syndrome could not be confirmed by modern authors [4, 5]. It is important to keep in mind that the disorder tends to be chronic and may be dangerous for the partner or the delusional rival.

Securocentric group

Persecutory and related types

The persecutory type is characterized by the delusion of being persecuted or harmed. The theme of persecution and the kind of persecutors are very broad. In the eyes of the deluded individual, everything can be perceived as an indication of persecution and everybody as a persecutor, even persons trying to help. Patients tend to relate mutual activities of everyday life to themselves (as self-reverential delusions). Patients experience problems in interpersonal relationships and sometimes with the law. In some rare cases, the subject of persecution is not the patient himself, but a related person, hence *‘persecutory delusional disorder by proxy’*.

The phenomenology of persecutory delusional disorder can be classified into three types, according to the patient’s behaviour and reactions [4]:

1. The flight type.
2. The fight type.
3. The height type.

The *‘flight type’* is the most common and is characterized by ‘fleeing from the danger’, that is avoidance, isolation, and anxiety.

The *‘fight type’* is characterized by sthenic reactions, aggression, and sometimes also violence. It can be divided into two subtypes:

1. The ‘*assaultive*’ subtype is characterized by violent accusations against the assumed persecutors.
2. The ‘*querulous-litigious*’ subtype is characterized by convictions of being treated unjustly and incorrectly and of being discriminated against, insofar patients feel persecuted by institutions or persons, or even by the legal system.

The ‘*height type*’ is characterized by compensation of delusional persecutions by delusions of grandiosity.

Regarding prevalence and demography, the majority of cases of delusional disorder (approximately 60%) are included among the persecutory type, affecting more frequently men. Psychosocial adversity, like perceived ethnicity discrimination, may play a role in the development of persecutory symptomatology [18]. Though the diagnosis in many cases is stable over years, the persecutory type may change more often into schizophrenia than other types [4].

Querulous-litigious subtype

Although ICD-10 names a querulous-litigious subtype, this can be seen as a form of the persecutory subtype, as mentioned previously. *The affected individual fights against delusional injustice, seeking help of the courts or authorities or, in some cases, by debating.* This behaviour can sometimes be dangerous, showing the ‘Nemesis syndrome’—which means a subjective justified penalty, named according to Nemesis, the Greek goddess of high and divine vengeance. Patients with querulous-litigious delusions have sthenic and combative personalities, not seldom also showing obsessive features, and are willing to fight for their own satisfaction and compensation. But they are also isolated, because they usually do not win favours from their environments.

In a clinical setting, this subtype is rare. The ‘Halle study on Delusional Disorders’ found a querulous-litigious subtype in only three patients (0.03%) out of all 9969 admissions between 1994 and 2008—that is 7.0% out of all patients diagnosed with having a delusional disorder, which is in accordance with the findings of other authors [4]. A decrease in treated cases has been reported after the first half of the twentieth century [19]. At the University Clinic of Bern (Switzerland), the prevalence of patients with litigious symptomatology was 0.275% between 1922 and 1951, but only 0.09% between 1964 and 1993. Regarding psychotic querulous-litigious behaviour, the decrease in diagnoses was calculated as 74% between those two time periods [20]. One reason has to be taken into account—that patients with querulous-litigious delusions mostly contact the police or legal authorities, not the medical system. Another reason is probably that psychiatrists, on the other hand, do not have great interest in dealing with querulous-litigious patients because the psychiatrists themselves experience a number of difficulties with these patients—they fight doctors and their institutions through letters, emails, telephone calls, legal complaints, and even stalking behaviour. Another reason might be the difficulty in precisely distinguishing between querulous-litigious delusions, paranoid personality, and reality.

Grandiose type

Patients with this type show delusions of inflated worth, power, knowledge, identity, or special relationship to a deity or famous person. Although the official diagnostic systems define a grandiose type, experienced clinicians and researchers question its independent existence [4, 5]. Munro, for example, an expert in the topic, only

remembers two cases in his long period of clinical experience. Also the author of the present chapter encountered, over 40 years, primary delusions of grandiosity only in patients with mania, schizomania, schizophrenia, ecstatic forms of brief psychotic disorders, and organic psychosis, but never a primary grandiose type of delusional disorder. Nor did the ‘Halle study on Delusional Disorders’ find any case [4, 11, 12]. Possibly, the phenomenon could be explained by the following:

1. An independent ‘grandiose delusional disorder’ is so extremely rare that it practically does not exist.
2. Patients with grandiose type feel healthy, glorious, and superior and are self-confident. Hence, they do not seek help and usually do not harm anybody, and their social functioning is not impaired. So there is no reason to contact medical authorities.
3. There is a change in today’s delusional themes, in comparison to earlier times, and grandiosity has become rare or presents only in psychotic disorders with manic or hyperthymic mood.
4. Modern operational diagnostic systems allocate states previously diagnosed as ‘grandiose delusional disorder’ to other categories like mania, schizomania, schizophrenia, etc.
5. A thorough analysis of the background of delusion of grandiosity could reveal them as the ‘height’ reaction type or the persecutory type.

Grandiosity and persecution can be the opposite sides of the same coin, as illustrated by related and generally inseparable beliefs: ‘I am important enough to be singled out for persecution’ and ‘I am singled out for persecution because I am so important’; ‘they persecuted me, because I am such an important person’ or ‘they persecuted me, because I am such an intelligent person’ or ‘such a powerful person’, etc.; and ‘as I am so superior, they are not able to harm me. There is no danger for me. I don’t need to be afraid’. A flight into grandiosity may be one of the possibilities to compensate not only feelings of worthlessness and other negative thoughts and feelings, but also fear of persecution.

Thus, there is strong evidence that the very rare cases of the ‘grandiose type’ are simply a variation of the persecutory type, as it was presented previously [4, 5].

Delusional misidentification

Delusional misidentification is characterized by misidentification of persons, but sometimes also of animals or inanimate things.

It is a non-specific phenomenon, symptom of various psychotic disorders, but obviously very rare as an independent delusional disorder. The content of the delusion is almost always threatening to the existence of the individual, related persons, or even the whole human race. Hence it could be mostly allocated to the securogenic type. The group of delusional misidentification syndromes do not include states in which the patient misjudges his environment due to clouded consciousness.

Delusional misidentification has varying phenomenology, giving rise to the following subtypes.

Capgras syndrome (named according to the French psychiatrist Joseph Capgras, one of its descriptors in the twentieth century—although it was already repeatedly described in the nineteenth century [4]) is the core of the group of misidentification syndromes. The main belief of a patient with Capgras syndrome is that someone in

their environment, usually a close relative or a significant other, has been replaced by an identical-looking double. Only subtle details reveal the double; some hair behind the ear, some small movements, some minor details of the smile, etc. may be hints that the person is not the real one, but a replacement. The real person who has been replaced is thought to be absent. Patients usually indicate ‘dark powers’, ‘the evil’, ‘secret services’, ‘the Mafia’, or ‘enemies’ as having initiated the replacement. The ‘double’ is usually believed to be a spy or to be instructed to persecute and harm the patient, the city, the country, or even the whole world. The patient is occupied by uncertainties, is increasingly suspicious, feels great internal tensions, and is anxious, agitated, perplexed, and hostile against the ‘double’.

Other phenomenological variations of the misidentification syndromes are extremely rare, or even exotic, like the following:

Frégoli syndrome: the patient believes that imposters frequently alter their facial appearance to resemble familiar people in his environment. It is named after Léopoldo Frégolian, an Italian actor famous for his ability to transform himself on stage into various characters. The patient thus identifies the imposter (usually as the persecutor) in several persons, for example the doctor, next time the nurses or fellow inpatients, then perhaps in neighbours, the postman, and so on. However, the persecutor is always one and the same.

Intermetamorphosis: a delusion that people around the patient have transformed physically and psychologically into one another. The transformation may concern also animals, as well as objects. It also implies the transformation of one’s own person into someone else.

Subjective doubles: the patient believes in the existence of exact doubles of themselves. Although the syndrome of doubles of the self has superficial similarities to *heautoscopy*, the two phenomena are far from being identical. In cases of subjective doubles, the patients are convinced of the existence of another person associated with the delusional belief of being his or her double, while *heautoscopy* is a sort of hallucination, seeing one-self outside one’s own body.

Clonal doubles or clonal pluralization: it is characterized by the delusion that there are several persons looking very much alike, that is, as clones of one and the same person.

Zoocentric misidentification: the patient is convinced that pets have been replaced by others.

Inanimate misidentification: the patient is convinced that things have been replaced by other things or by their doubles.

Misidentification of time: it is characterized by the patient’s conviction that the present time has been substituted or that the usual passage of time has been changed in the sense of permanently repeating itself.

Somatocentric group

The somatocentric delusional disorders, somewhat broader than the somatic type of DSM-5 or ICD-10 (–11), focus on one’s own body and its functions. *The delusional theme concerns negative alterations of one’s own body image, bodily functions, and bodily health*, as in the following syndromes:

- Delusional parasitosis.
- Cotard’s syndrome.

- Delusional syndrome of one’s own odour (olfactory reference syndrome).
- Delusional pregnancy.
- Health threat and dysmorphia delusional syndrome.
- Lycanthropy and zooanthropy.

Delusional parasitosis

Delusional parasitosis is the delusion of being infested with parasites. The infested organ is usually the skin, but sometimes also the intestines, vagina, mouth, nose, etc.

The syndrome is known under various names: delusions of infestation, Ekbom’s syndrome, *präseniler Dermatazoenwahn* (this is the original name given to the syndrome by Ekbom and means pre-senile delusional parasitosis), chronic tactile hallucinosis, delusional infestation, monosymptomatic hypochondriasis, monosymptomatic hypochondriacal psychosis, acarophobia, and *névrodermie parasitophobique*.

The Swedish psychiatrist Karl Ekbom introduced the German term *Dermatazoenwahn* in 1938, describing seven cases, mainly women, aged between 50 and 60, who were complaining of itching and paraesthesiae and were stubbornly and fixedly convinced that the discomfort was caused by small animals (for example, insects, parasites). However, the phenomenon had already been described many decades before Ekbom [4]. But it is his main contribution—that he described it as a delusional syndrome.

The *phenomenology* of delusional parasitosis is very homogenous and extremely alike in all affected patients. Almost all patients describe very intense itching as the key symptom. They complain about little creatures or microorganisms crawling, biting, stinging, hopping, or running on or under their skin. They show a high level of suffering, but only few report actual pain. The skin sensations usually persist the whole day and may also disturb the patient’s sleep. More than one-third of the patients additionally describe sensations inside body openings or in the interior of their body: in their mouth, nose, inner ear, anus, intestines, lungs, or genitals. More than two-thirds of the patients present illusionary misidentifications or visual hallucinations related with the skin or parasites. Some patients even approach local health authorities or their general practitioners, carrying small containers with the ‘parasites’ with them, attempting to provide evidence of the cause of their torment. Thorough investigations of those objects usually reveal that they are small fragments of skin, hair, dried blood, scabs, dried nasal mucus, lint, textile fibres, dust, or excrement particles, etc., but in spite of such explanations, the patients are utterly convinced that these are parasites or their excretions.

The visual phenomena usually do not fulfil the definition of real hallucinations, because they are not perceptions without a stimulus; there is a stimulus—the small signs mentioned previously, which are misidentified by the patients as parasites. This can be defined as *illusionary misidentifications secondary to the tactile sensations or to the delusion of parasitosis*.

Other delusions secondary to the primary delusion (for example, delusions of reference) are possible, but based on, and derivable from, the primary delusional conviction. Other associated hallucinatory phenomena or misinterpreted perceptions (for example, visual, auditory, olfactory, or gustatory) are rare and without diagnostic relevance.

The prevalence of delusional parasitosis is not exactly known. Psychiatrists are likely to be the last specialists contacted by patients with delusional parasitosis. Most patients first seek help from dermatologists, general practitioners, or local health authorities. Only when distress and suffering seem to become unbearable do they seek a psychiatrist's advice. Nevertheless, delusional parasitosis, with approximately 0.5% of psychiatric inpatients, is not common. Females seem to be more frequently affected than males.

Although delusional parasitosis can manifest itself in every period of adult life, it is more frequent after the fifth decade, but not exclusively 'pre-senile', as Ekblom supposed.

Perhaps delusional parasitosis is the most common delusion that can be 'infectious'. Although the so-called *shared psychosis*, mostly in the form of *'folie à deux'*, is rare, the ratio of shared psychosis in delusional parasitosis seems to be higher than in other psychotic disorders [4, 5].

There has been long discussions, mostly in the anglophone literature, of whether delusional parasitosis is a type of hypochondriasis or whether it is more correct to define it as *hypochondriacal delusion of parasitosis*. However, only a minority of patients with delusional parasitosis fulfil the essential criterion of hypochondriasis, that is, excessive preoccupation with anxious self-observation and worries about having a serious disease. In contrast to such concerns regarding one's own health, many patients with delusional parasitosis deny every kind of disease; they empathetically underline that they do not have any physical or mental disorder; they are 'just attacked by parasites'. This is why many patients do not seek the help of a doctor, but of an exterminator, a parasitologist, or even of local health and hygiene authorities.

But it is also true that some patients, although not the majority, have a hypochondriacal background. Also, during the long-term course of their illness, some patients may move towards the hypochondriacal pole. From a theoretical point of view, it seems important to differentiate between delusions and tactile hallucinations. Some authors believe that delusions are secondary, whereas tactile hallucinations are primary. But as mentioned, in contrast to other types of hallucinations, it is extremely difficult to define a patient's bodily sensation as being hallucinatory or not.

Summarizing the literature on the topic, it can be concluded that both mechanisms—hallucinatory and delusional—may occur in the sense of *organic hallucinosis* or *delusional disorder*.

Delusions of parasitosis may manifest as symptoms of schizophrenia, of organic psychotic disorders such as delirium and cocaine abuse, or of other psychotic disorders. The distinction between autonomous delusional disorder of parasitosis and symptomatic delusional parasitosis due to other conditions usually is easy, assuming the other defining criteria of the previously mentioned disorders are fulfilled, that is, the criteria of schizophrenia, psychotic affective disorders, organic psychotic disorders, etc.

Treatment is that of the underlying condition (somatic or psychotic). Clinical evidence has shown the effectiveness of dopamine antagonists, occasionally in combination with antidepressants, in some cases of autochthonous and autonomous delusional disorder of parasitosis.

In regard to *prognosis*, it can be concluded, that although in some cases the syndrome can become chronic, in many cases the prognosis seems to be benign following adequate treatment.

Cotard's syndrome

Cotard's syndrome is a rare clinical condition, the most prominent symptom of which is the nihilistic delusion of denial of one's own body or parts of the body or even the delusion of being dead.

The syndrome was called after Jules Cotard, a French psychiatrist, to whom we owe the first systematic description in 1880, although the syndrome had been known before [4].

Patients hold the distinct delusion of being dead, not existing, putrefying, or having lost body parts, blood, internal organs, or very rarely their own soul. Symptoms of negation sometimes extend to the environment and even to the whole cosmos. Initially, the symptomatology is quite similar to that of derealization and/or depersonalization. The delusional beliefs determine the patient's behaviour. Patients being convinced that they do not have a stomach or any intestinal organs will refuse to eat or drink. Patients with the delusional conviction that their legs are dead or 'lifeless' will refuse to walk and will stay in bed for a long period of time, sometimes extending to several months. In severe cases, the patients no longer communicate with their surroundings. They present total negativism with mutism, in more severe cases even stupor. Thus, it is recommendable in patients with severe delusional depression, who develop stupor in the form of catatonic depression, to find out whether this is a consequence or a result of the patients' delusional conviction of negation. Analgesia, or even anaesthesia, has been observed in some patients.

Cotard's symptomatology is rare and can accompany severe psychotic depression but can also be observed in schizophrenia and organic brain damage; as an autonomous delusional disorder, it is apparently extremely rare. Insofar *treatment* of the syndrome depends on the underlying illnesses, it is symptomatic. Dopamine antagonists, alone or in combination with antidepressants and ECT treatment, could be effective.

Delusions of one's own odour (olfactory reference syndrome)

Delusions of one's own odour can be defined as the unfounded and uncorrectable conviction of a patient to emit a bad or foul odour.

There are several synonyms, which only partially are correct and identical with the delusional disorder of one's own odour: olfactory reference syndrome, delusions of bromosis or of smell, delusional halitosis, hallucinatory halitosis, imaginary halitosis, etc.

If the delusions of one's own odour are the only prominent symptom and there's no indication for another type of psychosis like schizophrenia, schizoaffective or depressive disorder, and if they are not caused by organic factors, they fulfil the criteria of an autonomous delusional disorder. Delusions of one's own odour must also be distinguished from social anxiety spectrum disorders in which the respective believes are not delusional.

Olfactory delusional disorder is not only very rare, but also very difficult to be identified as such. If the patients report on smells from other people or things of the environment, it usually indicates olfactory hallucinations. But when the patient reports on own body odours, distinction between delusion and hallucination is needed. If the patient reports *perceptions* of smell originating from their own body or body fluids and the smell cannot be perceived by other people, the patient may have hallucinations. In contrast, patients with symptoms of delusions of their own odour normally phrase it like: "No, I do not perceive any strange or other extraordinary odour coming from my body, but I am sure that I give off such smells.

I notice it from other people's reactions when I enter a room or when I am close to people. They look at me very strangely; their facial expressions change; they move away, they talk to each other meaningfully. It can only be related to my own odour, which I personally do not perceive. This is logical because people usually do not perceive their own odours."

The patients also give a reason for their strange and bad odours perceived by others: they have done or thought something wrong or immoral. For instance, a 28-year-old male patient believed that people knew he masturbated because the next day his body smelled strange and extraordinary. He never perceived that smell, but could conclude it from the reactions of his colleagues in the office. So even if a patient reports on own odours it needs to be differentiated whether it is an olfactory hallucinosis, which—other than delusions—often is related to temporal lobe epilepsy or other temporal lobe damages [4].

There are no statistical surveys on the prevalence of the autonomous delusional disorder, but only case reports, and even those are very rare.

Psychogenic factors, especially sensitive and anxious personality features, are reported to have pathogenetic or pathoplastic relevance.

Treatment with drugs for psychosis and psychotherapy may be effective, but findings are inconsistent. As a result of their condition patients suffer from severe impairment in work and social relationships [21].

Delusional pregnancy and Couvade syndrome

Delusional pregnancy (or delusional pseudocyesis) is characterized by the delusion to be pregnant (even in women with no sexual relations or in non-reproductive phases of life).

Although delusional pregnancy is not an extremely rare syndrome within major psychotic disorders, especially in schizophrenia, schizoaffective disorder, or psychotic mood disorders, it is extremely rare as autonomous delusional disorder. Delusions of pregnancy may last over a course of many years—in some reports over 25 years—and also in women over the age of 60.

Couvade syndrome is defined as the phenomenon in which husbands, boyfriends, or other exceptionally related persons of pregnant women develop symptoms of pregnancy too.

Couvade syndrome has apparently been well known since ancient times; it was even mentioned in the Greek myth of the 'Argonauts', and 2000 years ago, the Greek geographer Strabon reported on that phenomenon too [4].

The name *Couvade syndrome* was derived from the early French verb *couver*, which means to *brood* or to *hatch*. Couvade syndrome is a very rare syndrome in clinical reality, although some publications state the opposite. A reason for this discrepancy might be the fact that in some studies, certain symptoms having none or only little association with pregnancy (like toothache) are assumed to be an indicator for Couvade syndrome. There is no evidence that such symptoms are delusional. In contrast to Couvade syndrome, which is usually non-delusional, there are only few reports on *real delusions of pregnancy in men*, but as a symptom of psychotic or organic disorders, among other symptoms, especially in epilepsy, and post-ictal psychosis.

There is a plethora of theories trying to explain the phenomenon, for instance psychodynamic ones, but none of which has been proven.

Lycanthropy or zooanthropy

Lycanthropy or zooanthropy is a mainly delusional conviction that one has been transformed into a wolf or another animal (lykos is the Greek word for wolf).

Lycanthropy or zooanthropy is extremely rare. In international literature, over the last two centuries, only a few cases reported lycanthropic delusions. They are usually of short duration, lasting a few days or weeks, sometimes only hours, and seldom over a longer time. Mostly it is considered a symptom of major psychiatric disorders, especially of mood disorders, schizophrenia, or organic brain disorders, also involving alcohol and drug abuse, or psychogenic (dissociative or hysterical). Therefore, there is only little support to define lycanthropy as an autonomous delusional disorder [4].

Delusional disorders of health threat and dysmorphia (somatic type)

Patients with delusional disorder of health threat have unsubstantiated and uncorrectable convictions of having a severe illness or any other threat to their health.

Hypochondriac delusions is a usual synonym for the disorder, but the term is not only discriminating and inexact, but it also does not cover the broad spectrum of health threat delusions [4].

Diagnosis, especially differential diagnosis, of delusional disorder of health threat is really difficult, mainly because the boundaries to non-delusional (hypochondriacal) fears are diffuse, uncertain, and difficult to draw.

The spectrum of themes of delusions of health threat are as broad and variable as there are organic diseases. Delusional ideas may focus on all parts and organs of the human body. They may occur as an autonomous delusional disorder, but more often they develop as symptoms of a major psychotic disorder (schizophrenia, schizoaffective disorder, delusional depression, or organic psychosis). Delusional disorders of health threat may be based on the patient's own or the family's experiences. A successfully treated 'real' medical condition in the past can be the source of the theme of a later delusional disorder.

Delusional dysmorphia is characterized by the unsubstantiated and uncorrectable conviction that the body schema is unattractive or disproportioned.

Delusional forms of the conviction of being misshapen have to be distinguished from phobic fears with that content. Nevertheless, patients with delusions of dysmorphia—usually younger than in other types of delusional disorder—are very unhappy people. The adverse influence of the disorder on their social interactions is massive; patients isolate themselves and are irritable, envious, and insecure, with low self-esteem.

Unlike other somatocentric delusions, delusions of dysmorphia usually begin early in life, mostly in adolescence, sometimes even in childhood. Adolescence is a fruitful soil for ideas of dysmorphia or dysmorphophobia, which may, in some cases, develop into delusions of dysmorphia.

In summary, it can be concluded that presumably there might never be reliable statistics on the prevalence of delusional disorder of health threat or of dysmorphia. Most patients from the first category will seek help from various physicians, but not from psychiatrists or psychologists. And patients not only with delusions of dysmorphia, but also any kind of dysmorphophobia, will most likely seek advice from an aesthetic surgeon, rather than from a psychiatrist.

Delineation of delusional disorders of health threat or of dysmorphia from non-delusional health threat syndromes (hypochondria or hypochondriacal disorder) and body dysmorphic disorder remains difficult—this is one of the reasons why we do not have—and do not get—reliable epidemiological data.

Delusions of health threat and of dysmorphia are rare as autonomous and autochthonous disorders but are usually associated with depression, schizophrenia, schizoaffective disorder, or disorders of the brain.

Prognosis is largely related to response to treatment, which mostly consists of a multimodal therapy setting of drugs for psychosis and/or depression and psychotherapy. Some authors report better response to treatment in somatocentric delusional disorders than in other types [5].

It is no surprise that in somatocentric syndromes, the relevance of culturally accepted fears and beliefs has to be taken into account. Some *culture-related somatocentric syndromes* are phobic, rather than delusional—for example, koro syndrome (acute fear or conviction of patients of having a genital retraction, which leads to death), in South East Asia; Kaza basolo (fear of women that their clitoris has been stolen, in Central Africa); *Dhat syndrome* with anxiety and somatocentric contents, like weakness and exhaustion, associated with convictions that their cause is loss of semen, in India; or *taijin kyofusho* (fear concerning mainly dysmorphia), in Japan.

Prognosis

The prognosis of delusional disorder is discussed controversially, moving between pessimistic and optimistic views [4, 5]. According to evidence collected to date, the following can be concluded.

Delusional disorders are *highly stable* over many years, that is, in the great majority of patients, there is no syndrome shift in the course of the illness.

Symptoms usually *persist* over years or decades, and in some patients lifelong. Nevertheless, cases of some specific types of somatocentric delusional disorder, like delusional parasitosis, can have a benign prognosis after treatment with neuroleptics.

Although a number of patients suffer interactional problems with the social environment, which leads to early retirement, *autarky* remains intact in the great majority. This means patients are not impaired or disabled, live independently, and do not need any kind of support.

There exists *comorbidity* with depressive episodes, but reports vary considerably—approximately 30% to more than 70% of patients develop temporarily during course also depressive episodes; comorbidity with alcoholism seems to be lower, approximately 10%.

Controversially discussed in recent literature is an association of delusional disorder and dementia. Some studies found patients with delusional disorder at higher risk than the general population [22, 23], but others not [4, 11, 12].

Treatment

There is a lack of systematic, double-blind, randomized controlled trials on this topic, using methods similar to those in other psychotic

disorders. What we know about the efficacy of treatment is mainly from anecdotic reports or very small heterogenous samples.

Whereas some authors expressed therapeutic optimism mainly regarding dopamine antagonists [5], other investigations, as well as clinical experience, do not share such over-optimistic views [4]. Comparative trials did not find a better outcome in the group admitted after the introduction of dopamine antagonists in modern psychiatry, in comparison to the time before their introduction [24]. Nevertheless, some somatocentric delusional disorders, like delusional parasitosis, respond positively to treatment with dopamine antagonists [4, 5].

All reports on *electroconvulsive therapy* are anecdotal [4], just like reviews on the efficacy of *psychotherapy* in delusional disorder. One of the rare comparative psychotherapeutic trials [25] included only a small number of patients ($n = 11$ allocated to a cognitive behavioural therapy group; $n = 6$ to an attention placebo control group) for a relatively short treatment period of 24 weeks. Completers in both groups showed clinical improvement, but those in the cognitive behavioural group improved in more aspects.

Notwithstanding, long-term investigations proved that in spite of occasional or even continuous treatment in the majority of patients (up to 80%), the delusions remained for a long time unremitted [4, 11, 12].

The enormous difficulties associated with the treatment of patients with delusional disorder have to be taken into consideration, mainly because patients do not feel ill or disturbed and so refuse any kind of therapeutic help. Usually, such patients become dissatisfied, non-compliant, and suspicious, discontinue therapy, regard hospitalization as a hostile act, and often set off a long-lasting war of nerves against the treating staff, even after their discharge from hospital.

Any patient with delusional disorder might be difficult, but querulous-litigious patients are perhaps the most difficult and unpleasant ones—not only for their social environment and the legal system, but also for therapists. Their psychotherapists or psychiatrists are frequently persecuted by querulous-litigious patients and reported to university authorities, hospital administrations, ministries, or even legal representatives.

Nevertheless, some authors recommend an integrated method for treating 'paranoia', using a multimodal therapeutic approach of combination of psychodynamic (uncovering), interpersonal, cognitive behavioural, and pharmacological therapeutic techniques [26].

Prevention and early intervention in psychotic disorders

Emre Bora, Mahesh Jayaram, and Christos Pantelis

Introduction

What is early psychosis?

Psychosis is a severe mental illness that most often begins in late adolescence or early adulthood, though it can affect people across the lifespan. Early psychosis refers to the onset of symptoms or prodromal features that begin during early neurodevelopment. The term first-episode psychosis (FEP) is often used to refer to the first time psychosis is manifest, though this may be later in life (beyond adolescence). Psychosis is associated with a distinct break from reality and characterized by disorganized thinking and sometimes speech, delusions, hallucinations, and disturbances in behaviour and affect. It can also be associated with prominent motor/volitional disturbances, cognitive disturbances, and impaired insight (for discussion about the types of psychosis, see [1]). Early psychosis may be preceded by prodromal stages before full-blown psychosis is apparent. This may include changes to thought and perception, which are often vague, yet can be distressing. It is, however, important to consider these phenomena carefully across the stages, from prodrome (and even earlier) to psychosis, so that effective strategies for illness prevention and intervention can be put in place. In this chapter, we discuss the importance of early identification and treatment of early psychosis and its prodrome.

What are the prodromal symptoms of psychosis?

The ‘prodrome’ of psychosis (which includes, but is not limited to, schizophrenia) constitutes a period of change from baseline pre-morbid levels of functioning and may progress to a stage where patients are experiencing perceptual, mood, and behavioural changes prior to the onset of frank psychotic symptoms. Thus often, these are only recognized in hindsight, rather than ahead of time. Patients who develop schizophrenia, with the benefit of hindsight, are able to recall that they experienced prodromal symptoms about 80–90% of the time. Ten to 20% of patients with schizophrenia can develop the illness ‘out of the blue’, that is, without prodromal symptoms [2, 3].

In order to better understand and accurately identify prodromal symptoms, various groups have defined sets of phenomena that

characterize the prodrome and earlier stages. Some of these approaches were based on identifying individuals showing higher conversion rate, based on genetic risk, together with other vulnerabilities, including familial risk and functional decline, multiple affected family members, and familial risk together with cognitive deficits or negative symptoms [4, 5]. Other approaches aim to recognize individuals who are help-seeking due to emerging psychotic symptoms, who have not met psychotic disorder criteria as yet but are potentially in the prodromal phase [clinical high-risk (CHR) or ultra-high-risk (UHR) for psychosis]. An approach that seems to encompass all of these varied symptoms can be found in a key paper [6], which describes the contemporary thinking around CHR psychosis states. Broadly, there are two key concepts—the UHR criteria and basic symptoms (BS), both of which have similar criteria, with a goal of identifying those who would be more likely to transition to psychosis within a short time period (12–24 months). Preceding the CHR phase is the period relating to other factors leading to increased vulnerability. This is outlined further in [Fig. 63.1](#).

The notion of very early signs of psychosis has been evident in the literature for over 40 years. Gerd Huber introduced the concept of BS of psychosis, a relatively well-known concept in Germany, but less widely used elsewhere, which describes the early prodromal phases of psychosis [7, 8]. BS are subtle and sometimes vague (ill-defined) features experienced by the individual and may include elusive disturbances in thought, speech, mood, or bodily perceptions, and can also include cognitive-perceptive and/or cognitive disturbances [9]. The individual may use personalized coping strategies, such as avoidance of certain situations and social isolation, and may overcome them for at least a period of time. The development of psychosis and cognitive deficits are often associated with partial or complete loss of insight [10]. Together with more recent conceptualizations of prodromal symptoms, the approach of identifying the earliest prodromal stages of schizophrenia has provided the tantalizing possibility for early identification and treatment, with the hope of delaying, or even preventing, the illness. This approach also allows for the identification of brain changes and potential mechanisms in early psychosis and schizophrenia [11].

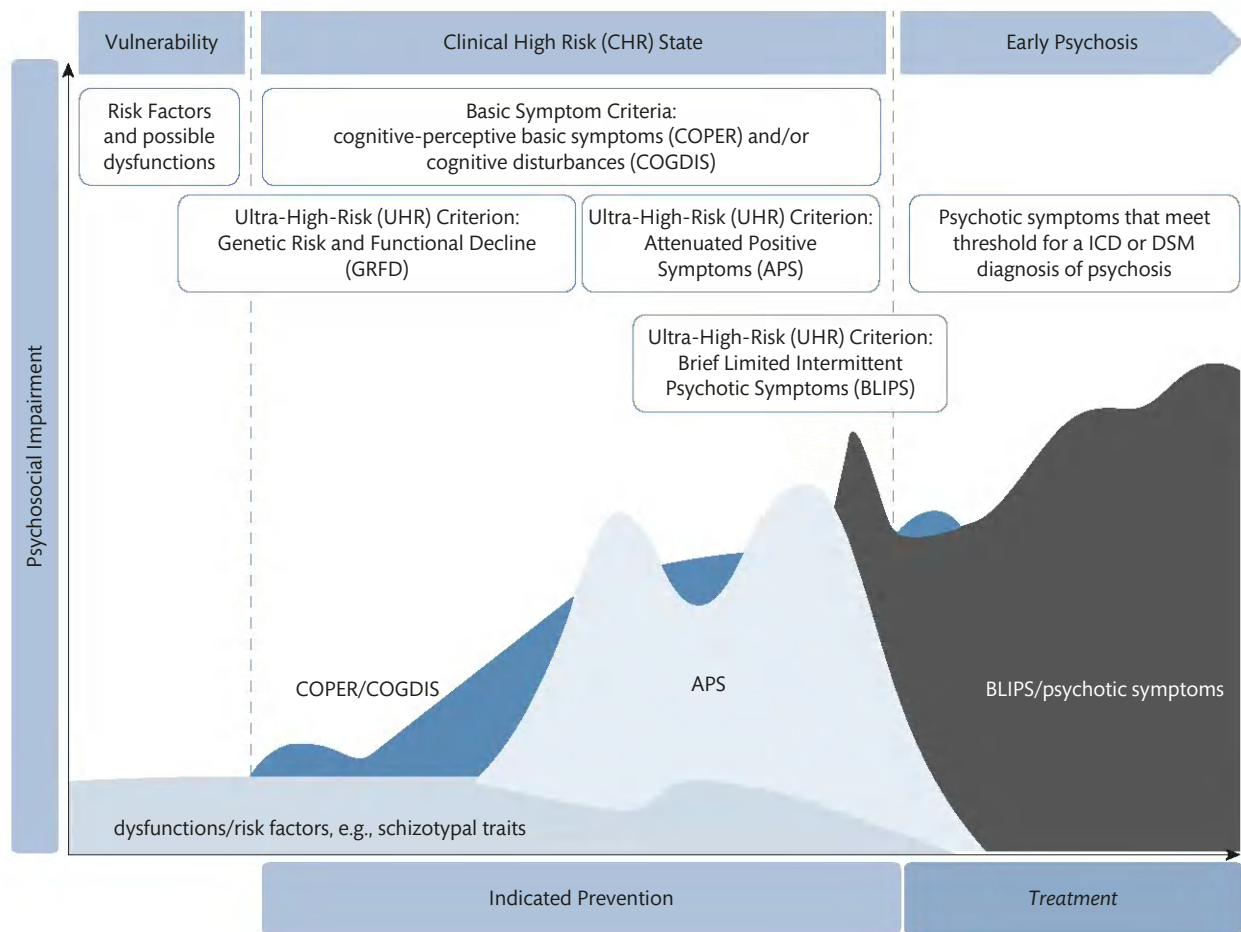

Fig. 63.1 Model of transition from CHR states to psychosis [6].

Reproduced from *Eur Psychiatry*, 30(3), Schultze-Lutter F, Michel C, Schmidt SJ, et al., EPA guidance on the early detection of clinical high risk states of psychoses, pp. 405–16. Copyright (2015), with permission from Elsevier Masson SAS.

The original concept of UHR for psychosis was defined according to the presence of state [psychotic-like experiences (PLEs), brief psychotic symptoms] and trait risk factors (schizotypy, family history), associated with a clinically significant drop in function, assessed using the Global Assessment of Functioning (GAF) scale [12]. Early studies indicated that 37% converted to psychosis within 12 months [13]. A meta-analysis of more recent studies using such criteria has identified the transition rate to be 22% [14]. The importance of this notion was the possibility of early/pre-onset identification and intervention to prevent or ameliorate psychosis and the possibility to examine neurobiological changes around the transition to active illness [11, 15, 16]. Important criticisms of this approach, however, are the focus on psychotic-like experiences (PLEs) and the lack of a clear boundary for transition to psychosis. Thus, to date, it is unclear that there is a discontinuity between the UHR state and psychosis, which requires longitudinal mapping of trajectories from pre-psychosis onset [17]. More recent conceptualizations suggest that a dimensional approach may be more appropriate [18].

The UHR criteria over the last two decades encompass other related concepts such as Brief Limited Intermittent Psychotic Symptoms (BLIPS), Attenuated Psychotic Symptoms (APS), Genetic Risk and Deterioration Syndrome (GRDS) Subgroup, and the Unspecified Prodromal Symptoms (UPS) group. Other groups

have defined genetic high-risk individuals, which potentially allows for an even earlier identification of pre-psychotic individuals at high risk for psychosis [19]. There is no consensus as to whether these are distinct entities or fall under the umbrella of UHR, as outlined in this detailed review [20].

Detection of individuals at ultra-high risk and conversion rates for psychosis

In recent years, there has been increasing effort to develop a greater focus on specific risk paradigms to identify individuals who have a higher risk and transition rate, in comparison to psychometric schizotypy, PLEs, and familial high-risk approaches. A number of structured interview methods, including Comprehensive Assessment of At-Risk Mental States (CAARM) and Structured Interview for Psychosis-Risk Syndromes (SIPS), have been developed to detect CHR groups [21]. In practice, the predominant presentation of the majority of individuals meeting CHR criteria is APS (85%) in a recent meta-analysis [22]. The same study also found that the conversion rate for developing psychosis was considerably higher across these risk paradigms, compared with psychometric schizotypy, PLEs, and family history (for example, the transition risk within 36 months was 20% for APS and 26% for APS + GRDS). Transition rate of BLIPS was much higher (39% within 24 months).

On the other hand, the positive predictive value of CHR criteria for transition to psychotic disorders in non-help-seeking individuals was only 5.7%. Similarly, the annual risk of PLEs for psychotic outcome was relatively low (0.56% per year) [23].

Staging model for psychosis

Following on from the work in defining UHR and psychosis transition, McGorry and colleagues [24] have proposed a staging model of psychosis (Table 63.1), which incorporates the earliest stages of psychosis and considers the onset and progression of the illness to chronicity. This model borrows from notions developed for cancer staging and treatment, and is appealing as it suggests that each stage may require different interventions/treatment strategies. The central concept for the psychoses is that earlier stages are characterized by differences neurobiologically and better functional abilities, and require different interventions. Thus, earlier stages may warrant less extreme measures, while later stages will likely require more radical interventions. Further, each stage may be associated with differences neurobiologically and there may be identifiable biomarkers by stage [25], though it is yet to be demonstrated that there are clear boundaries between the proposed stages.

McGorry and colleagues [26] have gone on to propose that the earliest stages, namely UHR or earlier, are less differentiated diagnostically, prompting them to consider that this represents a

‘pluripotential’ state, with the possibility of a number of diagnostic outcomes for the individual. However, it remains unclear if the condition at this stage is truly ‘pluripotential’ or whether progression to one or other psychotic condition has already been pre-determined by factors yet to be identified (for example, genetic). Current initiatives are attempting to use machine-learning and other analytical approaches to examine if features of the illness at its earliest stages may predict the onset of psychosis, diagnosis, long-term course, or functional outcomes [27].

Why is early intervention for psychosis important?

In general medicine, early intervention (EI) targeting prevention or disease modification has been a topic of interest for some time for a number of conditions such as diabetes, cancer, and cardiovascular diseases. EI aims to target pathophysiological processes causing a disorder, with the aim to cease or slow its progression before symptoms emerge or become chronic and untreatable. While the ideal goal of EI is prevention, in most cases, modification of the illness course is a more realistic outcome. The proposed staging model for schizophrenia and other psychotic disorders, as discussed, appears to have face validity as an appealing notion, to intervene early and reduce the damaging impacts of the illness, in terms of clinical outcome, as well as brain structure and function. However, the concept of EI in psychotic disorders is perhaps not as straightforward, compared to

Table 63.1 Staging model

Stage	Definition	Target populations and referral sources	Potential interventions
0	Increased risk of psychotic or severe mood disorder and no symptoms currently	First-degree teenage relatives of probands	1. Improved mental health literacy 2. Family education, drug education 3. Brief cognitive skills training
1a	Mild/non-specific symptoms (including neurocognitive deficits) of psychosis or severe mood disorder. Mild functional change or decline	Screening of teenage populations. Referral by: primary care physicians; school counsellors	1. Formal mental health literacy 2. Family psychoeducation, formal CBT 3. Active substance misuse reduction
1b	Ultra-high risk: moderate but subthreshold symptoms, with moderate neurocognitive changes and functional decline to caseness (GAF, <70)	Referral by: educational agencies; primary care physicians; emergency departments; welfare agencies	1. Family psychoeducation, formal CBT 2. Active substance misuse reduction 3. Omega-3 fatty acids 4. Dopamine antagonists/partial agonists 5. Antidepressant agents or mood stabilizers
2	First episode of psychotic or severe mood disorder. Full-threshold disorder with moderate to severe symptoms, neurocognitive deficits, and functional decline (GAF 30–50)	Referral by: primary care physicians; emergency departments; welfare agencies; specialist care agencies; drug and alcohol services	1. Family psychoeducation, formal CBT 2. Active substance misuse reduction 3. Dopamine antagonists/partial agonists 4. Antidepressant agents or mood stabilizers 5. Vocational rehabilitation
3a	Incomplete remission from first episode of care; patient's management could be linked or fast-tracked to Stage 4	Primary and specialist care services	1. As for Stage 2, but with additional emphasis on medical and psychosocial strategies to achieve full remission
3b	Recurrence or relapse of psychotic or mood disorder, which stabilizes with treatment at a GAF level, or with residual symptoms or neurocognition below the best level achieved after remission from the first episode	Primary and specialist care services	1. As for Stage 3a, but with additional emphasis on relapse prevention and strategies to detect ‘early warning signs’
3c	Multiple relapses, provided worsening in clinical extent and impact of illness is objectively present	Specialist care services	1. As for Stage 3b, but with emphasis on long-term stabilization
4	Severe, persistent, or unremitting illness (based on symptoms, neurocognition, and disability criteria). Patient's management could be fast-tracked to this stage at first presentation, based on specific clinical and functional criteria (from Stage 2) or because of failure to respond to treatment (from Stage 3a)	Specialized care services	1. As for Stage 3c, but with emphasis on clozapine, other tertiary treatments, and social participation despite ongoing disability

other medical conditions, due to the complexity of factors involved, the diagnostic difficulties given the reliance on psychopathology, which may be ill-defined at illness onset, the variable trajectory, and the importance of other comorbid prognostic factors (for example, stress, substance use, and other environmental insults). Further, EI programmes require substantial resources. Therefore, it is important to review the available evidence of efficacy and effectiveness of available EI models for psychosis, which should complement resources needed for those with established schizophrenia.

Interventions in the prenatal period and infancy

The greatest single risk factor for schizophrenia is genetic load [28], and recent studies attempt to delineate the genes relevant to the disorder [29], which provide clues for a number of potential treatment targets. Genetic susceptibility factors are likely to cause schizophrenia, with their negative influence on brain development from the prenatal period to later phases of brain development [11, 30]. Other critical events during early brain development, such as prenatal infection and starvation, and perinatal hypoxia are well-established risk factors for schizophrenia, while a range of other insults during early neurodevelopment, such as vitamin D deficiency, are also implicated [31], suggesting that public health measures at the population level may be important. Recent studies focus on the importance of gene–environment interactions [32], which should be examined across neurodevelopment. However, there is a lack of preclinical/animal research that examines gene–environment interactions across development and the impact on brain maturation. Such strategies would inform the development of novel pharmacological strategies relevant to the emergence of the disorder.

Public health measures to reduce the burden of psychotic illness

General non-specific public health measures, including nutritional health and better prenatal and perinatal care, can have a potential effect on reducing the risk for schizophrenia and co-occurring neurodevelopmental cognitive deficits. Another approach can be prenatal dietary supplementation to prevent schizophrenia, similar to the use of folate to reduce the risk of spina bifida and other disorders related to failure of closing of midline structures. Some authors have argued that prenatal choline supplementation, based on α -7 nicotinic receptor-related effects on neuronal inhibition deficits in schizophrenia, can reduce the incidence of schizophrenia. Low levels of vitamin D, folate, and retinol and increased homocysteine levels in early life have been proposed as risk factors for schizophrenia and neurodevelopmental disorders [33–35]. However, methodological difficulties, particularly the low population prevalence and the late onset around the beginning of the third decade of life, provide a significant challenge in testing the role of dietary supplementation during early development in reducing the risk of schizophrenia. Strategies to examine this question include long-term population-based studies where data are available at, or prior to, birth and/or targeting high-risk groups of individuals (for example, those with a positive family history).

A few RCTs have investigated the effect of prenatal choline supplementation on biological markers that have been associated with future schizophrenia risk (cognitive abilities and inhibition of P50 potential) in infants and children. In a placebo controlled trial of choline supplementation in pregnant women, babies in the choline

group had better P50 inhibition than controls at 1 month, but no difference was found at 3 months [36]. Another study found no evidence of cognitive differences at age of 1 year between choline and placebo groups [37]; however, maternal choline intake above 400 mg/day had significant effects on cognition at 7-year follow-up [38]. In a Finnish birth cohort study, vitamin D supplementation during the first year of life was associated with a reduced risk of schizophrenia in males [39]. Another Danish population-based case-controlled study found that both increased and reduced levels of vitamin D in neonates were associated with a higher risk of developing schizophrenia, suggesting a non-linear relationship [40]. Correcting abnormal levels of vitamin D and other deficiencies during early life may potentially reduce the incidence of schizophrenia. However, there is a need for longitudinal studies investigating the role of dietary supplements as an EI strategy, which could target high-risk subjects (for example, those with a positive family history).

It is also important to consider the possibility that the interaction of familial risk and environmental risks factors (nutritional, obstetric problems, stress) can increase the risk for infants, as women with psychosis are less likely to receive adequate prenatal care than healthy women. Multi-disciplinary teams (for example, obstetricians, neonatologists, nutritionists, psychiatrists, adult- and infant–parent-trained psychologists, and social workers) could address problematic prenatal issues, including nutritional deficiencies, lifestyle concerns such as the use of tobacco, alcohol, or other drug use, or life stresses including housing or violence in the home [41]. Enhancing parenting skills, supporting parents, and effective treatment of symptoms and cognitive rehabilitation in parents can potentially improve the resilience of a child at genetic risk for developing psychotic disorders [41]. Other than children of a parent with schizophrenia, strategies to identify high-risk children (for example, those with 22q11.2 deletion and other schizophrenia-related CNVs) might be appropriate for such interventions.

Intervention for specific and non-specific at-risk groups in childhood/early adolescence

An alternative approach involves interventions targeting non-specific risk factors such as trauma and stress, bullying, drug abuse, and migration in childhood and teenage years, which are associated with an increased risk of mental disorders, including schizophrenia. For example, evidence suggests that interventions for teens and their parents, which improve family communication and rule setting, can reduce the rate of subsequent drug abuse and associated problem behaviours [42]. Reducing peer rejection and bullying with social (anti-bullying programs) and individual (social skills training) interventions might be another potential strategy [43, 44].

The use of treatments as early as possible in the premorbid phase of the illness may also improve outcomes. Such intervention strategies are currently being investigated in those individuals identified as at CHR for psychosis; however, such studies are relatively few. Very few studies and case reports have provided evidence of short-term CBT and a web-based self-help programme in reducing PLEs [45]. However, there are some efforts to develop psychosocial intervention programmes targeting children with familial high and low risk presenting with developmental delays, PLEs, and emotional problems [46]. Cognitive remediation in children with neuropsychological difficulties can also potentially improve resilience of children at risk. Studies investigating trajectories of PLEs, social withdrawal,

cognitive development, and other potential antecedents of psychosis can help to identify target populations. For example, emerging evidence suggests that, while PLEs in children might be mostly benign and temporary, persistence of such symptoms are more likely to precede psychotic disorders and might be indicators of a need for interventions.

The strategy and focus in the last two decades on CHR for psychosis have provided the possibility to explore EI strategies in adolescence; however, there is currently only a limited focus on early (pre-emptive) intervention in childhood. This presents an important area of endeavour for future studies. Importantly, most of the proposed interventions have low risk and can benefit in enhancing resilience in a relatively large population, as childhood antecedents of psychosis have low specificity and can be associated with other psychopathologies.

Early intervention in adolescence and young adults

Goals and challenges for early intervention in individuals at clinical high risk for psychosis

Improving long-term outcome is the main goal for EI in individuals at high risk for psychosis. It is also hoped that EI in individuals at high risk can prevent or delay a first psychotic episode, which is often a very stressful experience for the individual and their family. Supporting individuals with mental illness and their families during late adolescence and early adulthood is also critical for helping individuals in pursuing academic or vocational goals, developing social and sexual relationships and developing skills necessary for independent living. EI programmes also emphasize the concept of phase-specific treatment, suggesting that treatments that have limited benefits in chronic patients can be helpful in at-risk individuals (for example, CBT, fish oil).

There are a number of conceptual and practical challenges in developing and implementing EI programmes in individuals at high risk for psychosis. The main challenge is the low positive predictive value of the current construct of high risk for psychosis. The majority of individuals who meet CHR criteria never develop psychotic disorders. Even though some of these help-seeking individuals might have subclinical psychotic conditions with a good prognosis, most (false-positives) would have non-psychotic conditions, including affective disorders, dissociative symptoms, trauma cluster B personality traits, and substance use. The heterogeneity of individuals meeting current CHR criteria has important implications for research and treatment of early psychosis. The problem of high false-positive rates leads to ethical problems, including use of drugs for psychosis and stigmatization in individuals who have no underlying psychotic disorder. For true positives, the current CHR criteria, including the condition of being a help-seeking individual, together with the demands of EI programmes, would lead to recruitment of individuals with milder psychotic disorders, rather than individuals with poor insight, non-adherence, and poor prognosis. Also, current criteria for detecting CHR omit negative and disorganized symptoms and cognitive deficits, which might be beneficial for identifying those individuals with the highest need for help. The heterogeneity of CHR is also a challenge for assessing the efficacy of treatment methods, as the individuals with different underlying psychopathological conditions can respond to different components of EI programmes. That it is called 'phase-specific' treatment for CHR

might be simply a reflection of the relationship between the heterogeneity of individuals with CHR and treatment response. Thus, some individuals might respond to treatments that do not work in chronic psychotic patients, as they have no underlying psychosis. On the other hand, dopamine antagonist drugs would remain as the main treatment of choice for true positives, if we were able to detect these individuals with sufficiently high accuracy. Stigma associated with psychotic disorder is another challenge in managing individuals with CHR.

Current evidence for efficacy of early intervention programmes

CHR has been by far the most commonly used high-risk paradigm in EI studies. Only a few studies have investigated the role of intervention in other high-risk paradigms. Several studies with small sample sizes have investigated the role of low-dose risperidone on first-degree relatives of individuals with schizophrenia presenting with negative symptoms and/or neurocognitive deficits (schizotaxia). These studies have provided evidence for a reduction of negative symptoms and cognitive deficits in these individuals [5, 47, 48]. Another study of standard vs integrated treatment (assertive community treatment, social skills training, and psychoeducation groups to patients and families) in schizotypal personality disorder individuals found lower transition rates to FEP in the integrated treatment group at 2-year follow-up (25% vs 48%) [49].

In accordance with the popularity of the CHR concept, a number of studies have investigated the effects of interventions with psychosocial and medication/dietary supplements in help-seeking individuals meeting CHR criteria. Many of these studies included control groups (that is, standard treatment and placebo). Some studies have reported reductions in symptom severity in both EI and control groups; however, most used conversion to psychosis as their primary outcome. Importantly, several meta-analyses of RCTs suggested that EI has generally produced significantly reduced conversion rates at 6- to 48-month follow-up [50, 51].

The use of dopamine antagonists in CHR individuals has been trialled early but has led to controversy about the ethics of this approach at such an early 'pre-psychosis' stage. Various drugs have been examined, including risperidone, aripiprazole, perospirone, and amisulpride, as a standalone or in combination with psychological treatment [50, 51], with few of these studies being RCTs [52–55]. These studies provided some evidence for efficacy of drugs in reducing the transition rate at follow-up. The ethical issues in prescribing dopamine antagonists in CHR include exposure of false-positive individuals to these medications and their side effects.

Alternative, less invasive pharmacological interventions showed initial promise and did not suffer from such ethical issues. These include the use of dietary supplementation with long-chain omega-3 polyunsaturated fatty acids (PUFAs/fish oil), which do not have any clinically relevant adverse effects. Initial findings suggested that PUFAs can be beneficial in improving outcomes, as suggested by the Vienna Omega-3 Study. This was the first RCT of omega-3 PUFAs in CHR, demonstrating that a 12-week intervention was associated with a significantly reduced risk of experiencing an FEP during a 12-month follow-up (5% for omega-3 PUFAs vs 28% for placebo) and with significant symptomatic and functional improvements [56]. Recently, findings from a longer follow-up (median = 6.7 years) of the same individuals suggested that benefits of this intervention

might be sustained. The cumulative conversion rate to psychosis at the longer-term follow-up was 9.8% (4/41) of subjects in the omega-3 PUFA group, and 40% (16/40) of subjects in the placebo group. This study was followed by two larger replication studies that investigated the effect of omega-3 PUFAs as an EI strategy. NEURAPRO-E is a multi-centre RCT (involving 304 participants), which compared outcome in one group treated with omega-3 PUFAs plus cognitive behavioural case management (CBCM) with a placebo plus CBCM group. Unfortunately, the outcome of NEURAPRO-E has not replicated the findings of the Vienna trial. In this study, there was no advantage of PUFAs, in comparison to placebo, for change in symptoms and functioning and 12-month transition rates (11.2% vs 11.5%) [57]. Similarly, the rate of psychotic conversion did not differ in the omega-3 fatty acid (13%) vs placebo (8%) samples in the recent NAPLS Omega-3 Fatty Acid Versus Placebo Study [58].

As a summary, studies in CHR suggest that psychological treatments and dopamine antagonists might reduce the incidence of developing a full-blown psychotic episode at 6- to 48-month follow-up. The findings regarding the effect of PUFAs are controversial; however, the larger multi-centre studies would suggest there is limited benefit. Importantly, the long-term effects of these psychosocial and pharmacological interventions on transition rates, functioning, and symptoms have not been clarified. Given the ethical issues of using potentially invasive treatments to groups of individuals with relatively low transition rates, psychosocial approaches are the mainstay of EI in CHR.

Early intervention in first-episode psychosis

Treatment of early psychosis

Pharmacological

Dopamine antagonists are the mainstay of treatment of psychosis and have an important role in treating acute episodes and reducing relapse rates in schizophrenia. Large multi-centre trials provide support for their use in early psychosis, as demonstrated by the European First Episode Schizophrenia Trial (EUFEST) [59]. In this study ($N = 498$), second-generation antipsychotics (SGAs) (also referred to as atypical antipsychotics) were tolerated better and were associated with lower discontinuation rates. The term 'second-generation antipsychotic' was the terminology used at the time to distinguish a heterogeneous group of new drugs from classical or 'first-generation' drugs for psychosis. This terminology will be used to describe the results of the trial, but it is not otherwise to be encouraged for reasons given in Chapter 10. While an initial analysis did not find significant differences between SGAs and low-dose haloperidol [a first-generation antipsychotic (FGA), classical or typical antipsychotic], subsequent analysis demonstrated a higher response and remission rate for most SGAs, compared to low-dose haloperidol [60], while there was a similar level of improvement in cognition [61]. A meta-analysis of drugs for psychosis in FEP indicated that olanzapine and amisulpride were relatively more effective than older drugs [62]. In considering the evidence in FEP, however, it is important to consider issues such as compliance and engagement with treatment strategies. Further, there are important decisions about duration of use of medication in young people, given the issue of diagnostic uncertainty at this stage of illness and the impact of adverse events

caused by these medications. Thus, milder forms of the illness will be apparent at this early stage; symptom remission will be more likely, and affective psychoses or substance-related psychotic disorders may have differing outcomes. Therefore, smaller doses might be sufficient in many patients with FEP, compared to chronic patients, and early dose reduction, in comparison to maintenance, might be associated with better functional outcome [63] and reduced side effect burden. In the short term, younger people might be susceptible to developing extra-pyramidal side effects, especially with older dopamine antagonist drugs, while the newer dopamine antagonists have histamine and serotonin-blocking properties associated with weight gain and metabolic syndrome. Weight gain is a particularly important issue in young people (that is, negative effect on self-esteem and peer relations) that can lead to non-adherence. Further, weight gain and metabolic syndrome can be associated with increased cognitive deficits, morbidity, and mortality in the long term. Most drugs for psychosis, with some exceptions (for example, ziprasidone), are associated with weight gain in FEP [64].

Like in chronic schizophrenia, psychological treatments might benefit individuals with FEP. Evidence suggests that CBT and family interventions are effective in FEP [65]. Recently, a number of studies have investigated the role of cognitive remediation in FEP, summarized in a meta-analysis [66], which confirmed significant, but modest, gains for verbal memory and social cognition, although the domain being examined may be important to consider [67]. Social skills training, psychoeducation, and vocational training have also been used in early psychosis [68, 69].

Psychosocial interventions

Most of the available early interventions in CHR studies used psychological interventions, with CBT being most commonly employed. Others [70] examined family-focused therapy (FFT), including a study investigating the effects of psychoeducational multifamily group treatment [71]. A number of these studies combined elements of various CBT, social skills training, psychoeducation, and family intervention and support (integrated treatments) [72–74]. A few studies investigating the effect of cognitive remediation in CHR [75, 76] have found that psychological interventions and cognitive remediation are associated with improved outcomes during the intervention period. Such studies are consistent with the notion that less invasive interventions would be appropriate at earlier illness stages, as proposed in the staging model. However, it should be noted that such interventions may also be useful at later illness stages.

Early intervention services

Specialized early intervention programmes for FEP

Programmes providing interventions for FEP are becoming commonplace in a number of developed countries. These services provide specialized assertive EI to improve outcomes in psychotic disorders. While implementing these programmes is costly and resource-intensive, it has been hypothesized that they can improve long-term outcomes (and decrease overall costs) as the first 3–5 years after FEP have been suggested to be a critical period for making a meaningful change to the future course of the illness. Another important

concept for EI in FEP is the duration of untreated psychosis (DUP). Patients with psychotic symptoms typically seek help for their symptoms after a considerable delay. Evidence suggests that longer DUP might be associated with poor prognosis [77]. Therefore, it is hoped that reducing DUP can improve long-term outcomes in FEP. EI in early psychosis can also reduce complications of onset of illness, including substance abuse, suicide, and inter-personal problems and family burden. EI programmes include intensive case management with low caseloads, assertive outreach, psychiatric treatment, and easy access to staff, providing psychoeducation, family interventions, and other psychosocial supports, which might include psychological treatments, social skills training, and vocational training. In most of these models, a specialist/standalone multi-disciplinary team provides EIs. Several alternative approaches, including the 'Hub and Spoke' model and enhanced community mental health care, also exist [78]. 'Hub and Spoke' models aim to overcome the challenges of providing EI in remote and rural areas, in which specialist staff within community systems are supported by a central 'hub'. In the enhanced community mental health care ('specialist within a generalist') model, staff in the community team have an EI role for some clients, in addition to their usual role.

It is also important to note that integrative treatment for psychotic disorders was initially developed in chronic patients. The original integrative treatment approach is based on a 'chronic disease' model, in which individuals need to be supported by intensive case management and specialist services, in order to function in the society or residential units. Studies on chronic schizophrenia have shown benefits of integrative treatment, in comparison to treatment as usual [79]. In the chronic disease model, it is not expected that long-term functioning of individuals would significantly improve a few years following discharge from such services. However, the promise of integrative treatment in EI services is changing the illness course and improving long-term functioning by intervening in the 'critical period' and by reducing the need of individuals for such services in the coming years. Therefore, it is important to test the long-term functioning of individuals and their capacity to maintain gains once the EI programme is ceased.

Evidence for short-term efficacy of EI in FEP

Currently, there are many EI services in Australia, North America, Europe, and Asia. A number of RCTs have investigated the efficacy of such programmes in comparison to treatment as usual (TAU). The Danish OPUS trial, which randomized 547 patients with FEP to either a 2-year specialized assertive EI programme or standard treatment, is the most comprehensive study to date that has examined short- and long-term outcomes [80]. Results of the OPUS trial showed positive effects on psychotic and negative symptoms, treatment non-adherence, level of functioning, secondary substance abuse, level of user, and family satisfaction in the EI group, in comparison to the TAU group. There was a reduction in the number of days patients used beds in the EI group, compared to the TAU group. A more recent EI trial—the Recovery After an Initial Schizophrenia Episode Early Treatment Program [NIMH RAISE-ETP (NAVIGATE)]—included 404 individuals with FEP. This study reported greater improvement in quality of life and symptoms, in comparison to usual community care. A number of smaller trials, including the smaller Lambeth Early Onset (LEO) study [82], the International Optimal Treatment (IOT) study subset [83], the

Croydon Outreach and Assertive Support Team (COAST) [84], the Specialized Treatment Early in Psychosis (STEP) [85], the Psychosis early Intervention and Assessment of Needs and Outcome (PIANO) [86], and the Early Psychosis Intervention Center (EPICENTER) [87] studies, had already reported similar benefits during the intervention period. Several studies recruited individuals who already completed an EI service [OPUS, Early Assessment Service for Young People with Psychosis (EASY) and Canadian Prevention and Early Intervention Program for Psychoses (PEPP)] and randomized them to prolonged EI (additional 1–3 years) and regular care groups [88, 89]. These studies found that prolonged EI was associated with sustained benefits, in comparison to the regular care group within the intervention period. It has been suggested that EI services might be cost-effective, as increased costs of integrated treatment are balanced by reduced days of inpatient admissions [85, 90]. In summary, the current evidence suggests that EI services are better than TAU in ordinary community mental health teams during the intervention period. This finding is similar to the outcome of integrative treatment studies in chronic schizophrenia [91].

Evidence for long-term efficacy of EI in FEP after ceasing intervention

Evidence suggests that EI can significantly reduce the DUP, however, the clinical significance of this finding is unclear. The Treatment and Intervention in Psychosis Study (TIPS) attempted to answer this question using a quasi-experimental design [92]. The TIPS study compared the outcome of individuals living in areas where public information campaigns and low-threshold early detection teams were established, compared to individuals living in other areas. In early detection areas, DUP was significantly reduced (from 16 to 4 weeks), but the clinical significance of this finding was dubious. At 10 years, half of the individuals in both areas were not remitted [93]. In the same study, the recovery rate was better in individuals in the early detection area, as they were more likely to be in full-time employment (27% vs 11%). However, it is likely that baseline differences between groups can explain the observed findings, as patients from the early detection area had fewer positive and negative symptoms at presentation. Thus, low-threshold early detection approaches are likely to recruit a higher percentage of individuals with milder psychotic illness and shorter DUP. Clearly, better controlled studies are required to address this important question.

RCT studies comparing the long-term outcome of EI services and TAU can be more informative. A critical question for EI outcome research is whether time-limited intervention during a 'critical period', unlike similar interventions in chronic patients, dramatically improves long-term outcomes, in comparison to TAU, after individuals are discharged to regular services. To date, several groups have reported their findings regarding long-term outcomes. In contrast to findings suggesting short-term benefits of EI, a number of 5- to 12-year follow-up findings reported in the OPUS [80, 94], IOT [95], and LEO [96] RCTs have not found evidence for sustained benefits in EI groups, in comparison to TAU groups. Current evidence does not support the long-term sustaining benefits of EI after ceasing treatment. It was suggested that the duration of treatment in the EI service can be important for maintaining outcomes in the long term and that 2–3 years of intervention might be insufficient. As discussed, several recent ongoing studies investigated the effect of prolonged EI and recently completed prolonged intervention periods

[89, 97]. The Jockey Club Early Psychosis (JCEP) project is another ongoing study comparing effectiveness of 4 years and 2 years of EI and standard care [98]. When completed, 5- and 10-year post-intervention outcome findings of these studies may show whether prolonged EI, unlike the 2-year intervention, has sustained benefits after intervention is ceased. The findings to date therefore raise important questions about the benefits of EI services, unless such intervention can be sustained in the long term, perhaps even beyond an extended EI programme. Evidence is needed to inform decisions about the configuration of services and the balance between EI vs post-EI services.

Conclusions

Current evidence suggests that integrative treatment in early psychosis is more successful than 'treatment as usual' care in reducing symptoms and relapse rates and improving engagement. Offering high-quality, integrative, intensive, needs-based services that incorporate age-specific/relevant goals at all stages of psychotic disorders, including early, medium, or late stages, is the best service we can offer at this point in time. Emphasizing the importance of optimism and instilling hope for symptomatic and functional recovery should be implemented across all stages of psychosis. Early detection and intervention services and public awareness campaigns are important to increase the possibility for individuals with psychotic disorders to access help in the early stages of the illness. For individuals having potential prodromal symptoms, given the significant issue of false-positives identified by CHR criteria, together with the clinical heterogeneity of this population, a generic psychological treatment approach remains the main intervention for the foreseeable future. Studies investigating the trajectory of developmental antecedents of psychotic disorders and the effectiveness of pre-emptive interventions are clearly needed. Continuing research efforts to develop better and highly accurate markers of psychotic disorders and other mental disorders at pre-morbid and prodromal stages are critical for true EI, which could reduce the incidence and/or improve long-term outcomes for psychotic disorders.

Antipsychotic and anticholinergic drugs

Herbert Y. Meltzer and William V. Bobo

Introduction

The discovery by Delay and Denicker in 1953 that chlorpromazine was highly effective in alleviating delusions, hallucinations, and disorganized thinking was the seminal breakthrough in the treatment of schizophrenia, the first agent to produce sufficient relief of core psychotic symptoms to permit life outside of institutions for many patients with schizophrenia, and even a return to a semblance of normal function for those individuals with relatively little cognitive impairment. Chlorpromazine and the other typical (first generation) antipsychotic drugs introduced over the next 30 years were of immense benefit to people who experience psychotic symptoms as a component of a diverse group of neuropsychiatric and medical disorders, as well as drug-induced psychoses. Clinical and basic studies of these and the subsequent classes of drugs for psychosis have contributed to understanding the pathophysiology of schizophrenia and other forms of mental illness with psychotic features. The first generation of drugs for psychosis led to identifying the role of dopamine in psychosis, motor function, and some endocrine functions. This group of drugs led to the development of drugs with minimal motor side effects. These were marketed as 'atypical antipsychotics', as opposed to the older 'typical' drugs; they are also sometimes referred to as second- and third-generation antipsychotic drugs, and clozapine is the prototype. Their pharmacology is much more complex and involves, beyond interactions with dopamine receptors, direct and indirect effects on a variety of neurotransmitters, especially serotonin, glutamate, GABA, acetylcholine, histamine, and neuromodulators, such as brain-derived neurotrophic factor (BDNF), affecting synaptic structure and function. This chapter will describe the various classes of antipsychotic agents, with emphasis on the drugs with minimal motor side effects, their benefits and adverse effects, recommendations for use in clinical practice, and their mechanism of action (MOA). The drugs used to treat the extrapyramidal side effects (EPS) produced mainly by the typical dopamine antagonist drugs are also considered.

Classes of antipsychotic drugs

As explained in Chapter 10, the broad classification of psychotropic drugs has usually been on the basis of indication. It has been argued

there that we should move away from such classification to one based on the MOA. However, the present chapter explains how thinking around the MOA developed. The indication (antipsychotic) preceded the understanding of the MOA. Therefore, the conventional terminology is used here to illustrate how the field has developed. In most other chapters, which describe the many uses of these drugs, the older terminology is avoided where possible.

Antipsychotic drugs have been classified into two broad categories: typical and atypical [1]. Typical antipsychotic drugs are those which 'typically' produce EPS at clinically effective doses, including parkinsonism (muscle rigidity, tremor, bradykinesia), acute dystonic reactions, akathisia (restlessness), and tardive dyskinesia. The efficacy of typical antipsychotics is mediated by blockade of dopamine D2 receptors in the dorsal striatum and limbic system, which includes the nucleus accumbens, stria terminalis, and amygdala [2, 3]. However, their blockade of D2 receptors in the dorsal striatum leads to the motor side effects described previously [3].

The typical antipsychotic drugs are members of a variety of chemical families (Table 64.1). They vary in their affinity for the D2 receptor, with low-affinity drugs such as chlorpromazine, which require high doses for clinical efficacy, to high-affinity drugs, such as haloperidol, which are effective at lower doses (Table 64.1). Whereas typical antipsychotics are associated with EPS at therapeutic doses, atypical antipsychotic drugs are associated with a lower (but not absent) risk of EPS at clinically effective doses. As such, 'atypicality' of antipsychotic drugs is based on clinical effects on motor system functioning. Kapur and Seeman [4] proposed that the rate of dissociation of all antipsychotic drugs from the D2 receptor provides the basis for the distinction between typical and atypical antipsychotic drugs, with atypical antipsychotic drugs dissociating more rapidly. While this is true for clozapine and quetiapine, the atypical drugs risperidone, sertindole, olanzapine, and asenapine dissociate no more rapidly or even slower than haloperidol. As such, 'fast dissociation' cannot provide the pharmacological basis for atypicality for most of the drugs that are considered atypical. The pharmacologic basis for atypicality will be discussed subsequently. Sertindole is a phenylindole compound with a receptor profile which places it in the class of 5-HT_{2A}/D2 antagonist atypical antipsychotic drugs [5]. Concerns about it causing QTc prolongation have limited its use [6].

Low-potency typical agents are those in which the usual dose range in schizophrenia is ≥ 200 mg/day, whereas mid- to high-potency agents are those in which the usual dose range is between

Table 64.1 Selected antipsychotic drugs and classification

Drug name	Trade name (examples from pharmaceutical companies in the United States)	Chemical class	General class	D2 potency*
Aripiprazole	Abilify®	Dihydrocarbostyryl	Atypical	
Asenapine	Saphris®	Dibenzo-oxepino pyrrole	Atypical	
Blonaserin	Lonasen®	4-phenyl-2-(1-piperaziny) pyridine	Atypical	
Brexpiprazole	Rexulti®	4-piperazin-1-yl-4-benzo[B]thiophene	Atypical	
Cariprazine	Vraylar®	Dichloro-phenyl-piperazine	Atypical	
Chlorpromazine	Thorazine®	Phenothiazine	Typical	Low
Clozapine	Clozaril®	Dibenzazepine	Atypical	
Droperidol	Inapsine®	Butyrophenone	Typical	Mid
Fluphenazine	Prolixin®	Phenothiazine	Typical	High
Haloperidol	Haldol®	Butyrophenone	Typical	High
Iloperidone	Fanapt®	Piperidinyl-benzisoxazole derivative	Atypical	
Loxapine	Loxitane®	Dibenzazepine	Typical	Mid
Lurasidone	Latuda®	Piperidinyl-benzisoxazole derivative	Atypical	
Mesoridazine	Serentil®	Phenothiazine	Typical	Low
Molindone	Moban®	Dihydroindolone	Typical	Mid
Olanzapine	Zyprexa®	Thiobenzodiazepine	Atypical	
Paliperidone	Invega®	9-hydroxy metabolite of risperidone	Atypical	
Perphenazine	Trilafon®	Phenothiazine	Typical	Mid
Pimozide	Orap®	Butyrophenone	Typical	Mid
Promazine		Phenothiazine	Typical	Mid
Quetiapine	Seroquel®	Dibenzothiazepine	Atypical	
Risperidone	Risperdal®, Risperdal CONSTA®	Benzisoxazole	Atypical	
Sertindole	Serdolect®	Phenylindole	Atypical	
Thioridazine	Mellaril®	Phenothiazine	Typical	Low
Tiotixene	Navane®	Thioxanthene	Typical	High
Trifluoperazine	Stelazine®	Phenothiazine	Typical	Mid
Ziprasidone	Geodon®	Benzisothiazole	Atypical	

* Classification on the basis of potency of D2 receptor binding for typical antipsychotic drugs only.

2 mg/day and 175 mg/day. In general, the low-potency drugs are associated with more sedative, orthostatic hypotensive, and anticholinergic adverse effects than the high-potency agents, but also have less of a tendency to produce EPS. All typical antipsychotics are equally effective to reduce psychosis, but because of secondary pharmacologic features, they differ from one another with regard to their adverse effect profiles, for example EPS, weight gain, sedation, hypotension, etc. [7].

Atypical antipsychotics are characterized by a more diverse and complex pattern of pharmacological activity. Most are serotonin [5-hydroxytryptamine (5-HT)] 2A and dopamine D2 antagonists or D2 partial agonists, and many have a variety of activities at other receptors whose contribution to their mode of action is still being elucidated [2]. Substituted benzamides, for example amisulpride, also produce low EPS at clinically effective doses and may constitute another class of atypical agents. The prototypical atypical antipsychotic drug is clozapine, a dibenzodiazepine (Table 64.1) [8]. Other atypical antipsychotic drugs are shown in Table 64.1 [8–11]. These drugs are all more potent 5-HT_{2A} than D2 receptor antagonists, as well

as multi-receptor antagonists [12, 13], except for aripiprazole and brexpiprazole, which act as dopamine D2 receptor partial agonists [14, 15]. Amisulpride is a unique atypical antipsychotic drug that acts as an antagonist at dopamine D2 and D3 receptors and at the serotonin 5-HT₇ receptor. Cariprazine is a dopamine D2 and D3 receptor partial agonist, with high selectivity towards the D3 receptor [16]. As will be discussed, the atypical antipsychotic drugs differ not only with regard to pharmacological activity and adverse effects, but also with regard to efficacy [17, 18]. Atypical antipsychotic agents have been shown to have advantages, albeit modest, in treating negative and mood symptoms [19–21] and to improve some domains of cognitive dysfunction in patients with schizophrenia, related primary psychotic disorders, and perhaps other psychiatric disorders [22–24].

Pharmacology

There is abundant evidence that dopamine plays a key role in the aetiology of psychosis and the action of antipsychotic drugs [25].

The doses of typical antipsychotic drugs is highly correlated with their affinities for D2 receptors. Amphetamine and methamphetamine, which increase synaptic concentrations of dopamine, exacerbate delusions and hallucinations in some patients with schizophrenia, due to stimulation of a subgroup of D2 receptors in mesolimbic nuclei [26, 27] and the dorsal striatum. The cell bodies of mesolimbic and dorsal striatal dopamine neurons reside in the ventral tegmentum and substantia nigra, respectively [28]. The outflow of these regions to the thalamus and the cortex has been postulated to mediate psychotic symptoms. As such, blockade of mesolimbic and striatal dopamine D2 receptors is thought to be the basis for drugs to ameliorate psychotic symptoms, although the firing rate of the mesolimbic dopaminergic neurons is subject to multiple influences, including stimulatory serotonergic input from the median raphe nucleus [29].

A group of ventral tegmental dopamine neurons project to various regions of the cortex and comprise the mesocortical dopamine system. There is extensive evidence that these neurons are important for cognition, especially working memory [30], as well as negative symptoms [31]. Typical drugs occupy 80–95% of striatal D2 receptors in patients with schizophrenia at clinically effective doses,

though much lower occupancy can lead to control of psychosis [32]. EPS occurs at above 80% occupancy of these receptors. Blockade of D2 receptors in the anterior pituitary gland is the basis for their ability to stimulate prolactin secretion [33].

The prefrontal cortex has relatively low concentrations of D2 receptors and has a higher density of D1, D3, and D4 dopamine receptors [27]. The activation of D1 receptors in the prefrontal cortex may be especially critical for normal working memory and other executive-type functions subserved by this brain region. However, no D1 agonists are currently approved. D1-positive allosteric modulators have shown promise in preclinical studies as cognitive enhancers. Drugs which selectively block D4 receptors have not been found to have an antipsychotic effect [34]. There is extensive evidence that selective D3 receptor partial agonists and antagonists show promise to treat cognitive impairment and negative symptoms [35, 36]. The typical antipsychotic drugs vary in their *in vitro* and *in vivo* affinities for receptors such as the dopamine D1, histamine H1, muscarinic, α 1- and α 2-adrenergic, and serotonergic receptors (Table 64.2), which mediate effects on arousal, extra-pyramidal, cognitive, cardiovascular, gastrointestinal, and genitourinary function (Table 64.3) [15, 16, 37–42].

Table 64.2 Affinities of selected antipsychotic drugs at various neuroreceptors

Drug name	D2	5-HT1A	5-HT2A	5-HT2C	α -1	α -2	H-1	M-1
Aripiprazole	0.95	5.6	4.6	181.0	25.0	74.0	29.0	$\geq 6K$

All receptor-binding affinities are reported as K_i (nM) using National Institutes of Mental Health (NIMH) Psychoactive Drug Screening Program (PDSP) certified data, available online at <http://pdsp.cwrui.edu/pdsp.php>, unless otherwise specified. In general, the lower the K_i (nM) value, the higher the binding affinity for the drug at a given receptor site.

NA, human cloned receptor data not available.

* 9-hydroxy (9-OH) risperidone is marketed as paliperidone.

Table 64.3 Hypothesized therapeutic and adverse effects of receptor occupancy by antipsychotic drugs

Target receptor	Pharmacological activity	Therapeutic effect(s)	Adverse effect(s)
Dopamine D2	Antagonism or partial agonist effects	Reduction of positive symptoms	Extrapyramidal effects (EPS) Hyperprolactinemia
Serotonin (5-HT) 1A	Full or partial agonist effects	Cognitive enhancement Reduction of mood and anxiety symptoms	
5-HT2A	Antagonism	Reduction of negative symptoms Reduction of EPS Reduction of mood and anxiety symptoms Increased deep sleep	
5-HT2C	Antagonism	Reduced anxiety symptoms	Weight gain
Adrenergic α -1	Antagonism		Orthostatic hypotension Dizziness
Adrenergic α -2	Antagonism		Reflex tachycardia
Histamine H-1	Sedation	Sedation Drowsiness Weight gain	
Muscarinic (cholinergic) M-1	Antagonism	Reduction of EPS	Blurry vision Exacerbation of acute angle closure glaucoma Sinus tachycardia Constipation Urinary retention Memory dysfunction

Thioridazine is a relatively potent antimuscarinic agent. Most of the low-potency drugs for psychosis are potent α -1 and H1 antagonists, which contribute to orthostatic hypotension and weight gain, respectively.

The receptor-binding affinities of the atypical antipsychotic drugs have been related to their efficacy and side effect profiles. As noted previously, the most important determinant of atypicality for most of the currently available agents of this type is that they are more potent 5-HT2A than D2 receptor antagonists. An exception is aripiprazole, which combines potent 5-HT2A antagonism and 5-HT1A agonism, with partial D2 receptor agonism. Another exception is amisulpride, which is a selective D2/3 antagonist, with little pharmacological activity at 5-HT2A receptors. Combined 5-HT2A and less potent D2 antagonism is the most consistent principle yet discovered to produce a separation between antipsychotic action and interference with motor function [43]. The low potential for EPS with clozapine, and subsequently olanzapine, quetiapine, risperidone, iloperidone, ziprasidone, paliperidone, and asenapine is, in part, due to their relatively stronger 5-HT2 antagonist and weaker D2 antagonist properties. Direct and indirect 5-HT1A partial and full agonist effects of the atypical antipsychotic drugs have also been shown to contribute to their low EPS profile. The atypical antipsychotic agents have the ability to increase prefrontal cortical dopaminergic activity, compared with subcortical dopaminergic activity [44]. The ability to increase the release of dopamine in the prefrontal cortex may be to improve cognition and negative symptoms. It may also contribute to decreasing the release of dopamine in the mesolimbic region, because prefrontal dopamine neurons modulate the activity of corticolimbic glutamatergic neurons that regulate the activity of ventral and dorsal striatal DA neurons [30]. Clozapine and some of

the other atypical antipsychotic drugs that are also potent 5-HT2A antagonists also produce marked increases in prefrontal cortical and hippocampal acetylcholine efflux [45]. These atypical agents also produce marked increases in noradrenaline efflux in the prefrontal cortex, which is correlated in time and magnitude with the increase in extracellular dopamine [46]. It is of interest that in rodents, combining ritanserin (a mixed 5-HT2A/2B/2C antagonist) or M-100907 (a selective 5-HT2A antagonist) with a selective D2/3 antagonist resulted in increased prefrontal dopamine release [47, 48]. The importance of serotonin receptors other than 5-HT2A for antipsychotic action has received considerable attention. Activation of 5-HT1A receptors are believed to have a dopamine-modulating effect similar to that of 5-HT2A antagonism [49]. Under experimental conditions, 5-HT1A agonists have been shown to stimulate cortical dopamine release [50, 51], and in schizophrenic patients who were stabilized on haloperidol, the addition of tandospirone, a 5-HT1A partial agonist, resulted in improved neurocognitive performance [52]. This effect has also been demonstrated for buspirone, another 5-HT1A partial agonist [53]. Antagonism of 5-HT2C receptors also appears to result in cortical dopamine and noradrenaline release, as well as in the nucleus accumbens [54]. As is the case with 5-HT1A activity, not all atypical antipsychotic drugs are active at 5-HT2C receptors (Table 64.2). Like antagonism at histamine H1 receptors [55], 5-HT2C antagonist activity may be related to weight gain [56].

Clozapine, olanzapine, risperidone, and quetiapine are able to block the interference in prepulse inhibition produced by d-amphetamine, apomorphine, or phencyclidine at doses that do not interfere with locomotor function [57]. Clozapine and M100907 are able to block the effects of phencyclidine, an *N*-methyl-*D*-aspartate (NMDA) receptor antagonist, on locomotor activity in rodents [58].

The extent of involvement of other atypical relative to typical drugs at NMDA receptors and other glutamatergic targets is an area of active interest. Other receptor targets that are of special interest in terms of improving cognitive functioning and selected psychotic symptoms include M1 muscarinic, α -7 nicotinic, and α -1 and α -2 adrenergic receptors [59].

Administration, pharmacokinetics, and dosage

Administration

Typical antipsychotic drugs

The major use is for the treatment of schizophrenia. Other major uses that will be touched on briefly in this chapter include treatment of mood disorders such as major depression (as an adjunct to antidepressants) and bipolar disorder. Indications discussed in other chapters of this textbook include Tourette's syndrome and aggression. The major advantage of the typical drugs is their ability to improve positive symptoms in patients with schizophrenia, that is, delusions and hallucinations, and to rapidly reduce psychotic symptoms, as well as the core non-psychotic signs and symptoms of manic episodes (including agitation, hostility, aggressive behaviour, psychomotor agitation, and severe insomnia). Administration of typical drugs leads to the complete or nearly complete elimination of positive symptoms and disorganization of thought and affect in about 60–70% of patients with schizophrenia and an even higher proportion of those with psychotic mania and psychotic depression [60]. The antipsychotic response in schizophrenia and mania is sometimes apparent within a few days in many patients, but maximum benefit usually takes up to several weeks or months to unfold. A reasonable duration for a therapeutic trial with one of these agents is 4–6 weeks. It is not appropriate to switch medications after 1 or 2 weeks, even if a response is not apparent, unless side effects pose a serious problem. Positive symptoms (delusions and hallucinations) do not respond to typical drugs in about 10% of schizophrenic patients, even during the first episode [61]. Another 20% of patients with schizophrenia develop resistance to these agents during the subsequent course of their illnesses [62]. Development of resistance to typical drugs may occur at any time during the course of treatment, even after many years of control of positive symptoms. Such patients may respond to clozapine [63] or one of the other atypical drugs [61, 62]. The average doses of the typical neuroleptic drugs are given in Table 64.4. The best results with these drugs in terms of efficacy and side effects may be expected with the lowest dose needed to produce control of positive symptoms with the fewest EPS [7, 64].

Controlled studies have failed to find benefits from high-dose strategies or combining two or more typical antipsychotics. Increasing the dose of these agents when patients fail to respond rapidly, for example within days, should be avoided. Augmentation with a benzodiazepine may be useful to decrease anxiety until the lower doses of drugs produce adequate control of positive symptoms [7, 64]. Patients who receive high doses of these drugs adequately are at greater risk of hyperprolactinaemic effects, EPS, and tardive dyskinesia and are generally better treated with an atypical antipsychotic drug.

However, improvement in positive symptoms is only one element in the treatment of schizophrenia. Additional efficacy factors of major importance are summarized in Table 64.5.

Tolerability and safety factors, such as compliance, tardive dyskinesia, weight gain, and medical morbidity, are also major elements in outcome and influence the choice of a typical or atypical drug. Typical drugs are not as effective as atypical drugs for improving primary negative symptoms [65]. Abnormalities in specific domains of cognition (Table 64.5) are present in first-episode schizophrenic patients at a moderate to severe level and show additional deterioration during the course of illness [66]. Approximately 85% of patients with schizophrenia are clinically impaired in one or more domains of cognition [67, 68]. Cognition has been shown to be the most critical determinant of functional capacity among patients with schizophrenia, even more so than positive symptoms [67]. Typical antipsychotic drugs usually do not improve cognitive function [70]. Development of tardive dyskinesia may diminish the possibility of obtaining benefit from atypical antipsychotic to improve cognition [71].

All of the typical drugs are likely to be equally effective in treating either the initial presentation or recurrent psychosis due to breakthrough of symptoms, despite compliance, or because of having stopped medication [7, 62, 64]. First-episode patients with schizophrenia usually require much lower doses than patients with two or more episodes, suggesting some progression of the disease process or the development of tolerance to the mechanism of action of these drugs [72]. Doses for more chronic patients should be in the range of 5–10 mg of haloperidol equivalents per day (Table 64.4) for up to 4–6 weeks, unless there is a major need for chemical means to prevent harm to self or others, to decrease excitement, or to induce sleep [73]. Auxiliary medications for anxiety and sleeplessness, for example benzodiazepines, may supplement these low doses [74].

Parenteral injections of haloperidol, chlorpromazine, or other dopamine antagonists/partial agonists may be needed for patients who refuse oral medication or where very rapid onset of action is needed to control acutely dangerous behaviours if less restrictive means either fail or cannot be utilized safely. Commonly, haloperidol (2–10 mg) with or without lorazepam (2–4 mg) is delivered intramuscularly every 30–60 minutes, as required, up to three doses. Doses of haloperidol given intramuscularly in such situations generally should not exceed 18 mg per day. Oral medication should be substituted as soon as feasible. If positive symptoms fail to respond to a single trial of a typical drug at adequate doses in patients with schizophrenia, there is evidence that switching to another typical antipsychotic, even of a different chemical class, is unlikely to produce greater control [7, 60, 62]. This is likely to be true for other indications for the use of antipsychotic agents as well.

In cases of repeated illness relapse due to poor compliance or when patients prefer it, the use of long-acting (for example, depot) injectable medications, typically administered once every 2–4 weeks, should be used. The use of injectable antipsychotic medication has been associated with lower rates of relapse and rehospitalization and greater global improvement, compared with oral typical antipsychotics [75], possibly as a result of ensured drug delivery. Long-acting injectable drugs should not be given to ameliorate acute behavioural disturbances.

In summary, typical antipsychotic drugs may be less desirable than atypical antipsychotic drugs for some patients because of their greater risk for EPS, tardive dyskinesia, and prolactin elevations and lower adherence. On the other hand, typical antipsychotics are less expensive, on average, than atypical antipsychotic drugs.

Table 64.4 Oral dosing of antipsychotic drugs

Typical antipsychotic drugs				
	Equivalent doses (mg/day)	Starting dose	Titration schedule	Dose range (mg/day)
Chlorpromazine ^a	100	15–50 mg 2–4 times daily	As clinically indicated	300–1000 (divided once daily to four times daily)
Fluphenazine ^b	2	0.5–10 mg/day (divided every 6–8 hours)	As clinically indicated	5–20
Haloperidol ^c	2	0.5–5 mg twice daily	As clinically indicated	5–20
Loxapine	10	10 mg twice daily	As clinically indicated	30–100
Mesoridazine	50			150–400
Molindone	10	50–75 mg/day divided 3–4 times daily	As clinically indicated	30–100
Perphenazine ^d	10	4–8 mg three times daily (8–16 mg 2–4 times daily if hospitalized)	As clinically indicated	16–64
Thioridazine	100	50–100 mg three times daily	As clinically indicated	300–800
Tiotixene	5	2 mg three times daily	As clinically indicated	15–50
Trifluoperazine	5	2–5 mg twice daily	As clinically indicated	15–50

For elderly patients or those with renal or hepatic problems, the doses of drug may need to be reduced by one-half or more.

^a Short-acting IM formulation may be given 25–50 mg (may repeat after 1–4 hours, as required); may gradually increase the dose up to 400 mg IM every 4–6 hours (maximum of 2000 mg/day)—may be needed for severe cases.

^b Short-acting IM formulation may be given 2.5–10 mg/day at every 6- to 8-hour intervals; depot IM formulation may be given 12.5–25 mg every 3 weeks.

^c Short-acting IM formulation may be given 2–5 mg every 1–4 hours; depot IM formulation may be given at approximately 10–20 times the stable oral dose every 4 weeks.

^d Short-acting IM formulation may be given 5–10 mg every 6 hours (maximum of 30 mg/day).

Atypical antipsychotic drugs			
	Starting dose	Titration schedule	Dose range (mg/day)
Asenapine	5 mg twice daily	As clinically indicated, to usual effective dose range of 5–10 mg twice daily	5–10 mg twice daily
Aripiprazole ^{a,b}	10–15 mg daily	As clinically indicated, every 2 weeks	10–30
Blonanserin	4 mg twice daily	As clinically indicated, to usual effective dose range of 4–12 mg twice daily	4–12 mg twice daily
Brexpiprazole	1 mg daily	Increase to 2 mg/day on days 5–7, 2 mg/day or 4 mg/day on days 8+	2–4
Cariprazine	1.5 mg daily	As clinically indicated, to usual effective dose range of 1.5–6.0 mg/day	1.5–6.0
Clozapine	12.5 mg once daily to twice daily	Increase by 25–50 mg/day until usual effective dose of 300–450 mg/day after 2–4 weeks	150–600
Iloperidone	1 mg twice daily	Increase to 2, 4, 6, 8, and 12 mg twice daily on treatment days 2, 3, 4, 5, 6, and 7 (respectively)	6–12 mg twice daily
Lurasidone	40 mg daily (with food)	As clinically indicated, to usual effective dose range of 40–160 mg/day (all doses with food)	40–160
Olanzapine ^{c,d}	5–10 mg daily	As clinically indicated, by 5 mg/day every 7 days	10–30
Paliperidone ^e	6 mg/day	As clinically indicated, by 3 mg/day every 2–4 week increments, up to 12 mg daily	6–12
Quetiapine	25 mg twice daily	Increase by 25–50 mg 2–3 times daily on days 2 and 3, to target dose of 300–400 mg daily (QD –TID) by day 4. Further increases as clinically indicated by 25–50 mg twice daily every 2 days	300–800
Risperidone ^f	0.5–1 mg twice daily	Increase by 0.5–1 mg twice daily on days 2 and 3, with further dose increases thereafter by 0.5–1 mg increments every 7 days as required	2–8
Ziprasidone ^g	20 mg twice daily with food	Increase by 20–40 mg twice daily every 2 days to target dose of 80 mg (all doses with food)	120–200

For elderly patients or those with renal or hepatic problems, doses of drug may need to be reduced by one-half or more and titration may be slower.

^a Short-acting IM formulation may be given at 9.75 mg, though the lower 5.25 mg dose may be indicated in some situations.

^b There are two long-acting IM formulations. Aripiprazole monohydrate may be initiated at 400 mg as a gluteal or deltoid injection (continue oral aripiprazole for 2 weeks), with once-monthly dosing at 400 mg (160–300 mg once monthly if there are adverse reactions, in pharmacogenetic CYP2D6 poor metabolizers, or if taken with drugs that inhibit CYP2D6 or 3A4). Aripiprazole lauroxil may be initiated at 441–882 mg (continue oral aripiprazole for 3 weeks), followed by repeated administration every 4 weeks [441 mg (deltoid or gluteal injection), 662 mg (gluteal injection only), or 882 mg doses (gluteal injection only)] or every 6 weeks (882 mg dose only).

^c Short-acting IM formulation may be given 10 mg as required (may be repeated after 2 hours, up to 30 mg/day).

^d Long-acting IM formulation may be initiated at 210 mg or 300 mg every 2 weeks for a total of 8 weeks, followed by maintenance dosing (150–405 mg every 2–4 weeks).

^e There are two long-acting IM formulations of paliperidone. The once-monthly long-acting injectable form may be initiated at 234 mg (deltoid injection), followed by a 156 mg deltoid injection on day 8. Maintenance doses are given by deltoid or gluteal injection once monthly in the 39–234 mg dose range. The once-quarterly (every 3 months) long-acting injectable form can be considered after successful treatment with the once-monthly form for at least 4 months and may be initiated at 273–819 mg.

^f Long-acting IM formulation may be initiated at 25 mg Q 2 weeks (continue oral risperidone dose for 3 weeks), with increases as clinically indicated every 4 weeks up to a dose of 50 mg Q 2 weeks.

^g Short-acting IM formulation may be given 10–20 mg as required (may be repeated Q 2–4 hours as needed, up to 40 mg/day).

Table 64.5 Target signs and symptoms for the pharmacological management of schizophrenia

Target	Description	
Positive syndrome	Hallucinations Delusions	Typically the most amenable to treatment with all antipsychotic drugs
Negative syndrome	Avolition Apathy Anhedonia Lack of responsiveness Poor rapport with others Passive social withdrawal Poverty of speech Affective flattening	Robustly correlated with functional impairment in schizophrenia More difficult to treat pharmacologically and may require longer to respond than positive signs and symptoms Pharmacological adjuncts may be needed, though understudied Atypical antipsychotic drugs are believed to be more efficacious than typical antipsychotics
Hostility/excitement	Verbal or physical aggression	Typically amenable to treatment with all antipsychotic drugs Use of parenteral formulation may be required
Mood and anxiety symptoms	Depressed mood Anxious mood Nervousness Panic symptoms Suicidal ideation	Believed to be more responsive to treatment with atypical antipsychotic drugs Clozapine has demonstrated superiority for treating chronic suicidality in schizophrenia
Cognitive impairment (psychopathological definition)	Disorientation Problems with abstraction Attentional problems Preoccupations Disorganized thought processes	Some domains respond favourably to antipsychotic drug treatment, though response is often incomplete
Cognitive impairment (neuropsychological testing definition)	Working memory Attention/vigilance Verbal learning/memory Visual learning/memory Problem-solving Processing speed	Neuropsychological deficits, like negative signs and symptoms, are robustly correlated with functional outcome in schizophrenia Very difficult to treat with medication alone Atypical antipsychotic drugs are believed to be superior to typical antipsychotics, though effect sizes are only mild to moderate for the former

Atypical antipsychotic drugs

There are major advantages for the atypical drugs, and these agents are recommended as first-line treatment [76, 77]. They are the most widely prescribed drug treatment for schizophrenia, mania, and psychotic depression in clinical practice in many parts of the world. There are many such drugs which share some pharmacology but also have unique features. New ones are still being added, some with markedly different core features. With one exception—pimavanserin, recently approved for treatment of the psychosis of Parkinson's disease [78], all the atypical antipsychotic drugs directly affect dopamine D2 receptors, usually as antagonists, but also as partial agonists, for example aripiprazole and brexpiprazole. However, D2 receptor actions are part of a multi-receptor profile, which includes actions on multiple dopamine, serotonin, and other receptors. Some atypical antipsychotic drugs (for example, clozapine, olanzapine, quetiapine in its immediate-release form, risperidone, and ziprasidone) are no longer patent-protected and are available in less expensive generic brands. Most of the atypical drugs will be off patent by 2020. Although the conversion from branded to generic (and vice versa) forms of antipsychotic drugs is relatively easy in most patients, not requiring cross-titration, close monitoring is required during the switch, particularly with clozapine [79].

The relative effectiveness of atypical, compared with typical, antipsychotics for the treatment of schizophrenia has been the subject

of some controversy, particularly after the publication of the initial phase results of three large studies—the Clinical Antipsychotic Trial of Intervention Effectiveness (CATIE) conducted in the United States [80], the Cost Utility of the Latest Antipsychotic drugs in Schizophrenia Study (CUtLASS) conducted in the UK [81] and the European First Episode Schizophrenia Trial (EUFEST) conducted at numerous clinical sites across Europe and in Israel [82]. Broadly, these trials had less stringent inclusion criteria than those typically encountered in experimental randomized trials and focused on outcome measures other than symptom change such as time to study drug discontinuation for any reason and quality of life. In general, these studies failed to demonstrate the superiority of atypical over typical antipsychotics across these effectiveness outcomes, although the second phases of two of these trials showed superior effectiveness of clozapine over comparator antipsychotics for patients considered to have treatment-resistant schizophrenia [83, 84], and olanzapine was shown to have superior effectiveness to comparator drugs in CATIE phase 1 (CATIE-1). Although the pragmatic and comparative effectiveness aspects of these trials were innovative, their methodologies and results have been subject to criticism, based on dosing imbalances between individual antipsychotics in CATIE-1, the inclusion of sulpiride (which has atypical properties) and long-acting injectable antipsychotics in the 'first-generation' antipsychotic drug treatment arm (no long-acting injectable agents

in the 'second-generation' antipsychotic arm) in CUtLASS phase 1 (CUtLASS-1), questionable sensitivity of the chosen effectiveness endpoints to between-drug differences in outcome, the channelling of patients with tardive dyskinesia away from treatment with typical antipsychotics, and high rates of cross-contamination between treatment arms owing to antipsychotic drug switching (CUtLASS-1) [85–88].

Clozapine

Clozapine was synthesized in 1959 as part of a project to discover antipsychotic drugs with low potential for EPS. It proved to be one of the most interesting and clinically important compounds ever discovered. It was labelled as being 'atypical' because of its ability to block amphetamine-induced locomotor activity, one of the most widely accepted models for antipsychotic effects, without producing catalepsy in rodents, the leading model for causation of EPS in humans. Subsequent clinical studies showed it to have the lowest EPS liability of any antipsychotic drug [89]. Clinical trials in the 1960s and 1970s demonstrated efficacy for positive symptoms [90]. In 1975, 6 years after its introduction in Europe, clozapine was reported to produce a high rate of agranulocytosis. Six deaths occurred in clozapine-treated patients in a geographically restricted area of Finland over a short period of time. Clozapine was withdrawn from general use, although it remained available for humanitarian use [91].

Clozapine was reintroduced in 1989 after it was demonstrated to be superior to chlorpromazine to improve positive and negative symptoms in 300 patients who were resistant to the action of at least three typical antipsychotics [92]. Thirty per cent of the patients treated with clozapine responded after 6 weeks of treatment, compared to 4% of the chlorpromazine-treated patients. Subsequent studies have shown that 40–60% of patients will respond within 6 months of initiating clozapine treatment. Other predictors of response include weight gain and absence of atrophy in the prefrontal cortex [61]. Clozapine has been shown to uniquely reduce the risk of suicide in schizophrenia [63, 93]. It has also been shown to improve some aspects of cognitive function, especially verbal fluency, immediate and delayed verbal learning and memory, and attention [22–24]. *N*-desmethylclozapine is the major metabolite of clozapine. It is an M1 muscarinic receptor agonist and has been shown to have beneficial effects on working memory [94].

Because of the side effect profile of clozapine and because it has not been shown to be superior to other drugs for treatment-responsive schizophrenia [95], it is not generally used as a first-line drug. On the other hand, monitoring neutrophil counts for the development of agranulocytosis or granulocytopenia and improved methods of treating agranulocytosis have made it much safer to use. Clozapine is under-utilized in many parts of the world. All schizophrenia patients with persistent psychotic symptoms after two adequate trials of other drugs should be considered for a trial of clozapine, which should be 6 months in duration, before concluding it is ineffective.

Clozapine is usually given twice daily, but sometimes more than half of the dose or the entire dose is given at bedtime to minimize daytime sedation. The daily dosage is gradually titrated to the target range described in Table 64.4. Patients who are treatment-resistant usually require doses of 400 mg/day or higher, or a minimum blood concentration of 350 µg/L [96]. Typical or non-clozapine atypical antipsychotic drugs should be discontinued either before beginning clozapine or by eliminating them over a 1- to 2-week period as the

dose of clozapine is increased. Typical antipsychotic drugs would be predicted to interfere with some of the benefits of clozapine and should not ordinarily be prescribed with clozapine.

Determination of clozapine plasma levels is useful whenever patients are not responding adequately. It may be useful to augment clozapine treatment with valproic acid or other mood stabilizers (such as lithium, carbamazepine, lamotrigine, or topiramate), anxiolytic drugs, or an antidepressant [63]. The choice of augmenting agent is largely driven by symptomatic considerations, or pharmacokinetic interactions in the case of fluvoxamine. However, none of these strategies have strong empiric support. One exception may be the addition of sulpiride, which may result in a significant reduction in symptom burden when added to clozapine [97]. Electroconvulsive therapy (ECT) also resulted in a modest further reduction in symptoms when used in conjunction with clozapine and appears to be well tolerated [98]. It is difficult to postulate a rationale for adding another atypical drug, with the exception of amisulpride, because of their similarity in pharmacology to clozapine, although a modest number of short-term studies have shown modest benefit with adjunctive aripiprazole for attenuating psychotic symptoms when combined with clozapine [99]. It should be discontinued if side effects are intolerable or if there is no apparent response after a 6-month trial of clozapine alone and subsequent trials with augmentation therapy. Clearly, further studies involving clozapine partial- or non-responders are urgently needed. It should be noted that discontinuation of clozapine can precipitate a severe relapse, even when clozapine is slowly tapered [100].

Risperidone

Risperidone is a first-line drug for the treatment of schizophrenia [101]. Definitive data are lacking for its efficacy in patients who have treatment-resistant schizophrenia, although preliminary evidence suggests that the use of higher doses of long-acting injectable risperidone [up to 100 mg intramuscularly (IM) every 2 weeks] may be effective [102]. Risperidone may be useful in patients who fail to tolerate other antipsychotic agents because of side effects not shared by risperidone such as anticholinergic effects. Risperidone is well tolerated in low doses by the elderly and has been widely used in the United States for the treatment of a variety of senile psychoses [103, 104]. Its efficacy against haloperidol was established in a series of multi-centre trials which demonstrated advantages for risperidone in overall psychopathology in mainly chronic schizophrenic patients in an acute exacerbation at doses in the 6–8 mg/day range. However, these doses have proven to be higher than is needed for most patients in clinical practice, possibly reflecting some of the problems in generalizing from controlled clinical trials. The doses for schizophrenia most often used in non-elderly adults are now 4–6 mg/day. First-episode patients may not tolerate higher doses (for example, above 5 mg/day), and some may respond to as little as 1–2 mg/day. Treatment-resistant patients have been shown to respond to long-acting risperidone at doses of 50 or 100 mg every 2 weeks [105].

Beyond treatment of acute symptoms, risperidone is also effective for long-term maintenance phase and relapse prevention. For instance, relative to haloperidol, risperidone has also been associated with a lower risk of relapse (34% vs 60%) over a minimum of 12 months of treatment [106]. In another study that retrospectively compared rates of rehospitalization for patients who received

treatment with risperidone, olanzapine, or typical antipsychotics, rehospitalization rates for risperidone and olanzapine were similar and both were significantly less than those of patients treated with typical antipsychotics [107].

Risperidone is usually initiated at low doses (for example, 1–2 mg daily) and is titrated into the dosage range provided in Table 64.4. The medication is often initiated in twice-daily dosing; however, because its primary active metabolite 9-OH risperidone is pharmacologically equivalent to its parent drug and because it has a longer elimination half-life, once-daily dosing is also possible. Risperidone is available in soluble water and liquid forms, which may be advantageous for patients who have swallowing difficulties or require taking their medication in a non-pill form for other reasons, including their own preference.

For patients who have a history of poor compliance leading to frequently relapsing illness, or for those who prefer it, a long-acting injectable form of risperidone is available (Table 64.1) for administration every 2 weeks. Response may be expected to occur in the 25–50 mg (per every 2-week dose) range [108]; however, oral risperidone must be continued through at least the first 3 weeks of treatment with the long-acting injectable form before being slowly tapered. Supplementation with oral medication may be required when the dose of the long-acting drug is upwardly adjusted due to breakthrough psychotic symptoms.

Risperidone has more of a tendency to produce EPS than other atypical antipsychotics, but this can be minimized by using the lowest dose which controls positive symptoms and adding an anticholinergic drug, if necessary [109]. Among atypical drugs, risperidone and paliperidone produce the greatest increases in serum prolactin, particularly in women [110]. Elevations in prolactin levels as a result of treatment with risperidone do not always translate into clinical symptoms such as sexual dysfunction or gynaecomastia in men and menstrual changes and breast discharge in women [110].

A meta-analysis of six studies comparing risperidone to typical antipsychotic treatment indicated risperidone was superior for treating negative symptoms [111]. Risperidone has also been shown to improve cognition in schizophrenia, more so than typical antipsychotic drugs [23]. Improvement in working memory was greater than that of other domains.

In summary, risperidone is a first-line pharmacological treatment of schizophrenia. It may have advantages over typical drugs with regard to negative symptoms, cognition, and EPS, but it does produce dose-dependent increases in EPS risk and large increases in serum prolactin levels, even compared to typical antipsychotic drugs. The long-acting injectable form of risperidone is preferred in patients with problems with oral drug compliance. Risperidone in its long-acting injectable form has also been shown to be effective for the prevention of relapse or hospitalization during bipolar maintenance treatment, although it may be more effective for preventing manic or mixed episodes than depressive episodes [112].

Olanzapine

Olanzapine is also a first-line treatment for schizophrenia [77]. Some treatment-resistant patients respond to olanzapine at doses in the 20–40 mg/day range, but the side effect burden may be treatment-limiting for some patients, especially weight gain and related metabolic effects [113].

The efficacy of olanzapine in treating psychosis and negative symptoms in patients with an acute exacerbation of schizophrenia has been established in multiple large-scale, multi-centre trials [114]. In these trials, olanzapine at doses of 10–20 mg/day has been superior to placebo and equivalent or superior to haloperidol in some measures of total psychopathology and positive or negative symptoms. For example, in one North American multi-centre trial, olanzapine (15 ± 5 mg/day) was superior to haloperidol (15 ± 5 mg/day) in the treatment of negative symptoms [115]. Olanzapine improves primary negative symptoms, rather than secondary negative symptoms [116].

Olanzapine has also been found to be effective as a maintenance treatment of schizophrenia [117]. The estimated relapse rates, defined as the need for hospitalization, during a 1-year period in three studies of patients receiving olanzapine for maintenance treatment were 19.6–28.6% [117].

Olanzapine has been reported to improve cognitive dysfunction [23, 24] in patients with schizophrenia or schizoaffective disorder. Pharmacoeconomic studies and investigations of medication effects on quality of life measures indicate that olanzapine has a beneficial cost–outcome profile. For instance, in one investigation, the higher cost of olanzapine, relative to haloperidol, was offset by olanzapine treatment-associated reductions in rehospitalization and overall treatment costs [118].

The average clinical dose of olanzapine is 12.5–20 mg/day, but many patients respond to lower doses (for example, 10 mg daily) [119]. A principle advantage of olanzapine is its once-daily dosing and the feasibility of starting the medication at a dose that is clinically effective for most patients. For acute situations where rapid control of agitation, hostility, or other dangerous behaviours is required, olanzapine is available as a short-acting injectable medication (Table 64.1) [120]. For patients with frequent relapses owing to poor adherence to oral medication, a long-acting injectable form of olanzapine is available. A small number of patients experienced excessive sedation, fatigue, dizziness, or delirium owing to inadvertent *intravascular* injection of long-acting injectable olanzapine [120]. Olanzapine long-acting injectable must therefore be administered by trained individuals, along with close observation and additional safety measures (such as avoidance of driving) that address the risk of developing post-injection syndrome symptoms.

In summary, olanzapine is an effective atypical drug with specific advantages in terms of its once-a-day administration, low risk for EPS, and efficacy for cognitive dysfunction and negative symptoms. Clinically significant weight gain and related dysmetabolic adverse effects may be a problem for some patients, as will be discussed. Olanzapine has been shown to effectively reduce manic symptoms in adults with bipolar I disorder [21] and to effectively reduce depressive symptoms when used as a pharmacological adjunct for the treatment of refractory unipolar major depression and acute depressive episodes in patients with bipolar I disorder [121, 122].

Quetiapine

Quetiapine has been shown to be as effective as typical antipsychotics in the acute treatment of schizophrenia, with low EPS risk and no effect on serum prolactin levels [123, 124]. Quetiapine and clozapine both appear to bind more loosely to striatal D2 receptors than other antipsychotic drugs, and both drugs show antipsychotic activity at D2 receptor occupancies that are well below the 60% threshold

identified for most other antipsychotic drugs [125]. In spite of this similarity with clozapine, quetiapine does not appear to have efficacy comparable to clozapine for treatment-resistant patients.

The efficacy of quetiapine for acute-phase schizophrenia is supported by results from several RCTs that documented superiority of quetiapine, relative to placebo, across several doses, with some patients responding to 150 mg/day and others requiring 750 mg/day [123]. For instance, in one high- (750 mg/day) vs low-dosage (250 mg/day) study, both dosage groups evidenced greater reduction in positive symptoms, relative to placebo; however, the differences were significant only for the high-dose group [124]. In another study that assessed multiple fixed doses of quetiapine (75–750 mg/day), compared with haloperidol and placebo, significant differences in improvement over placebo for quetiapine were observed in the dosage range of 150–750 mg/day [123].

Quetiapine's effect on negative symptoms continue to be investigated. One placebo-controlled comparison documented improvements in negative symptoms with quetiapine treatment across a wide range of doses, with the greatest improvement reported at 300 mg daily [123]. In the high- vs low-dose study reviewed previously, the high-dose group also experienced greater improvement in negative symptoms, relative to placebo [124]. Like risperidone and olanzapine, quetiapine appears to improve depressive symptoms and certain cognitive deficits [23, 24] associated with schizophrenia or schizoaffective disorder. The improvements in cognition with quetiapine appear to be superior to those of haloperidol [126].

These results suggest that overall the greatest improvement in positive and negative symptoms may occur when quetiapine is used at the higher end of its dosage range. The average clinical dose appears to be between 300 and 500 mg/day, usually given twice daily, though some benefit from the medication when given only once daily. The effects of using higher doses for patients who do not respond adequately to these doses are uncertain. A titration of the dosage is required after initiating the medication. From the viewpoint of EPS and hyperprolactinaemic effects, quetiapine appears to confer only low risk. As such, like clozapine, it appears to be well tolerated, even among patients with idiopathic Parkinson's disease [127]. Sedation may be a limiting side effect for some, especially during dosage titration. Weight-related, metabolic, and other adverse effects will be discussed in greater detail.

Quetiapine is one of the best studied pharmacotherapies for bipolar disorders. In addition to its effectiveness for reducing the acute symptoms of mania [128], quetiapine is effective for the acute treatment of depressive episodes in patients with bipolar I and II disorders [129, 130]. Quetiapine has also been shown to be effective as a bipolar maintenance treatment [131].

In summary, quetiapine also appears to be effective for a wide range of schizophrenia-associated symptoms and confers a lower level of risk in terms of antidopaminergic adverse effects. The dosage range of this medication may be quite wide, though patients may have a greater chance of benefiting from the medication at the higher end of this range. Quetiapine is a first-line option for treating acute manic episodes in patients with bipolar I disorder, and depressive episodes in patients with bipolar I or II disorder. Quetiapine has also been shown to reduce depressive symptoms in adults with inadequate response to some antidepressants such as selective serotonin reuptake inhibitors (for example, fluoxetine,

etc.) and serotonin–noradrenaline reuptake inhibitors (for example, venlafaxine, etc.) [132].

Ziprasidone

Ziprasidone has a varied receptor occupancy profile. Like most atypical antipsychotic drugs, it displays high-affinity 5-HT_{2A} binding, coupled with relatively lower-affinity D₂ receptor binding. Ziprasidone is also a 5-HT_{1A} agonist, as well as both a serotonin and a noradrenaline reuptake pump inhibitor [133]. This profile predicts a wide range of pharmacological activity against core psychotic symptoms and negative and affective symptoms, as well as neurocognition.

Ziprasidone, like quetiapine, has been shown to be superior to placebo for the reduction of total psychopathology and positive and negative symptoms in patients with schizophrenia [134, 135]. There is limited evidence to suggest superiority over typical antipsychotics with regard to improvement in positive and negative symptoms [134, 136]. Studies of multiple fixed doses of ziprasidone vs haloperidol at conventional doses indicate that ziprasidone yields similar efficacy to haloperidol for reducing positive symptoms and global psychopathology at a dose of 160 mg/day [136].

Ziprasidone significantly improved negative symptoms and reduced the risk of relapse, compared to placebo, in a 1-year maintenance study in stable hospitalized chronic schizophrenic patients [137]. These maintenance-phase effects were not dependent on the daily dose of ziprasidone. In a 28-week comparison with haloperidol, the two groups evidenced similar overall effects for positive symptoms; however, between-group differences were documented, favouring ziprasidone for negative symptoms and EPS [138]. Ziprasidone was effective against depressive symptoms associated with schizophrenia in one study at a dose of 160 mg/day [139]. Significant improvements in multiple cognitive domains have been reported among ziprasidone-treated patients in a variety of treatment contexts [140]. Such changes appear to be unrelated to improvements in other symptoms of schizophrenia. Ziprasidone treatment has been associated with significant improvement in quality of life measures in one post hoc data analysis [141]. Further investigation of the effect of ziprasidone on health-related quality of life and similar outcomes are warranted. Ziprasidone treatment of schizophrenia appears to be cost-effective, relative to no treatment [142]. Further cost–benefit studies are needed.

The dose range of ziprasidone for acute treatment appears to be between 80 mg/day and 160 mg/day, and higher doses within this range may be more effective (Table 64.4). Doses greater than 120 mg/day appear to be required to achieve approx. 60% dopamine D₂ receptor blockade [143], the D₂ receptor occupancy threshold that appears to coincide with efficacy against positive symptoms, as presented earlier. The medication is usually given twice daily, although some may take the medication once daily at night-time. Titration of the total daily dose into the recommended range is required after initiating the medication. One critical aspect of medication administration for ziprasidone is the requirement that the medication be taken with food. There appear to be profound differences in bioavailability at equivalent doses between the fed and unfed state [144]. A full meal, as opposed to a light snack, appears to be required. Therefore, patients are encouraged to take their medication with meals.

A short-acting intramuscular formulation of ziprasidone has been developed, which should be useful in situations where more rapid action is needed. This formulation is available in two doses (10 mg and 20 mg), the preferred dosage being 20 mg due to a significantly greater reduction in agitation, relative to the lower dose [145]. Use of the short-acting injectable form can facilitate a transition to oral medication and may reduce the time required to titrate the daily dose of ziprasidone to one that is likely to be effective.

Ziprasidone appears to be well tolerated. Treatment-emergent EPS burden is low [135, 136]. Initial problems with somnolence or behavioural activation are usually self-limited, although temporary use of clonazepam or other benzodiazepine at low doses may improve tolerability, especially during the titration phase, should the latter occur. Importantly, data from both short- and long-term studies indicated that ziprasidone is not associated with clinically significant changes in weight, glycaemic measures, or markers of lipid homeostasis [146].

Ziprasidone can result in partial blockade of the slow potassium rectifier current in the cardiac conduction system, which may result in prolongation of the QTc interval [147]. On the other hand, ziprasidone was not shown to be associated with an elevated risk of non-suicidal mortality, relative to olanzapine, in a large simple trial of over 18,000 patients with schizophrenia [148]. Under routine circumstances, screening electrocardiograms are not required. Nevertheless, caution may be warranted for individuals who are at risk for significant prolongation of the QTc interval, including patients who take medications other than ziprasidone that prolong the QTc interval. Concomitant use of CYP450 3A4 inhibitors does not appear to pose a significant risk [149].

In summary, ziprasidone appears to be a useful additional atypical antipsychotic agent because of its favourable side effect profile, including no weight gain—a major problem with olanzapine and clozapine—and no prolactin elevation, which is a less serious side effect of risperidone. Patients should be instructed to take the medication with food. Ziprasidone treatment may result in an increase in the QTc interval; however, in a great majority of cases, this is not clinically significant. Although it is effective for treating acute manic episodes in patients with bipolar I disorder [128], it has not been shown to be clearly effective for bipolar depression when used as an adjunct to mood stabilizers [150].

Aripiprazole

Aripiprazole is pharmacologically distinct from the drugs reviewed previously in that it combines partial D2 receptor agonism with high-potency 5-HT_{2A} antagonism. As a partial D2 receptor agonist with low intrinsic activity, it will generally reduce dopamine D2 receptor stimulation [151]. Conversely, it should act primarily as an agonist when endogenous dopamine is limited, as may be the case in the prefrontal cortex in patients with schizophrenia [30]. For this reason, aripiprazole is sometimes referred to as a 'dopamine stabilizer.' Aripiprazole also functions as a potent 5-HT_{1A} partial agonist [152].

The efficacy of aripiprazole in the treatment of acute schizophrenia at doses ranging between 10 mg and 30 mg (taken once daily) was established on the basis of four short-term randomized controlled studies [153]. Relative to placebo, efficacy against negative symptoms was also demonstrated [154]. Long-term superiority of aripiprazole (vs placebo) for relapse over 26 weeks [155] and medication

compliance and symptom response (vs haloperidol) for up to 52 weeks has also been established [156]. One study reported on the effectiveness of flexibly dosed aripiprazole (15–30 mg daily) among patients with schizophrenia with a history of resistance to treatment with olanzapine or risperidone [157]. Aripiprazole is an effective maintenance treatment with a favourable side effect profile, particularly for weight gain [158, 159]. However, it does cause akathisia and some nausea, particularly early in its usage. Aripiprazole has been reported to have beneficial effects on neurocognitive performance, but the data are rather limited [160].

Treatment with aripiprazole is usually initiated with 10–15 mg daily, although some patients may not be able to tolerate these doses due to agitation, nausea, or vomiting. Doses as high as 30 mg are sometimes indicated. An oral solution form is also available. Aripiprazole is also available in a water-soluble, as well as an acute intramuscular, form. The acute injectable form appears to be effective in the dosage range of 5.25–15 mg [161]. The recommended dose is 9.75 mg.

Several long-acting injectable forms of aripiprazole are available for patients who prefer or require long-acting injectable medications [162]. The first is aripiprazole monohydrate, a once-monthly injectable form of aripiprazole. The recommended starting and monthly maintenance dose of once-monthly long-acting injectable aripiprazole is 400 mg in the absence of interacting medications [163]. Oral aripiprazole (10–20 mg daily) must be taken for at least the first 14 days of long-acting aripiprazole initiation. More recently, aripiprazole lauroxil, a prodrug of aripiprazole, has also become available as a once-monthly injectable medication [164]. The recommended starting and monthly maintenance doses are 441 mg, 662 mg, or 882 mg, which correspond roughly to oral aripiprazole daily doses of 10 mg, 15 mg, and 20 mg or more. The highest dose (882 mg) can be administered once every 6 weeks via gluteal injection. Oral aripiprazole must be taken for at least the first 21 days of aripiprazole lauroxil.

For mood disorders, aripiprazole has been shown to be effective as an adjunctive treatment in adults with major depressive disorder who responded poorly to antidepressants [165]. Aripiprazole has been shown to effectively reduce manic symptoms in adults with bipolar I disorder—both alone and as an adjunct to mood stabilizers [166]. However, aripiprazole has not demonstrated clear benefit for treating bipolar depression [167].

Aripiprazole is generally well tolerated, with an adverse effect profile similar to placebo in short-term studies involving patients with acute schizophrenia and in longer-term studies of chronic, stable patients [153]. As is the case with all atypical antipsychotic drugs, the EPS burden is lower than that of typical antipsychotics. In summary, aripiprazole appears to be effective as an acute and long-term maintenance treatment for schizophrenia and related psychotic disorders at recommended doses, though some patients may require higher doses. Aripiprazole was initiated in most studies at doses of 10–15 mg once daily; however, some patients may require a slower titration following a lower starting dose. This medication is available in many forms, all of which appear to be very well tolerated. Aripiprazole is effective as an adjunctive treatment for patients with major depression who respond suboptimally to antidepressants and as monotherapy or adjunctive treatment for acute manic episodes in patients with bipolar I disorder. Important benefits from a tolerability viewpoint include very low rates of prolactin elevation and a low risk of weight gain and metabolic adverse effects.

Paliperidone

Paliperidone is the 9-OH metabolite of risperidone, which has a longer elimination half-life than the parent compound, as reviewed previously. Paliperidone, which is pharmacologically similar with regard to receptor occupancy profile to risperidone, is available commercially in an extended-release oral form and in two long-acting injectable forms.

The short-term efficacy of oral paliperidone has been established on the basis of multiple randomized, placebo-controlled studies [168]. In these studies, all doses of paliperidone were superior to placebo for reducing global psychopathology and positive symptoms, as well as negative symptoms, anxious/depressive symptoms associated with schizophrenia, and hostility/excitement. The recommended starting dose of oral paliperidone is 6 mg, given once daily. Doses may be upwardly adjusted at 3 mg/day increments, up to 12 mg daily. Elevations in prolactin levels are like those observed with risperidone treatment.

Paliperidone is available in once-monthly and 3-monthly long-acting injectable formulations. Long-acting injectable paliperidone has been shown to be effective for maintenance treatment in patients with schizophrenia [169, 170]. The paliperidone once-monthly long-acting injectable formulation is initiated at 234 mg (paliperidone palmitate salt) IM (deltoid muscle) on day 1, followed by 156 mg IM (deltoid muscle) 7 days later. The typical maintenance dose is 117 mg IM (deltoid or gluteal muscle) once monthly, with a range of 39–234 mg IM 1-monthly, depending on effectiveness and tolerability.

In summary, paliperidone appears to be safe and effective for both short- and long-term treatment of schizophrenia. The EPS and prolactinaemic adverse effect burden may resemble that of risperidone, but this notion requires prospective investigation. Oral paliperidone can be started at a clinically effective dose. Long-acting injectable forms are also currently available.

Amisulpride

The efficacy of amisulpride for the treatment of positive symptoms has been established over a wide dosage range (200–1200 mg daily) in treatment studies of up to 12 months' duration [171]. In general, it appears that higher doses (above 400 mg/day) are effective for treating patients with predominantly positive symptoms, although efficacy against negative symptoms has also been demonstrated [172, 173]. Low-dose amisulpride (approx. 300 mg/day) has been reported to be effective in treating negative symptoms in schizophrenics with predominantly negative symptoms [174, 175]. Amisulpride may improve primary negative symptoms [174, 175]. Amisulpride produces minimal EPS but may result in increased prolactin levels [176]. There are some data which suggest it can improve depressive symptoms in schizophrenia [177]. There are no data on its efficacy in treatment-resistant patients. Because its pharmacology is quite distinct from that of the 5-HT_{2A}-based receptor antagonists previously discussed, amisulpride may be useful in patients who fail to tolerate that class of drugs. Amisulpride has also been demonstrated as being superior to haloperidol on quality of life measures and global functioning [178] and to significantly improve quality of life over 12 months of treatment [179] in patients with schizophrenia. Sulpiride is closely related to amisulpride and is widely used in the UK and some other regions of the world, but it is not licensed in the United States. Information

about its typical and atypical properties are not as clear as for amisulpride and will not be discussed here.

Lurasidone

Lurasidone, like most other atypical antipsychotic drugs, exhibits potent 5-HT_{2A} blockade, coupled with D₂ receptor blockade [39]. In addition, lurasidone is a potent 5-HT₇ receptor antagonist and a 5-HT_{1A} partial agonist, with moderate affinity for α ₁-adrenergic receptors and negligible binding activity at other monoamine receptors and at dopamine and serotonin transporters [10, 39]. Lurasidone is metabolized almost entirely by CYP3A4 and has a mean elimination half-life of 18 hours. Similar to ziprasidone, lurasidone must be taken with food in order to ensure adequate exposure to the medication [10].

The short-term efficacy of lurasidone for treating schizophrenia is established on the basis of multiple acute-phase randomized, placebo-controlled studies [180–183]. In these studies, lurasidone was superior to placebo for reducing global psychopathology, positive symptoms, and negative symptoms in the 40–160 mg dose range. The efficacy of lurasidone (40–80 mg/day) for the maintenance treatment of schizophrenia was recently demonstrated in a randomized, placebo-controlled withdrawal study [184]. During the double-blind maintenance phase of the study, lurasidone significantly delayed time to relapse, as compared with placebo. Lurasidone is associated with mild dose-dependent akathisia, but a low risk of weight gain and associated dysmetabolic effects [185].

The recommended starting dose of lurasidone is 40 mg, given once daily. The typical effective dose range is 40–80 mg daily. The maximum recommended dose is 160 mg daily with meals.

Lurasidone is also indicated for treatment of depressive episodes in patients with bipolar I disorder. The short-term efficacy of lurasidone monotherapy for bipolar I depression was demonstrated in a 6-week randomized, placebo-controlled trial [186]. Lurasidone at both 20–60 mg/day and 80–120 mg/day showed significantly greater improvement in depressive symptoms than placebo. In a second 6-week randomized trial, lurasidone was superior to placebo as adjuncts to lithium or valproate in adults with bipolar I depression [187]. Lurasidone was also shown to improve depressive symptoms and overall illness severity in adults with major depressive disorder and subthreshold hypomanic symptoms in short-term (6 week) randomized, placebo-controlled trials [188, 189].

In summary, lurasidone appears to be efficacious and safe for the short- and long-term treatment of schizophrenia. All doses must be taken with food to ensure adequate exposure to the medication. Its side effect profile appears to be favourable, compared with many other atypical antipsychotic drugs. Lurasidone is effective for treating acute depressive episodes in patients with bipolar I disorder, both as monotherapy and as an adjunct to lithium or valproate.

Asenapine

Asenapine is also a potent antagonist at dopamine D₂ and serotonin 5-HT_{2A} receptors [10]. Asenapine also binds with relatively high potency to serotonin 5-HT_{2C}, 5-HT₆, 5-HT₇, histamine H₁, and α ₁-noradrenergic receptors where it acts as an antagonist, but has negligible affinity for muscarinic M₁ receptors [10, 12, 190]. Asenapine also binds with high affinity to 5-HT_{1A} receptors where it acts as a partial agonist [191].

The efficacy of asenapine for acute-phase treatment of schizophrenia was demonstrated in two randomized, double-blind, placebo-controlled trials [192, 193]. In these studies, asenapine at doses of 5–10 mg twice daily demonstrated superiority over placebo for reducing psychotic and negative symptoms. The longer-term efficacy of asenapine in adults with schizophrenia was investigated in two published randomized studies [194, 195], including one relapse prevention study [196]. In the relapse prevention study, patients who were clinically stable at the end of an open-label pre-randomization phase were randomized to double-blind continuation treatment with sublingual asenapine 10 mg twice daily or placebo for an additional 26 weeks. During double-blind treatment, relapse rates were significantly lower and mean time to relapse was significantly longer with asenapine than placebo.

Asenapine has also been shown to be an effective treatment for manic and mixed episodes in adults with bipolar I disorder on the basis of four randomized trials [196]. Efficacy for this indication has been demonstrated at both the 5 mg and 10 mg twice-daily doses in adults [197].

Asenapine is available as a rapidly dissolving tablet formulated for absorption via the buccal mucosa [10]. Swallowing asenapine tablets renders the drug ineffective. For adults, asenapine is initiated at a dose of 5 mg sublingually twice daily. The recommended dose range across indications in adults is 5–10 mg twice daily.

Iloperidone

Iloperidone exhibits high affinity for dopamine D2 and D3 and serotonin 5-HT_{2A} receptors where it acts as an antagonist [8, 10]. Iloperidone binds with moderate affinity to dopamine D4, serotonin 5-HT₆ and 5-HT₇, and α 1-noradrenergic receptors, and with low affinity to dopamine D1, serotonin 5-HT_{1A}, and histamine H1 receptors [10]. Iloperidone has no significant affinity for muscarinic cholinergic M1 receptors, but its antagonism of α 1-noradrenergic receptors leads to orthostatic hypotension [10]. Thus, even though the clinically effective dose range of iloperidone for treating adults with schizophrenia is 6–12 mg twice daily, the recommended starting dose is low (1 mg twice daily). Dose titration is required in order to lower the risk of treatment-emergent orthostatic hypotension [10].

The 6–12 mg twice-daily dose range of iloperidone has been shown to be effective for treating acute symptoms of schizophrenia [198–200]. The long-term safety and efficacy of iloperidone were established in three 52-week, randomized, double-blind, multi-centre trials, and pooled data from these studies have been published [201]. Iloperidone is available as solid oral tablets. As indicated earlier, iloperidone must be started at a low dose (1 mg twice daily) and slowly increased to a target dose of 6–12 mg twice daily over several days in order to reduce the risk of treatment-emergent orthostatic hypotension.

Brexpiprazole

Brexpiprazole is a partial agonist at 5-HT_{1A} and D2 receptors and an antagonist at 5-HT_{2A} and α 1B/2C-adrenergic receptors [202]. It acts as a moderate antagonist at serotonin 5HT₇ and 5HT_{2C} receptors and histamine H1 receptors, and has only negligible binding activity at muscarinic M1 receptors [15]. Brexpiprazole thus shares with aripiprazole high-affinity partial agonist effects at D2 and 5-HT_{1A} receptors, although brexpiprazole has higher intrinsic activity at 5-HT_{1A} receptors.

The efficacy of brexpiprazole for acute treatment of schizophrenia in adults is supported by two 6-week randomized trials [203, 204]. In one study, only the 4 mg brexpiprazole dose group (not the 1 or 2 mg dose groups) was significantly more effective than placebo [204]. Brexpiprazole was associated with significantly lower relapse rates than placebo (14% vs 39%) during a 12-month maintenance period in one study [205].

The most common and dose-dependent side effects of brexpiprazole include nausea, akathisia, headache, and modest weight gain. Brexpiprazole was associated with modest and dose-dependent increases in prolactin levels. No significant differences with placebo in the risk of adverse changes in glucose or lipid profiles were observed in short-term trials.

The results of randomized short-term trials also support the efficacy of brexpiprazole as an adjunct to antidepressants for major depressive disorder [206–208]. These studies enrolled patients with major depression and inadequate response to antidepressants who then failed to respond to a prospective trial of conventional antidepressant plus placebo, before being randomized to adjunctive brexpiprazole or placebo for 6 more weeks. In each of these studies, adjunctive brexpiprazole (1.5–3 mg) resulted in significantly greater reduction in depressive symptoms than placebo.

The recommended starting dose for schizophrenia is 1 mg/day. After 7 days, the dose should be increased to 2 mg/day, with further adjustment based on clinical response and tolerability, up to a maximum daily dose of 4 mg/day. For major depression, the recommended starting dose is 0.5 mg/day, followed by weekly dose titration up to 1.0 mg/day, and then to an initial target dose of 2 mg/day. The maximum recommended dose for adjunctive treatment of major depressive disorder is 3 mg/day.

Cariprazine

Cariprazine is a partial agonist at dopamine D3 receptors and a weaker partial agonist at D2 and serotonin 5-HT_{1A} receptors. Its mechanism of action is therefore distinct from that of most other atypical antipsychotics, so it may be a reasonable alternative treatment when other drugs fail and the patient is not clearly treatment-refractory. Cariprazine is a weak antagonist at 5-HT_{2A}, α 1-noradrenergic, and histamine H1 receptors [16, 209]. Efficacy for acute treatment of schizophrenia in adults has been demonstrated in multiple randomized trials across a wide range of doses (1.5–9.0 mg/day) [210–212]. Cariprazine has been shown to significantly reduce relapse rates in longer-term studies of patients with schizophrenia [213].

The efficacy of cariprazine has also been demonstrated for acute manic or mixed episodes in patients with bipolar I disorder. In these studies, cariprazine demonstrated significantly greater reduction in manic symptoms than placebo across a variety of doses, ranging from 3 mg/day to 12 mg/day [214–216] after 3 weeks of treatment. One 8-week randomized trial also demonstrated significantly greater improvement in depressive symptoms at a daily dose of 1.5 mg than placebo in adults with bipolar I depression [217].

In conclusion, cariprazine has demonstrated efficacy in multiple randomized trials for treating acutely exacerbated schizophrenia and acute manic or mixed episodes in patients with bipolar I disorder. For acute schizophrenia, higher cariprazine doses may be more effective than lower doses. Cariprazine has shown promise as a treatment for acute bipolar I depression and as an adjunct to

conventional antidepressants for patients with major depressive disorder who are responding poorly to treatment with antidepressants alone. Additional studies of cariprazine for bipolar depression and poorly responding major depression are needed to reach definitive conclusions about its role in treating each of these conditions.

Pharmacokinetics, metabolism, and drug interactions

Typical antipsychotic drugs

Typical antipsychotics are well absorbed when administered orally or parenterally. IM injection leads to more rapid and higher plasma levels. Peak plasma levels are reached in 30 minutes after IM injection and 1–4 hours after oral injection. Steady state is achieved in 3–5 days. The half-life for elimination is in the range of 10–30 hours. Metabolism of typical and atypical drugs occurs mainly in the liver, via the hepatic cytochrome (CYP)450 enzymes, particularly the 2D6 and 3A4 sub-families for most drugs. Dosing of typical medications are determined by clinical effects, and less by pharmacokinetic factors.

Pharmacokinetic drug–drug interactions at the level of protein binding are expected to be minimal, even though most typical antipsychotics are tightly bound to plasma proteins. Even so, appropriate therapeutic monitoring of drugs that are also tightly bound to plasma proteins but have a narrow therapeutic index (for example, warfarin, digoxin, phenytoin) when used in conjunction with typical antipsychotics is warranted. Interactions at the level of the CYP450 system are also thought to be minimal for most agents. Because smoking is so common among patients with schizophrenia and because smoking can be associated with potent induction of CYP450 1A2 isoenzymatic activity, dosage adjustments may be needed for selected antipsychotic drugs during any changes in smoking status. Other combinations with typical antipsychotics may be worth avoiding for other reasons such as increased central nervous system effects (for example, anxiolytics, other central nervous system depressants, anticholinergics, certain antihypertensive drugs), increased EPS (for example, metoclopramide, D2-blocking anti-nausea drugs, caffeine), impaired cardiac conduction (certain drugs combined with typical antipsychotics known to prolong the QTc interval), and neurotoxicity (lithium), especially among individuals who are more advanced in age.

Atypical antipsychotic drugs

Clozapine

There are wide variations in the pharmacokinetics of clozapine in patients. The average half-life is 6–12 hours. Plasma concentrations are higher in Chinese patients than in Caucasian patients, in non-smokers than smokers, and in females than males. The metabolism of clozapine occurs mainly in the liver. Clozapine's chief metabolite is *N*-desmethylclozapine, which has some biological activity. Clozapine is metabolized by CYP1A2, and several potential drug–drug interactions are thus possible. When agents that induce CYP1A2 are prescribed or ingested, close monitoring of patients for a worsening of symptoms is warranted. Plasma levels of clozapine of approximately 350 ng/mL are more often associated with good response than lower levels [218] and should be checked in such cases. Upward adjustment of the clozapine daily dosage will typically correct the problem. On the other hand, if a CYP1A2 inducer is discontinued (for example, sudden abstinence

from cigarette smoking, etc.) or a potent inhibitor is added, this may result in a rise in clozapine concentration and an increase in adverse effect risk [219]. Caution may also be warranted for drugs that are potent inhibitors of CYP2C19 and CYP3A4 [220]. In addition, caution is warranted when considering concomitant use of drugs which can also cause bone marrow suppression (for example, carbamazepine) or precipitously drop the seizure threshold.

Risperidone

Risperidone is well absorbed from the gut and is extensively metabolized in the liver by CYP2D6 to 9-hydroxyrisperidone in approximately 92–94% of Caucasians [221]. Thus, 9-OH risperidone is an active species in the majority of patients. About 6–8% of Caucasians and a small proportion of Asians have a polymorphism of the *CYP2D6* gene, which leads to poor metabolism of risperidone. For poor metabolizers of risperidone, the active moiety is mainly the parent compound. The half-life of the 9-OH metabolite is about 21 hours, whereas the half-life of risperidone is about 3 hours. Thus, risperidone can be used on a once-a-day schedule for normal metabolizers, whereas multiple doses are needed for those who are poor metabolizers. Risperidone should be titrated from 2 to 5 mg/day over at least a 3-day period to minimize hypotensive and neuromuscular side effects. Drugs known to induce or inhibit CYP2D6 and 3A4 may alter plasma levels of risperidone; thus, close monitoring is advised when such agents are added to ongoing risperidone treatment.

Olanzapine

Oral olanzapine has a half-life of 24–30 hours, which indicates that single daily administration is adequate [222]. The metabolic pathways of olanzapine involves CYP2D6, CYP1A2, and flavin-containing mono-oxygenases, as well as *N*-glucuronidation. It has a low potential for drug–drug interactions and requires extremely high concentrations, not likely to be achieved under clinical conditions, to inhibit CYP450 systems. Plasma levels of approximately 9.3 mg/mL have been reported to predict better clinical response to olanzapine in inpatients with an acute exacerbation [223]. Olanzapine is detectable in plasma immediately following the first injection of its long-acting injectable formulation; therefore, oral olanzapine is not required during the initiation of olanzapine long-acting injection therapy. Drugs that are known inducers or inhibitors of CYP1A2 may significantly affect plasma levels of olanzapine and alter its clinical effects at a given dosage; thus, active monitoring of symptoms and adverse effects is indicated if such agents are added. As is the case with clozapine, gender and smoking status may influence olanzapine levels, leading to adjustment in dosage [224].

Quetiapine

Quetiapine is well absorbed and is approximately 83% protein-bound [223]. Quetiapine is better absorbed after eating [225]. It has a half-life of 6 hours and is metabolized in the liver by CYP3A4 to inactive metabolites. Quetiapine has significant interactions with inducers and inhibitors of CYP3A4. Co-administration with these agents may require dosage adjustment. Once-daily dosing, a common dosing strategy for quetiapine, is also supported in the literature [226].

Ziprasidone

Ziprasidone has a half-life of 4–10 hours. Twice-daily administration is possible despite this relatively short half-life. Ziprasidone should always be taken after eating in order to facilitate absorption. About two-thirds of ziprasidone is metabolized by aldehyde oxidase into inactive metabolites. The remainder is metabolized by CYP3A4 and CYP1A2 into inactive metabolites. At the current time, there are no known drug interactions with ziprasidone at the level of aldehyde oxidase, since enzymatic activity does not appear to be altered by co-administered drugs. Although CYP3A4 appears to play only a minor role in the metabolism of ziprasidone, potent inhibitors or inducers of CYP3A4 may significantly alter plasma concentrations of ziprasidone [227] and may thus necessitate an adjustment in dosage. The use of concomitant medications that may prolong the QTc interval should be avoided. Ziprasidone is contraindicated for patients with a history of known QT prolongation, recent myocardial infarction, or uncompensated heart failure.

Aripiprazole

Oral aripiprazole is well absorbed from the gut and has an elimination half-life of 75 hours. It is metabolized primarily by CYP3A4 and 2D6 isoenzymes into an active metabolite dehydro-aripiprazole, which has a half-life of 94 hours. This pharmacokinetic pattern supports once-daily dosing. Aripiprazole is also available in a long-acting injectable form. The absorption of long-acting injectable aripiprazole following IM injection is slow; therefore, oral aripiprazole must be co-administered during the first 2 weeks of long-acting injectable aripiprazole therapy. The mean elimination half-life of aripiprazole is dose-proportional (approximately 30 days following 300-mg injections provided every 4 weeks; approximately 47 days following 400-mg injections given every 4 weeks). Because aripiprazole is metabolized by CYP3A4 and 2D6, known inhibitors or inducers of these isoenzymes may result in increased or decreased clearance of aripiprazole and dehydro-aripiprazole [228].

Paliperidone

Oral paliperidone is marketed in an osmotically controlled extended-release formulation, which results in steady release of active drug over a 24-hour period. Long-acting injectable paliperidone is available as a palmitate ester. Because the active moiety paliperidone is detectable in plasma after the first injection, co-administration of oral paliperidone is not required. The elimination half-life of paliperidone palmitate is variable, ranging from 25 to 49 days. Regardless of how it is formulated, hepatic metabolism is not considered a major route of clearance for paliperidone. Paliperidone is converted into metabolites that are not believed to contribute significantly to its overall pharmacological activity. Few significant drug–drug interactions at the level of the CYP450 system are therefore anticipated. Even so, the plasma concentration of paliperidone may be altered by drug interactions at CYP3A4 [229].

Amisulpride

Amisulpride has a half-life of 10–15 hours. It is well tolerated. As yet, there are no known drug interactions.

Lurasidone

Lurasidone is available as a solid oral tablet. The absorption of lurasidone is significantly increased when administered with food;

the area under the curve and C_{max} are increased 2- to 3-fold, respectively, in the fed vs the fasting state [10]. Lurasidone is extensively metabolized in the liver via the CYP3A4 isoenzyme. The mean elimination half-life of lurasidone is 18 hours.

Asenapine

Asenapine is available as a rapidly dissolving tablet for sublingual or buccal administration. Asenapine is absorbed by the oral mucosa, which results in a bioavailability of approximately 35%. Swallowing the tablet reduces bioavailability to <2% [10]. The consumption of liquids within 10 minutes of administration of asenapine can also significantly reduce its bioavailability, so it is recommended that eating or drinking be avoided within 10 minutes of asenapine administration. Asenapine undergoes direct glucuronidation by UGT1A4 and is metabolized in the liver by the CYP1A2 isoenzyme (and, to a lesser degree, by CYP3A4 and CYP2D6).

Iloperidone

Iloperidone has a half-life of 12–15 hours. Its absorption is not affected by food. Iloperidone is approximately 95% protein-bound and is extensively metabolized in the liver via CYP2D6 and CYP3A4 [230]. The mean elimination half-life of iloperidone is 18 hours for CYP2D6 extensive metabolizers, and 33 hours for slow metabolizers [10].

Brexipiprazole

Brexipiprazole is rapidly absorbed after oral administration and is eliminated primarily by hepatic metabolism (CYP3A4 and 2D6). The mean half-life of brexipiprazole at steady-state is approximately 91 hours.

Cariprazine

Cariprazine is rapidly absorbed after oral administration, and it is eliminated primarily by hepatic metabolism via CYP3A4 and, to a lesser degree, via CYP2D6. The mean elimination half-life of cariprazine is 2–5 days in the dose range of 1.5–12.5 mg/day.

Side effects

(See Table 64.6.)

Typical antipsychotics

The adverse effects that are most routinely concerning for typical antipsychotic drug treatment are EPS. High-potency dopamine antagonist drugs, such as haloperidol and fluphenazine, are more likely to produce EPS than low-potency agents such as chlorpromazine and thioridazine. There are a wide range of EPS produced by typical antipsychotics, including dystonic reactions when first administered, akathisia during the first 2–3 weeks, parkinsonism during the first several weeks with variable persistence, neuroleptic malignant syndrome at any time point but usually in the initial weeks, and tardive dyskinesia.

Dystonic reactions due to dopamine antagonist drugs can be treated with parenteral anticholinergic agents or diphenhydramine, an antihistamine with some anticholinergic properties. The use of anticholinergic and other agents to manage parkinsonism due to typical dopamine antagonist drugs will be discussed subsequently.

Table 64.6 Adverse effects of selected antipsychotic drugs

Typical antipsychotic drugs								
	EPS	Tardive dyskinesia	Prolactin elevation	Sedation	Weight gain	Orthostasis	Anticholinergic	Diabetes exacerbation and dyslipidaemia
Chlorpromazine	Mild to moderate (for low-potency drugs) to high (for high-potency drugs)	Moderate to high	Moderate to high (risk higher for high-potency drugs)	Mild to moderate (for high-potency drugs) to high (for low-potency drugs); lowest risk for molindone	Mild to moderate (for high-potency drugs) to high (for low-potency drugs); least for molindone	Mild to moderate (for high-potency drugs) to high (for low-potency drugs)	Mild to moderate (for high-potency drugs) to high (for low-potency drugs)	Low to moderate
Fluphenazine								
Haloperidol								
Loxapine								
Mesoridazine								
Molindone								
Perphenazine								
Thioridazine								
Tiotixene								
Trifluoperazine								

* See Table 64.1 for list of low-, mid-, and high-potency (with respect to dopamine D2 receptor blockade) antipsychotic drugs.

Estimates were derived by the chapter authors.

Ziprasidone	Rarely to low	Rarely	Rarely to low	Rarely to moderate	Low	Low to moderate	Rarely	Rarely

Estimates were derived by the chapter authors. In many cases, only limited data were available, particularly for newer agents.

Additional information based on references [10, 168, 185, 203, 253, and 254], and US drug label information (available online at <https://dailymed.nlm.nih.gov/dailymed/index.cfm>) for asenapine, brexpiprazole, cariprazine, iloperidone, lurasidone, and paliperidone.

There are insufficient data regarding the risk of tardive dyskinesia for asenapine, brexpiprazole, cariprazine, iloperidone, lurasidone, or paliperidone.

Source: data from the *International Psychopharmacology Algorithm Project (IPAP), Algorithm for the treatment of schizophrenia*, Copyright (2008), International Psychopharmacology Algorithm Project (IPAP).

Akathisia may be the most common EPS, occurring in up to 70% of patients treated long term with haloperidol [231]. The term refers to a subjective uncomfortable experience of motor restlessness which is relieved by movement. As such, patients will complain of discomfort and manifest increases in psychomotor behaviour. These symptoms can be distressing enough to cause agitation or suicidal behaviours [232]. Patient age does not seem to influence the risk of developing akathisia, but women are believed to be at higher risk. Diagnosis of this condition is necessary to prevent inadvertent increases in doses due to mistaken conclusion that discomfort from akathisia is due to worsening psychosis. This effect may be managed by reduction in dosage and switching to an atypical antipsychotic drug or a drug that is less likely to cause akathisia. Akathisia may respond to anticholinergic medications, usually within 3–7 days. Other options include low doses of benzodiazepines or β -adrenergic blockers, assuming no contraindications to either.

Parkinsonism caused by dopamine antagonist drugs resembles idiopathic parkinsonism. Diagnostically, severe dopamine antagonist-induced parkinsonism may resemble depression or negative symptoms of schizophrenia; however, the associated motor signs and time course of symptoms in relation to starting antipsychotic treatment distinguish the former. Like akathisia, the onset and severity of drug-induced parkinsonism is related to dosage; thus, a lowering of the dose or switching to a medication that is less likely to cause this effect may provide significant relief or ameliorate the parkinsonian signs and symptoms altogether. When this is not feasible, anticholinergic medications may provide relief, typically within 3–7 days. The response to anticholinergic medication is quite variable, however.

Tardive dyskinesia emerges at various rates, depending upon age, sex, and diagnosis [233, 234]. The rate in younger patients is between 3% and 5% per year. It is higher in bipolar than schizophrenic patients and much higher in people above the age of 60. It is related to the dose and will be less likely with lower doses of typical antipsychotics. Tardive dyskinesia is ordinarily reversible, although irreversible and/or extremely severe and rarely life-threatening forms can occur. The best way to minimize its occurrence is to use an atypical antipsychotic drug in lieu of a typical agent, since these drugs as a class are associated with a much lower risk of tardive dyskinesia [234]. Patients with mood disorders should generally not receive maintenance treatment with typical antipsychotic drugs, unless clinically necessary. There are no definitive treatments for tardive dyskinesia, though some controlled evidence supports the use of adjunctive ginkgo biloba extracts, amantadine, tetrabenazine, and valbenazine [235–240]. Generally, the best strategy is prevention through the use of atypical drugs and periodic screening with a structured assessment tool such as the Abnormal Involuntary Movement Scale (AIMS). There is some suggestion in the literature that continuation of antipsychotic treatment does not worsen tardive dyskinesia and may eventually result in stabilization and improvement of tardive symptoms. Switching to clozapine is useful to control tardive symptoms when they are very severe.

Neuroleptic malignant syndrome (NMS) is a rare, life-threatening side effect related to an apparent compromise of the neuromuscular and sympathetic nervous systems [241]. It usually occurs at the initiation of treatment with a high-potency dopamine antagonist but may occur with any of the typical (or atypical) agents at any point.

NMS is characterized by muscle rigidity, breakdown of muscle fibres leading to large increases in plasma creatine kinase concentration, fever, autonomic instability, changing levels of consciousness, and sometimes death. It is treated by immediately discontinuing all dopamine antagonist drugs, applying external hypothermia, and supporting blood pressure. Administering a direct-acting dopamine agonist, such as bromocriptine or pergolide, and dantrolene sodium, which blocks the release of intracellular stored calcium ions, may be useful adjuncts. After successful treatment of NMS, an atypical antipsychotic should be used, even though these agents, including clozapine, may also induce NMS.

The typical dopamine antagonist drugs produce a wide variety of other side effects, including weight gain, seizures (especially pimozide), sedation, hypotension, elevated liver enzymes, retinitis pigmentosa (thioridazine), orthostatic hypotension, prolongation of the QTc interval (low-potency phenothiazines, pimozide), and anticholinergic effects (mesoridazine, chlorpromazine, thioridazine). All of the typical dopamine antagonist drugs produce marked increases in serum prolactin levels, with increases being greater in females than males [33]. Prolactin elevations may affect sexual function in both males and females, with difficulty achieving erection or orgasm being among the most common side effects [33].

Atypical antipsychotic drugs

Clozapine

Agranulocytosis

It has now been reliably established that clozapine produces agranulocytosis in slightly <1 per 100 patients [242, 243]. The peak of agranulocytosis with clozapine occurs between 4 and 18 weeks and then falls off sharply. Weekly monitoring of the white cell or absolute neutrophil count is required for 26 weeks in most countries, with the frequency decreasing to biweekly or monthly thereafter, sometimes on a voluntary basis. In the United States, monthly monitoring is required, assuming no haematological abnormalities after 1 year of treatment. With monitoring, agranulocytosis can usually be detected before infection sets in or becomes overwhelming. Discontinuation of clozapine, beginning treatment with colony cell-stimulating factors, and the usual procedures for treating an infection are usually effective in restoring the white cell line.

Other side effects

Clozapine produces a wide range of side effects [243]. These can generally be managed by dose adjustment and concomitant medications. Clozapine produces hypotension because of its potent α 1-adrenoceptor antagonism and must be slowly titrated in most patients. Low-dose glucocorticoid treatment may be helpful in some patients with severe hypotension. Clozapine rarely, if ever, produces significant EPS, although some cases of akathisia and NMS have been reported.

Major motor seizures are another important side effect of clozapine. They are dose-related, with the incidence being about 2% in patients at low doses and 6% at doses >600 mg/day. They are sometimes preceded by myoclonic jerks. Valproic acid and dose reductions are usually effective in preventing the progression of myoclonic jerks or treating major motor seizures. Other anticonvulsants can be combined with clozapine, if needed, though caution would be

clearly warranted with the use of carbamazepine due to its potential for bone marrow suppression.

Hypersalivation is a common side effect that usually responds to anticholinergic therapy or clonidine. Exacerbation of obsessive-compulsive symptoms has been reported with clozapine. Augmentation with an SSRI or lithium carbonate is usually effective.

Weight gain is a frequent side effect of clozapine, with about 30% of patients gaining >7% of body weight [243]. Dietary changes and exercise are useful in minimizing this effect. A related problem is the emergence of insulin resistance or type 2 diabetes or exacerbation of existing diabetes, with or without atherogenic changes in the serum lipid profile. There have also been reports of diabetic ketoacidosis that emerged in the context of clozapine treatment. Of the atypical drugs, clozapine and olanzapine are associated with the highest risk for clinically significant weight gain, as well as abnormalities in glycaemic control and lipid homeostasis [146].

Somnolence, tachycardia, hypertension, constipation, and stuttering are also side effects of clozapine. Tachycardia is treated only when the pulse is >100 beats/minute. β -blockers are effective to reduce the heart rate but may also result in synergism of hypotensive effects [243].

There have been reports of clozapine-associated myocarditis and cardiomyopathy [244]. The presence of eosinophilia accompanied by cardiotoxic signs, such as tachycardia, fatigue, orthostasis, or respiratory problems (many of which are adverse effects of clozapine), should alert the clinician to the possibility of myocarditis and the need for medical evaluation.

Finally, treatment with clozapine may not uncommonly result in an asymptomatic mild elevation in hepatic transaminase levels; however, there have also been reports of hepatotoxicity in the setting of clozapine treatment. Polypharmacy appears to be a risk factor. Cases of fulminant hepatotoxicity leading to liver failure are rare.

Risperidone

Risperidone is associated with moderate weight gain, comparable to that of typical dopamine antagonist drugs in most cases and less than that of clozapine and olanzapine [146]. Risperidone also produces some postural hypotension because of its α_1 -adrenoceptor-blocking properties. Risperidone produces greater increases in serum prolactin secretion than any of the other atypical antipsychotic drugs [33]. The increases appear to be at least comparable to those of typical antipsychotics [245]. At higher doses, particularly above 6 mg daily in most adults, the incidence of EPS also increases [246], though typically not to the degree observed when using typical dopamine antagonist drugs in clinical practice. Risperidone, like clozapine and other agents of this type, can sometimes exacerbate or induce symptoms of obsessive-compulsive disorder and tics, probably due to its antiserotonergic properties. This can be counteracted in some patients by the addition of an SSRI. Risperidone is not associated with agranulocytosis or increased risk of seizures. Because of its low affinity for muscarinic receptors, risperidone treatment is not associated with significant anticholinergic effects.

Olanzapine

Olanzapine also produces dose-dependent EPS, including some dystonic reactions in patients with schizophrenia, but these are less frequent and severe than those produced by typical dopamine antagonist drugs or risperidone [245]. Olanzapine is less well tolerated

than clozapine in patients with Parkinson's disease. Olanzapine, like other atypical drugs, is associated with a lower risk of tardive dyskinesia than typical antipsychotics.

The major side effect of olanzapine is weight gain [245]. Large weight gains due to increased appetite occur in 10–15% of olanzapine-treated patients during the first 6 months of treatment. Another 20–35% gain between 7% and 10% of baseline body weight. These gains tend to persist for as long as patients continue the medication. Like clozapine, olanzapine is also associated with higher risk of insulin resistance, glycaemic changes, and the development of atherogenic dyslipidaemias [146]. Cases of diabetic ketoacidosis associated with olanzapine treatment have been reported.

Olanzapine is also associated with an increase in liver enzymes, orthostatic hypotension, anticholinergic side effects, and sedation. Many of these adverse effects are time-limited and reduce in intensity or resolve over the first few weeks of treatment with continuous use. Olanzapine produces transient increases in serum prolactin levels, which are smaller in magnitude than those produced by typical dopamine antagonist drugs or risperidone [33, 245].

Olanzapine, like other agents of this type, can occasionally exacerbate or induce symptoms of obsessive-compulsive disorder and tics, probably due to its antiserotonergic properties. This can be counteracted in some patients by the addition of an SSRI. Olanzapine is not associated with agranulocytosis or increased risk of seizures.

Quetiapine

Quetiapine appears to have fewer EPS than either risperidone or olanzapine [225, 245]. Quetiapine is tolerated in patients with Parkinson's disease to a much greater extent than risperidone or olanzapine. The incidence of EPS with quetiapine in schizophrenic patients appears to be comparable to placebo. The major side effects with quetiapine are headache, agitation, dry mouth, dizziness, weight gain, and postural hypotension [245].

With regard to weight gain and other metabolic effects, quetiapine treatment appears to confer moderate risk—similar to that of risperidone, but less than that associated with clozapine or olanzapine treatment [146]. Far less is known about the long-term effects of quetiapine on markers of glycaemic and lipid homeostasis. Nevertheless, clinically significant changes in serum lipids have been reported.

Decreased serum thyroid hormone levels, increased hepatic transaminases, and elevated serum lipids have been reported. Decreases in total and free thyroxine, when they occur, are mild and non-progressive and are not believed to be clinically significant. The effect may be dose-dependent. Similar to clozapine, asymptomatic elevations in hepatic transaminases may be encountered early in the course of treatment, followed by a return to baseline values. Animal studies suggest an increased risk of cataracts [245]. Periodic ophthalmological screening for lenticular opacities is recommended by the manufacturer, though no causal relationship between the use of quetiapine and the development of cataracts has been demonstrated to date.

Ziprasidone

Ziprasidone does not appear to significantly increase serum prolactin concentration and has a very low risk of EPS, weight gain, and changes in markers of glucose handling and lipid metabolism. Its major side effects are nasal congestion and somnolence [245], the

latter of which is usually transient. There has been some concern of cardiac arrhythmias related to increased QTc interval; however, perusal of the available data does not reveal a significant problem in this regard. However, caution is warranted when considering the co-administration of ziprasidone with other drugs that are known to prolong the QTc interval, since ziprasidone has been associated with a significant increase in the QTc interval of 16.6 ms, which was greater than that with other atypical antipsychotics and haloperidol, but less than that with thioridazine [247]. Screening for electrolyte abnormalities and cardiac disease (including recent myocardial infarction, congestive heart failure symptoms, and arrhythmias, with or without syncope) may be indicated prior to starting ziprasidone.

Aripiprazole

Aripiprazole is well tolerated and does not appear to routinely cause hyperprolactinaemic changes at recommended dosages, although EPS has been reported to occur with aripiprazole, particularly for patients with affective disorders (major depression, bipolar disorders) [248]. Aripiprazole is also not associated with lower risk of clinically significant increases in weight or changes in markers of glucose handling or lipid homeostasis, relative to several other atypical drugs such as clozapine, olanzapine, quetiapine, and risperidone [146]. Aripiprazole, ziprasidone, and lurasidone are believed to have the most advantageous metabolic risk profiles [146, 185].

Paliperidone

Paliperidone was also well tolerated, with the most common side effect being tachycardia. Rates of discontinuation due to adverse effects are very low. The risk of hyperprolactinaemia with paliperidone appears to resemble that of risperidone, although no head-to-head comparisons have been carried out. The changes in prolactin levels may be dose-related [168]. The EPS burden associated with paliperidone during short-term studies was low for the 6-mg dose; however, at higher doses, the incidence of EPS appears to be higher [168]. Short-term weight gain in a meta-analysis of 15 randomized trials was shown to be +1.2 kg; however, measures of metabolic effects with paliperidone showed no significant changes from baseline [185]. Similar results were found for paliperidone during medium-term treatment [249].

Lurasidone

The most common adverse effects of lurasidone are somnolence, akathisia, nausea, and parkinsonism. The occurrence of akathisia appears to increase in a dose-dependent manner, up to 120 mg/day [10], and appears to be higher with lurasidone than with aripiprazole or asenapine, based on indirect comparisons vs placebo [250]. Minimal changes in body weight were observed among lurasidone-treated subjects in short-term studies [185]. In a pooled analysis of longer-term studies, there were only minimal changes from baseline in body weight, and the incidence rates of clinically significant weight gain (an increase of $\geq 7\%$ above baseline) and weight loss (a decrease from baseline by the same amount) were 16% and 19%, respectively [251].

Asenapine

The most common adverse effects of asenapine are insomnia, somnolence, and EPS, including dose-dependent risk of akathisia [10]. Transient oral hypoesthesias (usually resolved within 1 hour) have

also been reported. Preliminary data suggest that asenapine may be associated with a similar degree of short-term body weight gain as paliperidone (+1.2 kg), but with low risk of clinically significant short-term changes in metabolic measures [185]. The relative risk of clinically significant weight gain (defined as a $\geq 7\%$ weight increase from baseline) vs placebo was 4.1 (95% CI 2.3–7.4) [185].

Iloperidone

The most common side effects from short-term studies of iloperidone were dizziness, dry mouth, somnolence, and dyspepsia. Iloperidone was not shown to increase the risk of EPS during short-term follow-up [10]. Iloperidone was associated with numerically higher rates of orthostatic hypotension (20%) than haloperidol (15%) and risperidone (12%), although orthostatic hypotension with iloperidone generally did not persist past the first 7 days of treatment. Statistically significant increases in the QTc interval were observed with iloperidone treatment at all tested dose ranges [252]. Iloperidone has been associated with a statistically significant increase in body weight and changes in lipid profiles, relative to placebo, but these results were based on analysis of only one clinical trial [185]. Additional studies of iloperidone's anthropometric and metabolic effects are needed.

Brexpiprazole

Dose-dependent adverse effects of brexpiprazole include nausea, akathisia, and headache [253]. Brexpiprazole has also been associated with modest weight gain, but as yet no significant differences from placebo with respect to adverse changes in glycaemic or lipid profiles have been observed in short-term randomized trials [253]. There is no consistent evidence yet of clinically relevant short-term changes in prolactin concentration with brexpiprazole therapy. Brexpiprazole 2 mg has been associated with decreases in prolactin levels, while the 4-mg dose has been associated with increased prolactin concentrations [203]. Additional studies are needed to clarify brexpiprazole's anthropometric, prolactinaemic, and metabolic risk profile.

Cariprazine

Common adverse effects of cariprazine include insomnia, extrapyramidal symptoms, akathisia, sedation, dizziness, anxiety, and gastrointestinal distress [254]. Cariprazine appears to be associated with greater risk of clinically significant weight gain than placebo [254]; however, no statistically significant differences in adverse metabolic parameters or cardiovascular-related events have been observed. Additional studies are needed to better define the adverse effect profile of cariprazine, particularly over longer-term treatment.

Indications and contraindications

The main indication for antipsychotic drugs is the treatment of all phases of schizophrenia, including acute, florid symptoms of psychosis, and the prevention of relapse. Important other uses include the acute treatment and prophylaxis of mania, the acute treatment of depressive episodes in patients with bipolar disorders (for some agents such as quetiapine, olanzapine, lurasidone, and cariprazine) and major depression with psychotic features, the psychosis, agitation, and aggression of various dementias, the treatment of psychoses

due to L-dopa or other dopamine agonists in Parkinson's disease, Tourette's syndrome, treatment-resistant obsessive-compulsive disorder, self-injurious behaviour, porphyria, anti-emesis, intractable hiccoughs, and in some cases as antipruritics. Some current research has suggested that antipsychotic drugs may be of use to prevent the onset of schizophrenia by administering them to individuals who are in the prodromal phase of the illness. Several atypical antipsychotic drugs are being trialled on an experimental basis for various character disorders such as borderline, schizoid, and schizotypal personality disorders. Clozapine, which has the lowest incidence of EPS of any of the antipsychotic drugs, has some special applications in neurological conditions such as essential tremor and the treatment of water intoxication syndrome in schizophrenic patients. Uses in other psychiatric and neurological conditions may be expected to emerge, as the safety profile of these agents is better described.

Anti-parkinsonian agents

Anticholinergic drugs

Anticholinergic, antihistaminic, benzodiazepines, dopamine agonists, and β -blockers are of importance in the management of EPS. They are usually needed with typical dopamine antagonist drugs, but some patients will require such treatment when taking atypical antipsychotic drugs. Anticholinergics and antihistaminics (for example, diphenhydramine) are used to treat acute dyskinesias and dystonias, parkinsonian side effects, and akathisia [255]. These agents block the effects of increased acetylcholine release due to D2 receptor blockade in the basal ganglia. The most widely used anticholinergic drugs are benztropine (1–6 mg/day, usually in divided doses), biperiden (2–16 mg/day in two or three doses), procyclidine (5–30 mg/day), and trihexyphenidyl (1–15 mg/day in a single or divided doses).

These anticholinergic agents are competitive antagonists of the five subtypes of muscarinic receptors (M1 through to M5). They have minimal antagonist effects at nicotinic cholinergic receptors. Blockade of cholinergic receptors on intrastriatal neurons by these agents restores the cholinergic balance, which is disrupted by blockade of D2 dopamine receptors. Other central effects include impairment of various forms of memory. Elderly patients, in particular, may develop anticholinergic-induced agitation, irritability, disorientation, hallucinations, and delirium because of the natural loss of cholinergic neurons with ageing.

Side effects

These agents have some preference for the central nervous system, but peripheral anticholinergic effects are to be expected. Blockade of vagal tone in the heart produces tachycardia. Other adverse effects include decreased bladder function, urinary retention, and decreased bowel motility leading to constipation and impaction. Decreased saliva and bronchial secretions contribute to dry mouth and increased dental caries, while decreased sweating increases the risk of heat stroke. Blockade of muscarinic receptors in the eye cause pupillary dilatation and inhibition of accommodation, leading to photophobia and blurred vision. The muscarinic receptors in the basal ganglia are predominantly M2, whereas those in the periphery are M1. The rank order of anticholinergic drugs for relative selectivity for the M2 receptor is biperiden, procyclidine, trihexyphenidyl, and benztropine. All these agents can cause dry mouth, blurred

vision, urinary retention, constipation, and increased intraocular pressure. They may cause anticholinergic delirium in elderly patients or after taking high doses. Biperiden is less likely to cause peripheral anticholinergic effects. Benztropine, biperiden, and trihexyphenidyl may cause euphoria because of their ability to inhibit dopamine re-uptake and they may be subject to abuse.

Indications

Anticholinergic drugs or the antihistamine diphenhydramine are given IM for the treatment of acute dystonic reactions. They are usually effective within minutes and may have to be repeated. It is usually not necessary to prescribe an oral anticholinergic following a dystonic reaction, though some may require their brief use, depending on which antipsychotic is prescribed. These agents should not be given prophylactically, unless the patient is at established risk for EPS at the dose of antipsychotic which is being started. If akathisia or parkinsonism develops following treatment with a typical dopamine antagonist drug, the first consideration should be whether to continue to use the offending agent, drop the dosage, or substitute with an atypical antipsychotic drug. If decreasing the dose of antipsychotic drugs is not clinically feasible, substituting with an atypical agent is clearly the recommended choice since it avoids all the unpleasant side effects of anticholinergic agents.

Other drugs

Amantadine, which also has antiviral actions, is able to increase the release of dopamine in the basal ganglia, which diminishes the release of acetylcholine. It may improve drug-induced EPS [255, 256]. It has also been reported to improve sexual function and decrease weight gain due to dopamine antagonist drugs. But it may also cause worsening psychosis, increased arousal, agitation, and indigestion. As such, caution is warranted when using amantadine to treat EPS. The usual oral dose is 100–400 mg/day.

β -blockers, such as propranolol, atenolol, and pindolol, are useful for treating akathisia and tremor [255]. They may cause bradycardia, and particularly immediate-release forms should not be stopped abruptly due to rebound tachycardia.

Benzodiazepines, such as clonazepam, lorazepam, and diazepam, are useful for treating akathisia, acute dystonias, and acute dyskinesias. They can cause drowsiness and lethargy, and have abuse potential.

Conclusions

Dopamine antagonist/partial agonist drugs are the principle treatment for schizophrenia, and selected agents are widely used in other psychotic and non-psychotic disorders such as bipolar disorder and major depression. Their main benefits are to treat psychotic symptoms across various illnesses. The atypical drugs have largely displaced the typical ones because of lower EPS and tardive dyskinesia risk profiles. However, several atypical drugs are associated with higher risk of weight gain and dysmetabolic effects. Atypical, but not typical, drugs appear to improve negative symptoms and cognition. New atypical drugs for psychosis continue to be developed, including those with partial agonist activity on presynaptic dopamine receptors and more extensive interactions with serotonergic receptors [257]. Several atypical drugs have established effectiveness—or have shown promise—for treating bipolar depression and major

depression (as adjunctive therapy). Long-term treatment of affective disorders with typical antipsychotics is generally avoided, owing to heightened risk of tardive dyskinesia in such patients.

Dopamine antagonist/partial agonist drugs are useful as both acute and maintenance treatment to prevent the recurrence of psychotic symptoms in patients with schizophrenia and related psychotic disorders. The greater EPS and tardive dyskinesia risk of the typical antipsychotics, coupled with their lesser efficacy to improve negative symptoms and cognition, suggest that atypical agents are preferred, whenever possible, for long-term treatment. These advantages must be balanced against the greater long-term risk of weight gain and adverse metabolic effects associated with some atypical antipsychotic drugs. Clozapine, despite its risk of agranulocytosis and adverse metabolic effects, is the treatment of choice for patients with treatment-resistant schizophrenia. Although they have been considered together here as a single group, atypical antipsychotics have somewhat different pharmacologic profiles. Outside of clozapine for refractory schizophrenia, it is not yet clear which of these agents should be trialled in a given patient, but ongoing research may clarify this. These compounds, as well as others expected to be approved for use in the near future, will need to be compared with each other to determine if differential indications exist. Side effect differences among these drugs, as well as the availability of long-acting preparations, may help clinicians choose among them. As long as the typical drugs remain in use and for some patients who receive atypical agents, anticholinergic and other anti-parkinsonian drugs will continue to be necessary to treat EPS.

Because of the high rates of poor adherence to drugs in patients with schizophrenia and other disorders, it is important to develop more long-acting injectable atypical antipsychotics. Fortunately, several typical and atypical antipsychotic drugs have long-acting injectable formulations that are currently available for clinical use.

While the current group of atypical antipsychotic drugs is predominantly characterized by relatively more potent 5-HT_{2A} than D₂ receptor antagonism, or by partial D₂ agonist effects, new pharmacological strategies will emerge for drugs with lower EPS liability than the typical antipsychotics. Because newer antipsychotic drugs are so effective in treating core psychotic symptoms, while limiting the risk for EPS, the remaining challenge rests in the development of agents that effectively treat other important features of schizophrenia, such as cognitive impairment and negative symptoms, without the metabolic and other side effects associated with these agents. Finally, the development of biomarkers, particularly genetic measures, to enable personalized medicine and reduce the number of therapeutic trials required to find optimal treatments for patients requiring drug treatment for psychosis remains a long-sought goal in the field that may be achievable in the near term [258–260].

Treatment and management of patients with schizophrenia

Joseph P. McEvoy, Kammarauche Asuzu, Daniel W. Bradford,
Oliver Freudenreich, and Katherine H. Moyer

Overview

In this chapter, *treatment* will be defined as ‘medical care given to a patient for an illness or injury’ [1]. The treatment section will focus on biological aspects of schizophrenia and comorbid medical illnesses for which efficacious somatic treatments are available, including:

1. Positive psychopathology (delusional beliefs, hallucinatory perceptions, and disorganization of thinking and behaviour) associated with excessive dopamine release, which responds adequately to first-line antipsychotic medication (FL-APM.)
2. Positive psychopathology which does not respond adequately to FL-APM, for which a trial of clozapine is indicated.
3. Comorbid medical illnesses that shorten the lifespan of patients with schizophrenia, including those caused or worsened by treatment with FL-APM or clozapine.

In this chapter, *management* will be defined as ‘the manner in which someone behaves toward or deals with someone or something’ [1]. The management section will focus on:

1. Dealing with enduring deficits in cognition, motivation/expression, and sensorimotor function resulting from biological processes for which no somatic treatments are currently available, that are prominent in a subset of patients.
2. Dealing with enduring deficits in self-control, manifest in comorbid substance use disorder (SUD), impulsive character traits, and high-risk and disruptive behaviours, that are prominent in a subset of patients.
3. Dealing with enduring distress from adverse childhood experiences, ongoing life stress, and external and internalized stigma.

Treatment (medical care) can only be delivered effectively if clinical care systems modify their expectations of patients’ functional capacities and accommodate clinical interactions and environments to *manage* (deal with) the enduring attributes of patients with schizophrenia.

Team-based care, for example, comprehensive first-episode psychosis (FEP) treatment programmes, integrated mental health care/primary care treatment programmes, and assertive community treatment (ACT) programmes, may offer the greatest benefit for the majority of patients with schizophrenia.

The enduring attributes of patients with schizophrenia interfere with chronic illness self-management. Family and important others (for example, partners, friends, and certified peer specialists) can assist where patients’ functional capacities are limited; they should be welcome as members of care teams.

Treatment

Medical care for dopamine-related positive psychopathology (FL-APM)

Dopamine release in the terminal fields of ventral tegmental area (VTA) neurons is increased in the majority of unmedicated patients experiencing FEP or recurrent psychosis and is correlated with the severity of positive psychopathology [2]. Dopamine release in these regions is involved in the assignment of salience to items of sensory experience and intrapsychic life [3].

Patients entering FEP report experiences compatible with inappropriate assignment of salience to random observations and thoughts—‘There is a brightness and clarity of outline of things around me. Last week I was with a girl and suddenly she seemed to get bigger and bigger’, ‘The sun seemed too big for me and it was coming closer’, ‘Big, magnified thoughts come into my head when I am speaking and put away the words I want to say, and make me stray away from what was in my mind’ [4].

FL-APM act by binding, as antagonists or partial agonists, to dopamine D2 receptors in the terminal fields of VTA dopamine neurons, shielding them from excessive dopamine. These dopamine neurons subsequently reduce their activity, shifting into depolarization block [5].

The efficacy of FL-APM is greatest early in the illness. Therapeutic benefit occurs at lower doses of FL-APM in FEP, and a higher

percentage of patients achieve remission of positive psychopathology (all items rated 'mild' or less, that is, they are uncommon and non-intrusive and do not drive behaviour), in comparison to chronic, multi-episode patients [6].

The goal of treatment with FL-APM is the achievement and maintenance of sustained remission, which is associated with better quality of life. For most patients, uninterrupted treatment with FL-APM is necessary for sustained remission.

Treatment with FL-APM should be initiated early. Longer duration of unmedicated psychosis (DUP) prior to FL-APM for FEP is associated with reduced likelihood of remission, more prominent negative psychopathology, and poorer functioning [7]. Longer cumulative duration of unmedicated relapses during the years following FEP is associated with loss of brain volume, more prominent cognitive impairment, and more FL-APM-resistant positive psychopathology [8].

The benefits of sustained remission with uninterrupted FL-APM are large. The risks of relapse are grievous, including derailment from trajectories of development (school, work, independent living, and relationships), violence, self-injury, hospitalization, or incarceration.

It appears that a minority of patients in sustained remission can be withdrawn from FL-APM after FEP and maintain good function and quality of life [9]. However, clinicians cannot identify these patients prospectively.

If a remitted patient insists on FL-APM discontinuation, gradual tapering over several months, with close observation by others (for example, family) and regular clinical contact, may permit early detection of relapse and re-initiation of FL-APM before grievous consequences occur.

Non-remitted patients are highly likely to rapidly relapse after FL-APM discontinuation, and FL-APM discontinuation should be discouraged [10].

Interruptions in treatment with FL-APM following FEP are common (50% in the first year), delay the achievement of remission, and increase the likelihood of relapse 5-fold [11]. Factors associated with relapse include comorbid SUD, lack of insight, and lack of engaged family [12], all acting through the final common pathway of interrupted FL-APM.

Impaired insight, an enduring deficit, is associated with higher levels of psychopathology and cognitive impairment, and reduced brain volumes, in patients with FEP [13].

Long-acting injected (LAI) FL-APM provide real-time, accurate information regarding treatment interruption. If patients fail to present for, or refuse, scheduled injections, clinicians and engaged family/others can express concern. Shared decision-making is undertaken with shared facts.

Tolerability

There is little difference in efficacy, but substantial differences in side effects (and the ease with which side effects can be mitigated) among the FL-APM. Many FL-APM and many strategies to mitigate their side effects are available. It is reasonable to propose to patients the goal of minimal or no subjective distress or objective toxicity with FL-APM.

Clinicians may select 2–3 FL-APM to prescribe regularly, so as to become experienced and skilled in their use. Characteristics to consider include:

1. Side effects that can be mitigated by sensible dosing or well-tolerated concomitant medications.
2. Once-daily dosing of oral preparations.
3. Availability of LAI preparations.
4. Affordability.

Clinicians should describe common potential side effects of any FL-APM prescribed and strategies to monitor for, and mitigate, them. Patients should have contact information for clinicians, so that relief of side effects is quickly achieved and FL-APM discontinuation avoided.

Early-onset extra-pyramidal side effects (EPSEs)

Dystonic reactions are spasmodic contractions of the face, neck, trunk, and/or extremities that can be frightening and uncomfortable, occurring most commonly in young male patients receiving high doses of FL-APM with preponderant dopamine D2 antagonism (for example, haloperidol). Dystonic reactions can be rapidly relieved by intramuscular anticholinergic or benzodiazepine medications. Clinicians may then consider switching the FL-APM or lowering the dose.

Restlessness (akathisia) occurs most commonly during treatment with haloperidol-like FL-APM or dopamine D2 partial agonists (for example, aripiprazole). Unrelenting restlessness has been associated with suicide and violence. Clinicians should inquire about, and observe for, (pacing, foot-tapping) restlessness. Clinicians may consider switching the FL-APM. Otherwise, extended treatment with β -blocking agents or benzodiazepines may be necessary to mitigate restlessness.

Bradykinesia-rigidity indicates excessive dopamine D2 receptor antagonism (calling for reduced FL-APM dose) or intrinsic susceptibility (suggesting consideration of clozapine). Tailoring individualized doses of haloperidol-like FL-APM to the 'neuroleptic threshold', at which point minimal bradykinesia-rigidity can be detected on examination, but no coarse EPSE is present, offers the therapeutic benefit of these agents with good tolerability [14].

Anticholinergic medications prescribed to treat early EPSE of FL-APM have dose-related side effects, including dry mouth, blurred vision, constipation, and cognitive impairment [15]. Reduction in coarse EPSE produced by anticholinergic medication is not accompanied by a reduced risk for tardive dyskinesia (TD). Dose reduction of FL-APM is the preferred approach to coarse EPSE.

Late-onset EPSE

Tardive dyskinesia (TD) is manifest as involuntary, purposeless, repetitive movements commonly involving the lips (for example, pursing or smacking), jaw, and/or tongue, but also the upper regions of the face (blinking), distal extremities, and trunk. Patients with TD have difficulty not moving.

The movements can be disfiguring and stigmatizing. 'Mild' movements in a patient whose job requires social interaction may have 'severe' repercussions.

TD is believed to result from enhanced sensitivity of striatal dopamine D2 receptors (after years of deprivation of dopamine), which respond excessively to ambient synaptic dopamine.

Patients with FL-APM-resistant schizophrenia, especially those who are violent, may receive high doses of FL-APM, leading to TD.

Clozapine may relieve FL-APM-resistant positive psychopathology and TD in such patients [16].

Inhibitors of vesicular monoamine transporter-2 (VMAT2) block the uptake of dopamine into presynaptic vesicles of nigrostriatal dopamine neurons; these agents significantly reduce the severity of TD [17].

Neuroleptic malignant syndrome (NMS) is characterized by muscle rigidity that may be intense, creating heat and dissipating moisture. Immobility prevents fluid intake and increases the risk for infection and thromboembolism. Muscle fibre breakdown releases myoglobin that can precipitate in renal tubules in the setting of dehydration. FL-APM should be discontinued until NMS is resolved.

Supportive care focusing on hydration, identification and treatment of infection, prevention of thromboembolism, and treatment with dopamine agonists (for example, amantadine) and benzodiazepines reduces morbidity and mortality [18].

In severe cases that do not respond to supportive care, dantrolene (reduces excitation–contraction coupling in skeletal muscle) or electroconvulsive therapy should be considered. Extended muscle rigidity may result in persistent contractures.

Prolactin-related side effects

Elevated prolactin levels result from antagonism at tubero-infundibular dopamine D2 receptors, located outside the blood–brain barrier (BBB), by FL-APM that penetrate the BBB poorly (for example, risperidone). Breast enlargement/lactation and sexual dysfunction may result in men and women, and menstrual cycling may be suppressed in women. Bone demineralization may result from reductions in oestrogen levels [19].

Clinicians may consider preferentially prescribing FL-APM that do not elevate prolactin.

Weight gain and metabolic side effects are discussed in Antipsychotic medications may cause or worsen modifiable risk factors, p. 671.

Medical care for positive psychopathology that responds inadequately to FL-APM

Approximately 80% of FEP patients achieve remission of positive psychopathology over months of uninterrupted treatment with FL-APM; in most, substantial improvement is apparent within days. Approximately 20% are *treatment-resistant* at FEP and remain so thereafter [20]. *Earlier onset of FEP and longer DUP* prior to initiation of FL-APM reduce the likelihood of remission.

During the years following FEP, the *duration of unmedicated psychotic relapses* is associated with accrued FL-APM-resistant positive psychopathology and reduced brain volume [8]. Approximately 33% of patients become FL-APM-resistant, no longer demonstrating correlations between dopamine release and positive psychopathology [21].

Clozapine reduces positive psychopathology and mortality [22] in at least 40% of FL-APM-resistant patients, reduces aggression in patients selected for aggressiveness [23], and reduces self-injury in patients selected for self-injury [24]. Community tenure (avoidance of hospitalization or incarceration) is increased with clozapine.

Clozapine is under-utilized. Clinicians unfamiliar with the use of clozapine may consider referring FL-APM-resistant patients to clinicians who are experienced in its use.

Clozapine should be considered after two FL-APM trials have failed to produce adequate therapeutic benefit. Olanzapine may

offer the greatest therapeutic benefit among FL-APM and should be considered for the second trial [25]. For early-onset psychosis or if aggression or self-injury is prominent, clozapine should be considered after one failed FL-APM trial. Patients who prove to be exquisitely susceptible to EPSE or who have experienced NMS may do best with clozapine.

Augmentation of clozapine with *electroconvulsive therapy* may reduce positive psychopathology, aggression, or self-injury in incomplete responders to clozapine alone [26].

Clozapine side effects

Agranulocytosis occurs in approximately 1% of clozapine-treated patients, most commonly during the first 3 months of treatment [27]. Risk evaluation and mitigation strategies (REMS) guide monitoring.

Myocarditis occurs in approximately 0.2%, most commonly during weeks 3–4 of treatment. Monitoring eosinophil count, inflammation (for example, C-reactive protein), and muscle damage (for example, troponin) at baseline and at weeks 1–4 permits early detection and discontinuation of clozapine prior to extensive heart damage [28]. Slower titration of clozapine dose may reduce risk.

Seizures occur in 2–6%; risk is greater with prior seizures (for example, febrile seizures in childhood), head injury, and higher clozapine dose [28]. Therapeutic drug monitoring may avoid excessive clozapine blood levels. Myoclonus during dose titration foreshadows seizures [29].

Salivary pooling, related to increased salivation and decreased swallowing, may increase the risk for aspiration, especially during sleep. Quaternary anticholinergic agents (for example, glycopyrrolate) reduce salivation and do not penetrate the BBB [30].

Constipation is common and can lead to adynamic ileus and death. Daily stool softeners (for example, docusate) and a weekly osmotic laxative can be started when clozapine is initiated [31]. A stimulant laxative can be prescribed as needed.

Venous thromboembolism risk is increased 30-fold with clozapine [32]. Daily aspirin should be considered when starting clozapine.

There is *no therapeutic alternative* to clozapine in patients whose positive psychopathology, aggression, or self-injurious behaviour are resistant to FL-APM. Clinicians must strive to mitigate clozapine side effects for patients who benefit from its use, because few, if any, other therapeutic options exist.

Accelerated mortality

Patients with schizophrenia die more than 20 years earlier than general population controls, primarily from medical causes of death that are similar to those of the general population (heart attacks, strokes, cancer, and complications of diabetes mellitus) [33]. *Modifiable risk factors* (MRFs) (for example, insulin resistance, dyslipidaemia, hypertension, cigarette smoking) for these causes of death are more prevalent and more severe, at any age, among patients with schizophrenia than among general population controls [34].

Children later diagnosed with schizophrenia are less physically active than general population children. Medication-naïve FEP patients have higher rates of obesity, insulin resistance, and smoking than general population controls [35].

Patients with schizophrenia and comorbid SUD (*vide infra*) engage in more high-risk behaviours, resulting in higher rates of infection with bloodborne viruses [HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV)] than general population controls.

Rates of suicide, homicide, and accidental death are also increased.

Antipsychotic medications may cause or worsen modifiable risk factors

FL-APM have varying propensities to cause or worsen weight gain, insulin resistance, or dyslipidaemia, or to reduce physical activity through sedation or EPSEs [35]. Clinicians may consider preferentially prescribing FL-APM with minimal propensities to cause or worsen MRFs.

Olanzapine and clozapine have high propensities and should not be prescribed for patients who achieve adequate therapeutic benefit from more benign FL-APM. If olanzapine or clozapine are necessary to achieve adequate therapeutic benefit, pre-emptive mitigation strategies (see Interventions to mitigate modifiable risk factors, p. 671) should be considered when these agents are started.

Patients with schizophrenia commonly receive poor medical care

Rates of adherence to practice guidelines in general medical care settings are ‘considerably lower’ for patients with schizophrenia than for non-schizophrenic patients [33, 34]. Patients with schizophrenia and diabetes mellitus or hypertension [36] are less likely to receive guideline-concordant screenings, testing, and treatments. Following myocardial infarction, patients with schizophrenia are less likely to receive indicated reperfusion procedures [37].

Patients with schizophrenia and cancer die sooner than those with cancer alone. Including a psychiatrist in the cancer care team, ongoing prescription of antipsychotic medications, and prevention of relapse after cancer diagnosis significantly reduce the likelihood of disruption in cancer care [38].

The ‘chronic care model’ for optimal treatment and management of chronic biological illnesses envisions ‘*informed, activated patients*’ interacting productively with ‘*prepared, proactive practice teams*’ [39]. Patients with schizophrenia have difficulties being informed and activated because of distracting positive psychopathology and enduring deficits in cognition, motivation, and expression. Few medical care systems accommodate to make interactions with patients with schizophrenia more productive.

Interventions to mitigate modifiable risk factors

Providing uninterrupted antipsychotic medications is associated with decreased all-cause mortality in schizophrenia [40].

Co-localization of primary care in mental health care facilities simplifies the cognitive/motivational challenges that patients with schizophrenia must overcome (for example, appointments at multiple locations and different times), facilitates communication among treating clinicians, and improves primary care outcomes [41].

Embedding nurses in mental health care facilities to assist patients with schizophrenia in overcoming obstacles to care (for example, making primary care appointments and arranging transportation), instruct patients and their families in chronic illness self-management, and co-ordinate prescribing across mental health and primary care providers reduces MRFs and mortality risk [42]. Certified peer specialists may also assist patients with chronic illness self-management, in particular through increased physical activity and medication compliance [43].

Efforts at smoking cessation should include both individual or group psychosocial support and adjunctive pharmacotherapy.

Efforts without pharmacotherapy are rarely successful in patients with schizophrenia. In 12-week trials, varenicline is superior to bupropion/nicotine replacement therapy (B/NRT), and B/NRT is superior to placebo in achieving smoking cessation in patients with schizophrenia [44], but post-trial relapse rates are high. Maintenance treatment with varenicline is significantly superior to placebo in sustaining smoking cessation [45]. Neither varenicline nor B/NRT has been associated with worsening of psychopathology or suicide, relative to placebo. Clinicians treating patients with schizophrenia may consider becoming skilled in the use of varenicline and B/NRT.

Metformin [46] and liraglutide [47] are associated with weight loss and reduced insulin resistance in patients receiving dopamine antagonist medications with high propensities to cause or worsen MRFs. Clinicians may consider becoming skilled in their use. Topiramate reduces weight gain associated with antipsychotic medications [48].

Patients with schizophrenia are more sedentary than the general population. Diet and exercise programmes targeting weight and fitness may reduce MRFs in patients with schizophrenia, but they are not commonly available.

Women’s issues

Women with schizophrenia report more lifetime sexual partners and higher rates of being raped or engaging in prostitution, but are less likely to have been tested for HIV, than general population women. They report fewer planned pregnancies, more unwanted pregnancies, and more abortions [49].

Sexual violence is associated with more severe positive psychopathology, comorbid SUD, and homelessness. Among homeless women with schizophrenia, sexual violence (97% lifetime incidence) ‘amounts to normative experience’ [50].

The benefits of continuing antipsychotic medications through pregnancy to prevent relapse outweigh the low risks of teratogenicity. However, antipsychotic medications throughout pregnancy is associated with greater weight gain and risks for gestational diabetes. Women with schizophrenia have higher rates of preterm birth.

Clozapine treatment during pregnancy is associated with over 2-fold increase in gestational diabetes. Infants born to mothers taking clozapine are more likely to be ‘floppy’ and to experience seizures, and they must be checked for agranulocytosis [51].

Management

Enduring deficits in cognition, motivation/expression, and sensorimotor function

A subset of the offspring of patients with schizophrenia, including many who will later become psychotic, display deficits in cognition, motivation/expression, and /or sensorimotor function in infancy and childhood, long before the onset of psychosis [52].

In large population cohorts, characterized in childhood and followed through adulthood, a subset of those children who will later become psychotic display deficits in cognition, motivation/expression, and/or sensorimotor function [53].

At adult-onset FEP, prominent impairments in cognition, motivation/expression, and/or sensorimotor function are present in a

subset of patients and are associated with poor subsequent social and occupational function [54]. In early-onset FEP, prominent impairments are present in >80% of patients, in association with brain volume loss and FL-APM-resistant positive psychopathology [55].

During the years following FEP, increasing deficits in cognition and motivation/expression occur in a subset of patients, accompanied by brain volume loss and increasing FL-APM-resistant positive psychopathology [8].

Many, but not all, studies suggest that prominent impairments in cognition, motivation/expression, and sensorimotor function tend to occur in the same patients. Parsimony suggests the unproven possibility that the deficits share a common pathophysiology with variable distribution throughout the central nervous system. The deficits are enduring. They do not go away.

Cognitive deficits

At FEP, patients perform at a level 1.5 standard deviations below the general population, with particular deficits in learning and memory [56]. Patients with chronic schizophrenia perform at a level 1.5–2.5 standard deviations below the general population (in the range of the lowest 5–10% of the general population), substantially limiting their abilities to engage successfully in real-world tasks [57], for example, self-management of chronic mental and physical illnesses.

Patients with schizophrenia show pronounced hypoactivation of circuitry in the ‘multiple demand network’ of the left lateral prefrontal cortex, including portions servicing initial, rudimentary processes (for example, updating, set shifting, and inhibition), compatible with a broad disruption of neuropsychological performance encompassing multiple cognitive domains [58]. Structural imaging studies also demonstrate disruption of white matter tracts ‘facilitating information processing in the cortico-basal ganglia network’ in patients with chronic schizophrenia [59].

The effects of APM on cognition in schizophrenia appear to be minimal. Adjunctive pharmacotherapies targeting cholinergic, glutamatergic, or serotonergic neurotransmissions have, so far, failed to improve cognition. Cognitive remediation has shown benefit in improving function in some, but not all, trials and may be of greatest value in supported employment settings [60]. Long-term durability of effects is not established.

Cognitive function is associated with cardio-respiratory function in patients with schizophrenia. Twelve-week programmes that engage patients with schizophrenia in vigorous physical exercise appear to improve cognitive function [61] and brain volume. These gains do not persist after the exercise programmes end, as patients resume their pre-programme activity levels.

Modifications/accommodations to deal with cognitive deficits are discussed in Modifications and accommodations, p. 672.

Motivation/expression deficits

The assessment of ‘primary’ deficits in motivation/expression should be preceded by detection and correction of superficially similar phenomena, for example, akinesia or somnolence due to prescribed medications or SUD, catatonia, social withdrawal due to positive psychopathology (for example, paranoia), depression and anxiety, or behavioural regression due to isolation or social deprivation [62].

Deficits in motivation most powerfully predict social and occupational function [63]. Patients with schizophrenia appear able to experience pleasure when exposed to pleasant experiences but

have ‘difficulty using mental representation of affective value to guide decision-making and goal-directed behavior’ [63]. Areas of ‘dysconnectivity associated with reward responsivity’ have been identified in functional imaging studies [64].

At present, there is no convincing evidence regarding efficacy for any treatment for enduring deficits in motivation/expression [65].

Neurological soft signs

Neurological soft signs (NSS) are ‘non-localizing neurological abnormalities that cannot be related to impairment of a specific brain region’ [66]. Typical NSS include impairments in motor coordination, the sequencing of complex movements, and sensory integration (for example, right–left discrimination).

NSS are observed in dopamine antagonist medication-naïve FEP patients and in the majority of patients with chronic schizophrenia. NSS are strongly associated with cognitive and motivation/expression deficits and with FL-APM-resistant positive psychopathology [67].

Modifications and accommodations

Modifications are reductions in expectations as to what patients with schizophrenia can do, relative to general population controls. For example, patients with schizophrenia recall, on average, half as many words as general population controls after a single presentation of a word list [56]. They may do best with educational processes (for example, illness self-management information) that provide them with half as much information as the general population would be expected to remember. The information must be thoughtfully selected and include the critical facts to be transmitted.

Accommodations are adaptations in clinical interactions (for example, offering multiple brief sessions over time to transmit illness self-management information gradually) and in clinical environments (for example, co-localization of mental health and primary care) to achieve desired outcomes despite enduring deficits.

Modifications and accommodations are recommended for the informed consent process [68] in patients with schizophrenia, including adequate time for repeated presentations in minimally distracting settings, involving family members, consideration of multiple media (written, spoken, figures), and feedback testing: ‘Professionals ... and patients cannot be assured that they have understood one another—especially in the case of persons already known to suffer problems of comprehension—without some form of checking’ [69]. Clinicians may consider more widespread use of such procedures.

Clinical staff and family/important others may also provide functions that patients cannot offer (for example, activity therapists initiating outings that patients with motivation deficits do not initiate but may enjoy).

Patients with schizophrenia display a wide range of severity of enduring deficits. In an optimal system, safe and comfortable housing options, offering a range of independence (matched to patients’ cognitive function and initiative), would be available. However, the type of housing provided appears to be mostly driven by regional approaches to health planning [70]. Discussions about independence should include the risks of loneliness and of relapse [71].

In an optimal system, a range of opportunities for productive activities would be available, from sheltered workshops through accommodated work placements without pay (disability benefits are

preserved) and supported employment programmes. Only approximately 10% of patients with schizophrenia can support themselves through competitive employment, but approximately 70% can participate in productive activities with accommodations [72]. Patients who successfully manage their illness can serve as Certified Peer Specialists, trained to share their experiences and coping strategies with other patients, providing support with illness management, communication with clinicians, and overall health—maintaining hope and reducing internalized stigma [73].

Self-control

Across the general population, there is a gradient of self-control—‘an effortful regulation of the self by the self’ [74]. Self-control, assessed in early childhood, predicts multiple health, relationship, and achievement outcomes in adult life [75, 76].

Those in the lowest quintile of self-control display more SUD and criminality and poorer mental and physical health than the remainder of the general population, and they utilize disproportionate amounts of society’s health care and criminal justice resources [75].

Those in the highest quintile are characterized by conscientiousness—‘a large class of personality traits that include responsibility, industriousness, and orderliness’ [74]—which is associated with higher incomes and occupational prestige, more stable and satisfying relationships, better health, and greater longevity [75].

A subset of patients with schizophrenia display enduring deficits in self-control, manifest in comorbid SUD, disruptive behaviours leading to hospitalization or incarceration, poor engagement with treatment, poor illness self-management, poor physical health, and accelerated mortality.

Patients with schizophrenia appear more likely to mate [77, 78] and to cohabitate with [79] deviant individuals, including those with deficits in self-control. These pairings may result in offspring with schizophrenia and deficits in self-control and in environments in which high rates of adverse childhood experiences (ACEs) and adult trauma occur.

Comorbid substance use disorder

At FEP, at least 40% of patients use substances, predominantly marijuana or alcohol. Approximately half of those using substances cease without specific interventions. Patients who cease substance use are more likely to have engaged families, and their outcomes are as good as those of FEP patients without substance use [80].

Patients who continue substance use despite FEP, now diagnosed with comorbid SUD, have higher rates of first-degree relatives with SUD than other FEP patients [81]. They are predominantly male and demonstrate impulsiveness, sensation-seeking, and behavioural disinhibition [82], similar to general population individuals with SUD, features that are antithetical to conscientiousness. They are more likely to display features of conduct disorder in childhood and antisocial personality disorder (ASPD) as adults [83]. Risk for violence is modestly increased in schizophrenia, but substantially increased with comorbid SUD and ASPD [84].

Patients with schizophrenia and SUD have more frequent interruptions in antipsychotic medication, more severe positive psychopathology at cross-sectional assessments, higher rates of relapse and service utilization, lower rates of remission, and higher rates of completed suicide than patients with schizophrenia alone. Their

all-cause mortality rate is substantially higher (SMR 8.46 versus 3.61) than that of patients with schizophrenia alone [85].

Management and treatment of comorbid substance use disorder

Patients with schizophrenia and deficits in self-control are not help-seeking. Engagement may be initiated during hospitalization or incarceration, or through assertive outreach in the community.

Sustained engagement is simplified if patients reside with the family (who should also be engaged and supported) or have a residence (which may need to be provided as an initial priority).

Non-compliance with prescribed oral medication is to be expected. Some trials report reduced hospitalization or incarceration with LAI antipsychotic medication [86]. If compliance with oral medication and REMS procedures can be assured, clozapine may reduce substance use and positive psychopathology [87]. Trials with agents such as LAI naltrexone are needed.

A small percentage of patients with schizophrenia and SUD will engage in intensive, team-based approaches, for example Behavioural Treatment for Substance Abuse in Severe and Persistent Mental Illness (BTSAS) offering small groups twice a week for 6 months, motivational interviewing, monetary rewards for negative urine screens, and social skills training, that have been associated with a higher percentage of negative urine screens and fewer hospitalizations than standard care [88].

ACT teams bring treatment to patients with schizophrenia and deficits in self-control who are not help-seeking. Multi-disciplinary, well-staffed teams go out and find (assertive outreach) patients who do not come to clinic appointments, are available around the clock for crisis support, and directly provide (as opposed to making referrals for which patients will not show up) a broad range of services—‘helping with illness management, medication management, housing, finances, and anything else critical to the individual’s community adjustment’ [89]. In clinical trials, patients assigned to ACT teams have fewer hospital days and better patient and family satisfaction (and connection) than patients in standard care.

Incorporation of Certified Peer Specialists in ACT teams may improve the functioning of patients receiving ACT services and leads to fewer days of homelessness or hospitalization [90].

Adverse childhood experiences

In the general population, ACEs (for example, physical or sexual abuse, observed domestic violence, parental mental illness, death or separation/divorce, or placement in foster care) are associated with SUD, depression, and poorer health and quality of life in adulthood [91]. Environments in which one ACE occurs may also offer others, and ‘accumulating levels of adversity often produce graded decrements in development and functioning’ [92].

Patients with schizophrenia report more ACEs than the general population, and more ACEs are associated with more SUD, homelessness, incarceration, suicidal thoughts, and health problems (for example, HIV infection) [93].

Interventions to mitigate adverse childhood experiences

Early nutritional [94] and psychosocial enrichment [95, 96] programmes supporting mothers and children at genetic and/or environmental risk may improve outcomes.

Resilience, 'defined as a dynamic process encompassing positive adaptations (not merely the absence of pathology or dysfunction) within the context of significant adversity' [97], may explain variance in outcomes after ACEs. Early conceptualizations of resilience focused on traits within individuals presumed to impart hardiness. Later conceptualizations also highlight 'affectional ties within the family and with extra-familial informal support systems' [98] that can be protective and potentially restorative. Resilience is not a fixed set of attributes, but a dynamic process that can change in response to new challenges, opportunities, and emerging competencies. Resilience-enhancing interventions are discussed in Individual resilience training, p. 675.

Internalized stigma

'Stigma', directly translated, refers to a visible mark usually made by a pointed instrument. Current usage derives from the mark tattooed or branded into the skin of slaves or prisoners, denoting their undesirable status.

Internalized stigma, the degree to which patients accept that they are marked as less desirable, with less value or power, because of the presence of schizophrenia, is associated with greater feelings of depression, alienation, and perceived discrimination, and greater endorsement of unflattering mental illness stereotypes [99]. Clinicians may directly challenge internalized stigma through cognitive behavioural therapy [100].

Stigma resistance

Stigma resistance, the degree to which patients reject derogatory self-assessments, is associated with higher self-esteem and reported empowerment, higher levels of hope and quality of life, and less depression [101]. Having social contacts (family and friends) and being in outpatient treatment—perceiving that one 'matters' to others—are associated with greater stigma resistance [102, 103]. Better cognitive functioning and higher levels of the personality trait of self-directedness are associated with greater stigma resistance.

Stigma resistance and resilience overlap. Sustaining connectedness with family and important others and providing the experience of productive activities may be important strategies for strengthening stigma resistance.

Internalized stigma in caregivers

Caregivers of patients with schizophrenia report more internalized stigma than caregivers of patients with bipolar disorder or depression. Earlier age of onset of psychosis and longer duration of illness (markers of the degree of enduring impairment) are associated with higher levels of internalized stigma in caregivers [104]. Higher levels of internalized stigma are associated with higher levels of psychological morbidity in caregivers [105] and should be a target of family psychoeducation and support.

Assignment of stigma by the public

The public assigns stigma based upon diagnosis (the most severe, for example, schizophrenia, assigned the most stigma), judgements of the intensity of treatment needed (for example, hospitalization vs outpatient care), and judgements of the level of associated psychosocial disabilities [106]. Efforts to improve the public's opinions of patients with schizophrenia have shown little effectiveness [107].

Non-psychiatric physicians responding to vignettes depicting various clinical populations expressed their least positive attitudes towards patients with schizophrenia and personality disorder and those classified as criminals. Mental health clinicians may preferentially refer patients with schizophrenia for non-psychiatric care to clinicians who have demonstrated more positive views of patients with schizophrenia.

The right beginning: comprehensive FEP treatment programmes

Comprehensive FEP treatment programmes are team-based and offer evidence-based pharmacological treatment, involvement of family, support for patients' education/employment goals, and individual psychosocial treatments, usually for a period of 2 years. Patients assigned to comprehensive FEP treatment programmes are more likely to remain in treatment, have less psychopathology and fewer hospitalizations, and have improved functioning, while receiving lower doses of antipsychotic medications, relative to patients assigned to TAU (treatment as usual). They report better quality of life and satisfaction with treatment and are more likely to be in school or working. Their families report less burden than the families of patients assigned to TAU [10].

Evidence-based pharmacological treatment

Sustained remission of positive psychopathology is the goal of pharmacological treatment. LAI FL-APM may be considered in patients with comorbid SUD, lack of insight, and/or no engaged family [108]. Use of the fewest medications, at the lowest effective doses, may offer treatment, with minimal or no side effects.

Interruptions in antipsychotic medication that lead to relapse can be detected quickly by team members (including family), and antipsychotic medication restarted. The duration of unmedicated relapse, not the occurrence, is associated with decline [8].

Monitoring of physical health and interventions to mitigate MRFs begins immediately in FEP treatment programmes [109]. Aerobic exercise may assist in managing weight and metabolic side effects and may benefit cognition and functioning [110].

Engagement of families

Family members fear relapse [111] and struggle with their relative's enduring deficits. They should be included in shared decision-making about medications. They should be encouraged to provide cognitive and motivational functioning that patients lack, for example, assisting with illness management and including patients in enjoyable activities.

Family members are a resource that clinicians strengthen through knowledge and support through appreciation and encouragement. Real-world successes—the prevention of relapse, the achievement of productive activity by their relatives—may reduce their internalized stigma.

Education/employment support

Assistance with education/employment may be the most attractive aspect of FEP treatment programmes for patients. Returning to productive activity (school or work) provides purpose and supports self-esteem, and offers opportunities for social engagement. Work may bring patients and their families additional income.

Current approaches place patients into productive activity rapidly as psychosis is controlled, in the hope of forestalling dependency and demoralization [112]. With team support, many patients successfully manage the challenges of school and work.

Individual resilience training

Patients in individual resilience training (IRT) ‘matter’—IRT focuses on their strengths and the achievement of their individual goals in recovery. Education about the psychotic episode and assistance in processing that experience are provided, and patients are taught strategies to prevent relapse. Overall functioning and illness management are approached through psychiatric rehabilitation techniques. Self-stigma and residual psychopathology are addressed through cognitive behavioural therapy techniques. Additional modules are available, as needed, to address SUD, traumatic experiences, and health maintenance. A training manual for IRT is available [113].

Comprehensive FEP treatment programmes—terminable or interminable?

At 5 years, that is, 3 years after 2-year FEP programmes have ended, the large differences between patients who participated and those relegated to TAU are attenuated, and at 10 years, the differences are undetectable [114]. Three- and 5-year treatment programmes provide extended advantages for patients over TAU [115, 116].

Schizophrenia is a chronic illness for which the standard of care should be chronic comprehensive treatment to prevent progressive decline [117]. Risk for relapse continues, and relapse prevention must be sustained. Deficits endure, and accommodations to support functioning must be sustained. Traumatic life experiences and medical illnesses accrue. Family members grow old. The tasks of clinicians are long and arduous but can be rewarded by assisting patients to sustain remission and experience productive and satisfying lives.

Diagnosis

Phenomenology

Phenomenology precedes diagnosis. Phenomenology reflects not only observed signs and symptoms, but also the subjective experience of the person with signs and symptoms. Further, phenomenology involves the interpretation of data obtained in the context of our current knowledge and prior theories. Based on phenomenology, this chapter analyses standard DSM and alternative non-DSM diagnostic approaches to mood disorders.

DSM-based definitions

The standard DSM-based definition for a depressive episode involves the occurrence of 2 weeks or more of depressive neurovegetative criteria, defined as the following: sleep alterations (insomnia or hypersomnia), appetite alterations (increased or decreased), diminished interest or anhedonia, decreased concentration, low energy, guilt, psychomotor changes (agitation or retardation), and suicidal thoughts. Along with depressed mood, the presence of four of eight of these criteria for 2 weeks or longer represents the standard definition of a DSM-5 ‘major depressive episode’.

If no manic or hypomanic episodes in the past are identified, then the diagnosis of a current major depressive episode leads to a longitudinal diagnosis of ‘major depressive disorder’ (MDD), which will be discussed in more detail later. Subtypes in DSM-5 for MDD are atypical features (which represent mainly increased sleep and appetite, along with heightened mood reactivity), melancholic features (defined by no mood reactivity, along with marked psychomotor retardation and anhedonia), and psychotic features (the presence of delusions/hallucinations).

Manic episodes are defined as euphoric or irritable mood with three or more of seven manic criteria, as follows: decreased need for sleep with increased energy, distractibility, grandiosity or inflated self-esteem, flight of ideas or racing thoughts, increased talkativeness or pressured speech, increased goal-directed activities or psychomotor agitation, and impulsive behaviour (such as sexual impulsivity or spending sprees). If such symptoms are present for 1 week or longer with notable functional impairment, a manic episode

is diagnosed, leading to a DSM-5 diagnosis of type I bipolar disorder. If such symptoms are present for at least 4 days, but without notable functional impairment, a hypomanic episode is diagnosed. If not a single manic episode had occurred ever, but only hypomanic episodes are present, along with at least one major depressive episode, then the DSM-5 diagnosis of type II bipolar disorder is made.

If manic symptoms occur for less than 4 days, or if other specific thresholds are not met for manic or hypomanic episodes, then the DSM-5 diagnosis for such bipolar-like conditions is ‘unspecified bipolar disorder’.

Manic episodes can be characterized by psychotic features (presence of delusions/hallucinations). If psychotic features are present, then hypomania cannot be diagnosed (since such features involve notable impairment by definition). Similarly, if a patient is hospitalized, irrespective of duration of manic symptoms, a manic episode is diagnosed, not a hypomanic episode, again because hospitalization involves notable functional impairment by definition.

If manic or hypomanic episodes are caused by drugs (like antidepressants), then the diagnosis of bipolar disorder is still made in DSM-5. This is an important change from DSM-IV where antidepressant-related mania/hypomania was viewed as an exclusion factor, which could not be used to diagnose bipolar disorder. Extensive research in the last two decades has shown that this DSM-IV exclusion is not supported scientifically and that mania/hypomania occur with antidepressants almost exclusively in persons who have bipolar illness, rather than in unipolar depression [1, 2].

Non-DSM-based definitions

In a non-DSM based approach to diagnosis, beginning with the phenomenology of mood disorders, an initial observation is that these conditions are not primarily disorders of mood. The term ‘mood disorders’ is a misnomer, if interpreted, as is commonly the case, to mean that mood is central to diagnosis. In fact, mood is variable in the phenomenology of these conditions, and the most consistent clinical features for diagnosis are psychomotor changes. One can have depression without any sad mood at all; instead anhedonia is present. One can have mania without any euphoric mood at all; instead irritability is present. Classically, depression was characterized by the slowing down of one’s thoughts, feelings, and movements. In other words, depression

involved psychomotor retardation. Classically, mania was characterized by the speeding up of one's thoughts, feelings, and movements. In other words, mania involved psychomotor activation. Thus, psychomotor aspects can be seen as central to these conditions [3, 4].

It might be suggested therefore that these conditions should not be called mood disorders, a term which was instituted officially by DSM-III in 1980. The older term 'affective' disorder captures some of the larger context of the phenomenology of these conditions. Some have suggested another phrase, like 'mood and movement' disorders [5], be used instead to capture the importance of the motor aspects of these conditions.

The term 'disorder' also can be questioned. It is another official term instituted by DSM-III in 1980, with the conscious intention of being 'neutral' as to aetiology. This neutrality, however, can come at the expense of clarity. The term 'disorder' is intentionally vague—some interpret it biologically to reflect a disease concept; others interpret it psychologically to reflect thought patterns or emotional experiences from the present or past; still others view it socially as reflecting medical interpretations of social conflict. The range of affective conditions is broad enough that it includes disease entities, as well as social problems and some forms of psychological developmental changes. All these varieties of affective conditions are conflated into one word with many meanings.

Mixed states

The most common approach to the description of the phenomenology of mood conditions contrasts depression and mania. While this clinical distinction can and should be made, it is not easy to make. It also is important to acknowledge that the phenomenology of mood conditions involves the frequent, if not usual, admixture of manic and depressive symptoms at the same time—called mixed states. In this scenario, a full-blown clinical depression may be present, but some manic symptoms may also be present such as rapid thoughts, increased sexual drive, and marked anger and mood lability. Thus, one can think of mood episodes on a spectrum from pure depression to pure mania, with many mixed states in between (Fig. 66.1).

Another variety involves classic psychomotor retarded depression, lasting weeks to months, interspersed with very brief bursts of manic symptoms lasting hours to days. A third variety involves a full-blown manic episode, but with the presence of sad mood or suicidal thoughts or other potential depressive symptoms such as guilt or low self-esteem.

When defined in this manner broadly, mixed states have been reported to be the most common presentation of mood states [6]. This broad definition includes concepts such as agitated depression and dysphoric mania. If defined in this way, mania and depression would be seen as uncommon pure variants of mood states, while the most common mixed states are a mixture of two.

Fig. 66.1 The mood episode spectrum.

If this phenomenology is correct, then it has important implications for the classification of diagnoses. The current diagnostic system is based completely on the distinction of depression and mania. If manic vs depressive states cannot be distinguished in most cases, then the current diagnostic system would be very difficult to implement validly. Put otherwise, the frequent presence of mixed states would invalidate the diagnostic system built on a mania vs depression dichotomy.

Psychosis

Classically, the key controversy in the phenomenology of mood disorders involved psychotic conditions like schizophrenia. This past debate thankfully has yielded to a gradual consensus, as the conceptualization of schizophrenia has evolved to a chronic and constant disease of delusions or hallucinations. This view, which dates back to Kraepelin, still is challenged at times, though often with a misinterpretation of Kraepelin's view of manic-depressive illness (MDI). His original MDI concept involved the basic idea that psychotic symptoms, if present, were not constant. They came and went. In contrast, psychotic symptoms were present in dementia praecox all the time. Kraepelin can be misinterpreted to hold that mood conditions recover completely forever. Then contemporary critics point to the fact that long-term symptoms are present in mood disorders, as in other chronic conditions like schizophrenia. In fact, the Kraepelinian view was simply that mood episodes are episodic, which means they have a beginning and an end. This episodicity does not imply that once an episode ends, there will never be any future episodes, that is, that the patient is 'recovered' forever. It implies that acute episodes end and temporary recovery occurs, unlike schizophrenia where acute exacerbations merge into chronic psychosis. Recurrence, not permanent recovery, was the essential feature of MDI [7]. In sum, the distinction between mood vs psychotic conditions can be made well by focusing on recurrence vs chronicity of symptoms. Cross-sectionally, as Kraepelin always held, they can look the same. The clinical picture of schizoaffective illness raises the question of occasional overlap between psychotic and affective conditions, which we will discuss later in this chapter.

Temperament

The concept of affective temperaments dates back at least 200 years and was systematized about a century ago by Emil Kraepelin and Ernst Kretschmer. In Kraepelin's texts, we read about 'manic temperaments' and 'depressive temperaments' [8]. Kretschmer developed these concepts [9], which eventually led to the concepts of hyperthymia and dysthymia, respectively. The main idea is that manic and depressive states present not only in episodes of attacks of severe symptoms, but also as mild symptoms that are present all the time, as part of the baseline personality of an individual. Thus, temperaments can be defined as mild versions of mood states, but they go beyond that initial concept to include basic differences in personality traits and in energy levels, as expressed in sleep patterns and behaviours such as sexual and social or work-related activities. Hence, the following brief descriptions apply [10]:

Hyperthymia involves a mild manic state as part of one's basic temperament. Such persons are high in energy, need less sleep than most people (often 4–6 hours nightly), have high sex drives, and are highly social, extroverted, often workaholics, and frequently humorous. They are described as the life of the party, as fun-loving,

and can engage in risk-taking behaviours that others avoid such as skydiving or bungee-jumping or motorcycle or airplane flying. They dislike routine and are spontaneous. They can be quite anxious and inattentive.

Dysthymia is the reverse, a mild depressive state as part of one's basic temperament. Such persons are low in energy, need more sleep than most people (often 10–12 hours nightly), have low sex drives, and are socially anxious, introverted, low in work productivity, and not humorous. They avoid risk-taking behaviours, are devoted to routine, and can be obsessive. They can be quite anxious, but not usually inattentive.

Cyclothymia involves constant alternation between mild manic and depressive states on a day-to-day, or a few days at time, basis. Such persons go up and down in mood and energy and activity levels, though they can be generally mostly extroverted and productive and social. They tend to be risk-takers at times and are unpredictable and spontaneous. They can be quite anxious and inattentive.

In the original view of Kraepelin and Kretschmer, these temperaments are mild variations of MDI. They are not separate or independent diseases or disorders, as the DSM system sets them up. They are part of the same condition, just mild versions, '*formes frustes*', as in the French term. This is no different than saying that mild adrenal insufficiency is related to, but not the same as, Addison's disease or that mild hypothyroidism is related to, but not the same as, Graves' disease. Affective temperaments are different in severity, but not in kind from severe depressive or manic illness.

This perspective differs from the DSM-III-based view of dysthymia and cyclothymia as 'axis I' conditions, rather than aspects of personality. Further successive DSM revisions have ignored hyperthymia completely. A useful resource is the TEMPS (Temperament Evaluation scale from Memphis, Pisa, and San Diego) scale, which is the most validated research scale to assess affective temperaments. As an aid to clinical diagnosis, a short self-report TEMPS scale can be invaluable [11].

Insight and the diagnostic process

A major aspect to the diagnosis of affective illness is the psychopathology of insight. In general, insight is preserved in depression, and impaired in mania [12]. Specifically, about one-half of patients with severe mania and the majority of patients with hypomanic states deny having those symptoms despite the actual presence of those symptoms observed by researchers. Further, insight appears to have a U-shaped curve in relation to severity; it is most impaired in hypomania and in severe mania but may be more present in moderate states of mania.

Since patients realize they are depressed but are often unaware that they are having hypomanic or manic states, they will present to clinicians complaining of the former and ignoring or denying the latter. Hence, clinicians may misdiagnose such patients as being depressed, rather than manic or mixed, or as having unipolar depression, as opposed to bipolar illness.

There are many reasons for the problem of lack of insight in mania. Part of the phenomenon probably is biological, with frontal or parietal function being affected in the manic state. Such lack of insight is known to occur in parietal lobe strokes and in association with frontal lobe injury, as well as other diseases such as Alzheimer's dementia and schizophrenia [13]. In addition to this biological basis, insight may be further impaired because of the cultural impact of

stigma against manic states, as well as simple lack of knowledge about such states.

To address this problem of insight and misdiagnosis, it is important to include family members and/or friends in the diagnostic interviews and even in treatment sessions, so as to get information from more than one source. While patients and family members report depressive symptoms equally, family members report manic symptoms twice as frequently as patients [14].

The patient, in short, is not a sufficient source of information to make diagnoses of affective illness. Confidentiality is not relevant, since at this stage the clinician is gathering information, not divulging it. It is a common clinical error to refuse to engage with family at the outset of a treatment relationship. This mistake, which is not needed to protect confidentiality, will lead to misdiagnosis in many patients.

In addition to obtaining information from outside sources, clinicians should use interviewing methods that take into account patients' natural inclination to deny manic symptoms. Generally speaking, it is best not to ask patients about manic criteria directly, but rather to ask open-ended questions that would capture those criteria. This way, the patient would report manic symptoms spontaneously without realizing that they are doing so. An example might be: 'Other than your depressive states, have you had periods of time where you felt the opposite?' Patients tend to want to discuss their depressive states in detail. Clinicians can begin the interview by allowing such discussion and by going into detail to understand the features of the depressive states. Assessment of manic states should be left to later in the interview. Further, even if specific manic or hypomanic episodes are denied by patients, the clinician should then turn to family members present and ask them about the same symptoms. If all episodic symptoms are denied by both patient and family, then the likelihood of misdiagnosis of bipolar illness is lowered notably.

Even then, clinicians should ask patients and family about their baseline temperament, to identify possible hyperthymia or cyclothymia. Again, open-ended questions are more likely to receive accurate answers: 'Tell me what your personality is usually like, when you're not depressed? What's your usual energy and activity level?'. Since 'energy' is a vague concept, it is useful to be specific about sleep—not just whether the patient feels it is adequate or not, but the actual time one goes to bed, the time one wakes up, and the quality of sleep during that time. Whether energy is high or low should not be based on the patient's opinion alone, again, but also based on the observation of family and friends, and also compared to the norm of the patient's peers.

Biological aspects of diagnosis

It is stated often that there are no valid biological 'markers' for psychiatric diagnosis. This statement is oversimplified. In the case of affective conditions, there are some biological testing methods that can be relevant to a more accurate diagnosis. Among these, the most important method is assessment of genetics via family history, but also in various settings, important evidence is relevant from neuroimaging, EEG testing, and neuropsychological testing.

Family history is very important in the diagnosis of mood conditions since bipolar illness is highly genetic, almost completely so based on twin studies, while DSM-defined MDD is much less genetic [15]. Further, other differential diagnostic conditions, like

personality disorder, also have much lower genetic heritabilities, based on a meta-analysis [16], than bipolar illness. Thus, a positive family history for bipolar illness is diagnostically important and rather specific for that condition. The absence of such family history needs to be investigated, rather than simply being accepted as reflecting no such family history. This is the case because bipolar illness, and MDI in general, have been proven to be underdiagnosed for at least half a century or longer [17]. Thus, even if family members sought psychiatric or medical diagnosis, the statistical probability would be that bipolar or manic conditions would be diagnosed less frequently than would have been truly the case. Further, social stigma is high now, but was even greater in previous generations, and is greater in non-Western cultures, all of which may be reflected in the absence of family histories for mood conditions in prior generations or in other cultures.

Neurological evaluation can inform diagnosis, specifically EEG, neuroimaging, and neuropsychological testing. These tests tend to be informative for mood conditions in a way that is different than how they are used for neurological diagnoses. For instance, EEGs are often seen as within the normal range if there is no epileptiform activity, but spiking or slowing of EEG activity has been associated with mood conditions, depending on location and laterality [4]. In general, it has been found that right temporal abnormalities are associated with depression, and left temporal abnormalities with mania. Quantitative EEG may be more sensitive to such mild abnormalities, as compared to standard EEG [4]. On neuroimaging, depression has been associated with hippocampal atrophy, and mania with amygdala enlargement, among other changes [18]. Further, white matter infarcts, often dismissed as variants of normal, are common and specific to vascular depression [19].

Perhaps the most common, and most misused, diagnostic test is neuropsychological testing. Misuse of such testing occurs when a cognitive function is identified immediately with a diagnosis; for example, attentional impairment is quantified and then ‘diagnosed’ as attention deficit disorder (ADD). In fact, attentional impairment can occur because of either depression and mania [20]. Neuropsychological testing is a snapshot in time and thus reflects the current mood state, rather than the longitudinal diagnosis. It can provide corroborative evidence for mood diagnoses or other cognitive conditions though. For instance, learning disabilities or IQ abnormalities can be identified. The pattern of abnormalities can suggest right vs left hemisphere dysfunction, which, combined with quantitative EEG and/or MRI, may support a pure depressive vs a bipolar diagnosis, with a predominance of left hemispheric abnormalities for manic or bipolar states, as opposed to right hemispheric abnormalities for pure depressive states.

Classification

Current classification of mood disorders

The current classification of mood disorders is based on the *Diagnostic and Statistical Manual of Mental Disorders*, the fifth edition of which (DSM-5) was published recently in 2013 [21]. Changes in DSM-5, compared to DSM-IV, were minimal for mood disorders. Specifically, for the diagnosis of a manic episode, a requirement for increased energy was added to the prior criterion of decreased need

for sleep. This requirement is redundant because the entire concept of decreased *need* for sleep implies increased energy. Nonetheless, the energy criterion was made explicit. For MDD, no changes beyond minor modifiers have been made since the basic criteria were set with DSM-III in 1980.

The most important change in DSM-5 was not to the criteria for manic or depressive episodes, but rather to the modifier for ‘mixed features’. The change here was that the prior mood episode definition for ‘mixed episodes’ was dropped, and the concept was moved to become a modifier for manic or depressive episodes. Thus, in DSM-5, mixed episodes are replaced with the terms ‘Bipolar disorder, current manic episode with mixed features’ or ‘Bipolar disorder, current depressive episode with mixed features’ and, importantly, ‘MDD, current major depressive episode with mixed features’. Thus, for the first time, a DSM revision acknowledges the diagnostic relevance of manic symptoms in persons who do *not* have bipolar disorder, that is, MDD with mixed features, which will be discussed further.

The DSM-5 concept of mixed features is defined as the presence of non-overlapping mood symptoms from the opposite mood states. Thus, a depressive episode would be said to have mixed features if multiple manic symptoms were present, excluding distractibility and irritability and agitation, which are considered ‘overlapping’ symptoms since they are part of the definition of a major depressive episode as well. The critique has been made that these overlapping symptoms are exactly those symptoms that are most common in mixed states; thus, excluding them would be like saying that one could not use the symptom of headache to diagnose migraine, since pain in the head overlaps with other non-migraine headache syndromes [22].

Critique of DSM-based classification

Besides specific issues related to mood conditions, as described in this chapter, DSM-based classification, in general, has been subject to criticism in recent years. The critiques that may have the most scientific merit are as follows.

DSM-based diagnosis is ‘pragmatic’ and is not based primarily on scientific studies. Leaders of DSM-III, IV, and 5 have been explicit that certain changes based on abundant scientific data, such as dimensions of personality traits, would not be included in official DSM diagnoses, while other definitions with very limited scientific data, like dysphoric mood dysregulation disorder, were included. These changes and failures to make change were based on judgments termed ‘pragmatic’, based on preferences of the psychiatric profession in the United States. This decision-making process may be utilitarian and socially needed, but it does indicate that scientific data are not the main sources of decision-making [23].

DSM-based diagnosis is overly conservative and resistant to change. The publication of DSM-5 in 2013 occurred with minor changes to DSM-IV overall (published in 1994), which also reflected little change from DSM-III (published in 1980).

As a corollary, DSM-based diagnosis impedes scientific research and hence retards progress in the profession [24]. This observation led the US National Institute of Mental Health (NIMH) in 2013 to direct that no future funded research should use DSM-based criteria. Alternative criteria—the Research Domain Criteria (RDoC)—have been instituted [25].

Non-DSM-based classification: manic-depressive illness and neurotic depression

The critique described is a rationale for being open to non-DSM-based classifications for mood conditions. Three major non-DSM approaches involve the diagnostic groupings of MDI, neurotic depression, and affective temperaments.

Manic-depressive illness

The central non-DSM-based classification of mood conditions is the pre-DSM III concept of MDI or the post-DSM definitions of mood spectra.

Manic depressive illness (MDI) was defined by Emil Kraepelin in 1898 and later editions of his textbooks, and used as thus defined for about century, until DSM-III in 1980. The Kraepelinian definition of MDI was that any recurrent mood episodes of any kind, depressive OR manic, constituted the diagnosis of MDI [7, 8, 26]. This is *not* the same thing as bipolar disorder, which became official with DSM-III, which meant the presence of depressive AND manic episodes, not depressive OR manic episodes. In other words, MDI meant bipolar illness *plus* unipolar depressive illness. It represented what is defined by DSM terms as bipolar disorder *and* most of MDD.

MDI was defined by *recurrence* of mood episodes as its diagnostic standard, not *polarity* of mood episodes. As long as recurrent episodes occurred, that is, they came and went and were repeated, the diagnosis was MDI. It did not matter if the diagnosis reflected 100 depressive episodes and zero manic episodes, or 100 manic episodes and zero depressive episodes. The diagnosis of MDI was the same in both cases. In other words, bipolar and unipolar courses were subtypes of the same illness, MDI, rather than two separate purported illnesses, as in the DSM system.

One reason that Kraepelin de-emphasized polarity and focused on recurrent course of illness was his observation, along with others, that most mood states were neither purely depressive nor manic, but rather mixed. Kraepelin defined six different types of mixed states, building on Weygandt [27], as opposed to the two pure depressive or manic states. Mixed states were the most common presentation of MDI, and thus it was not possible to define the illness by polarity, since most mood states were not at one pole or the other. DSM-III tried to ignore this problem away by refusing to define mixed episodes and by defining manic episodes very narrowly as being severe and lasting 1 week or longer. This definition, which conflicted with a large literature on mixed states and hypomanic episodes, was partially rectified by DSM-IV which accepted a definition of milder hypomanic episodes and introduced a definition of mixed episodes. However, hypomanic episodes were cut off at 4 days, without any scientific evidence for that cut-off duration, and mixed episodes were defined narrowly (requiring the presence of full syndromal mania and depression at the same time). DSM-5 has broadened the mixed definition somewhat, as noted, but it did not change the hypomania duration definition, despite the absence of evidence for the 4-day cut-off and the presence of some data supporting a shorter cut-off of 2 days [28]. Further, the definition of mixed states proposed by DSM-5 has been criticized as being conceptual primarily (focused on the concept of 'non-overlapping' symptoms), as opposed to extensive empirical evidence that most mixed states are broader and characterized primarily by psychomotor excitation—like rapid thoughts, marked rage/irritability, agitation, and impulsivity—added to

depressive features [22]. These empirically based mixed features are not part of the DSM-5 definition but are central to the non-DSM concept of mixed depressive and dysphoric manic states [29].

These DSM debates about duration of hypomania and definitions of mixed states are only relevant if the DSM distinction between bipolar disorder and MDD is accepted. If the older concept of MDI is accepted, then DSM controversies over details of mood states would not change the MDI diagnosis in any case.

Neurotic depression

Besides MDI, the other major non-DSM classification in mood conditions is neurotic depression [30, 31]. This diagnosis was made commonly before DSM-III in 1980, and it was targeted specifically for exclusion from DSM-III [32]. It was defined, as with MDI and unlike DSM definitions, primarily by its course, rather than cross-sectional symptoms; neurotic depression reflected a mood condition that was not severe, episodic, and recurrent—like MDI—but rather chronic, constant, but mild to moderate in severity. The mood symptoms were never manic, but rather depressed and anxious. Brief exacerbations could occur to higher severity, usually in the setting of psychosocial stress, but these periods of worsening were brief, usually days to weeks, followed by a return to a chronic baseline. In the United States, the terms 'neurotic and psychotic' were used in the mid-twentieth century loosely, based on psychoanalytic assumptions about the severity of repressed unconscious emotions. In Europe, the terms were used phenomenologically, with neurosis simply reflecting anxiety with some admixture of mild depressive symptoms, and psychosis reflecting the presence of delusions or hallucinations.

There was a robust debate about the validity of neurotic depression as a diagnosis in the 1970s, especially in the UK, but also in the United States [33]. Since the term was used differently in the two nations, the debate was not the same exactly. In the UK, neurotic depression became identified with 'exogenous' or 'reactive' depression, while psychotic depression was defined as 'endogenous'. Since MDI was always seen as a biological, and thus 'endogenous', disease, neurotic depression was seen in Europe as an entirely different kind of depressive condition than MDI. However, not all depressive episodes in MDI were psychotic, which led to the problem of how to differentiate non-psychotic depression in MDI (both bipolar and unipolar subtypes) from neurotic depression. In the UK debate, the focus was on the exogenous vs endogenous distinction, that is, on whether psychosocial stressors could be shown to differ in non-psychotic depressive states. As this factor was thrown into doubt based on research, the concept of neurotic depression was weakened accordingly. The definition of endogenous depression primarily based on the course of illness did not receive adequate attention though.

In the United States, the concept of neurotic depression fell into disfavour as being Freudian, even though it did not have psychoanalytic roots in Europe. In the course of DSM-III debates and decisions, as now documented in new historical research [32], the evolution of neurotic depression was as follows. It was replaced initially by the term 'minor' depression, as opposed to 'major' depression which was to be reserved for the more severe mood states of MDI (renamed bipolar disorder and unipolar major depressive disorder). Psychoanalytic groups in the United States objected to the term 'unipolar' as being seen as 'endogenous', and thus leading to likely drug, as opposed to psychotherapy, treatments. Those same

groups objected to the term ‘minor’ as likely to result in minor insurance reimbursement. Thus, all the proposed terms were lumped eventually into the diagnosis of ‘major depressive disorder’. There was still reluctance in the American clinical community to give up the term neurotic depression, so additional diagnoses were created or redefined—namely, generalized anxiety disorder and dysthymia—to compensate clinicians for giving up the concept of neurotic depression.

Affective temperaments

The third major non-DSM approach is the concept of affective temperaments, namely, dysthymia (constant mild depression), hyperthymia (constant mild mania), and cyclothymia (constant mild alternation between the two), as described previously. Using validated scale measures, about one-half of persons with mood conditions have an affective temperament [34]. Affective temperaments simply are milder versions of affective illnesses, as opposed to being categorically different conditions. A patient can have both unipolar depression and cyclothymic temperament, or bipolar illness and hyperthymic temperament. Indeed, genetic studies find that affective temperaments are quite frequent diagnoses in family members of persons with affective illnesses [35].

The concept of affective temperaments provides a dimensional approach to personality, with origins in affective illness, as opposed to the DSM-based categorical approach, with origins in psychoanalytic constructs. While the DSM revisions have recognized dysthymia and cyclothymia, those conditions have not been viewed as personality constructs, but as ‘axis I’ disorders, equivalent to bipolar illness or unipolar depression. This approach is not how those conditions have been defined and used for over a century. Further, DSM revisions have excluded and ignored the condition of hyperthymic temperament.

Like DSM-defined personality disorders, affective temperaments are present throughout life, persisting from childhood and adolescence. Thus, patients with cyclothymia have constant mood lability and impulsive sexuality, often interpreted as borderline personality, or constant problems with attention, often interpreted as attention-deficit/hyperactivity disorder (ADHD), as discussed in this chapter.

A post-DSM classification: spectrum concepts

After almost half a century of more research and clinical experience, one might ask how well DSM-based definitions of mood disorders have held up.

The main question relates to the radical distinction between MDI, as a single broad disease, vs two different and separate bipolar and unipolar conditions. The bipolar/unipolar dichotomy was justified in the 1970s, leading up to DSM-III, based on differences in the classic diagnostic validators of course, genetics, biological markers, and treatment response [36]. In other words, the claim that the presence or absence of manic episodes marked different diseases was supported by observations of differences in course, genetics, biology, and treatment between bipolar and unipolar groups. In particular, bipolar illness had an early age of onset (mean age of about 19 years vs about the late 20s for unipolar depression), brief depressive episodes (3 months or less, on average, in bipolar illness vs 6–12 months, on average, in unipolar depression), highly recurrent course (more frequent episodes in bipolar than unipolar illness, with rapid cycling, defined as four or more episodes yearly happening in about 25% of

bipolar illness cases, but in <1% of unipolar depression cases), genetic specificity (manic episodes were found in families of persons with manic episodes, but not in families of persons with unipolar depression), and differential treatment (antidepressants for unipolar depression vs neuroleptics and lithium for mania) [26].

In the intervening half century, all of these distinctions have been weakened and/or refuted. Regarding the course of illness, the common diagnosis of MDD in children, far below the mean onset of the late 20s, conflicts completely with the rationale that bipolar illness and MDD differ on that course criterion. Brief depressive episodes that occur multiple times yearly are diagnosed in patients with MDD commonly [37], whereas such course of illness should be rare if MDD was a different illness than bipolar disorder. Genetic studies have found high rates of depressive episodes, without mania, in persons with bipolar illness, and also frequent occurrence of bipolar illness in relatives of those with unipolar depression [35, 38, 39]. Treatment now overlaps considerably, with neuroleptic agents proven effective not only for mania, but also for depression, both in bipolar and unipolar types [40, 41]. Lithium has been well known to be effective not only for mania, but also for depression, both in bipolar and unipolar types [42, 43].

In short, the bipolar/unipolar distinction, now calcified in DSM-III through 5, has not been supported by further research in mood disorders and, in fact, research could be used to support the original MDI perspective of one broad mood illness.

Another perspective taken on this research would be to maintain the bipolar/unipolar dichotomy, but to recognize that it is not a strict distinction, but rather that there is one mood spectrum, with extremes of classic bipolar and unipolar cases, but with many cases in the middle of that spectrum. Some have called this concept a ‘bipolar spectrum’ [44] or a ‘manic–depressive spectrum’ (Fig. 66.2).

One might also refer to an ‘MDD spectrum’ which captures the different subtypes of depression described in this chapter, all of which were lumped together in DSM-III into one broad MDD category.

Such views would incorporate both the original MDI concept and the later observations of bipolar and unipolar variations [45] (Fig. 66.3).

The DSM approach to diagnosis generally is opposed to spectrum concepts, on a priori ‘pragmatic’ grounds of wanting to have a high threshold for psychiatric diagnosis to avoid ‘overdiagnosis’ [46]. Separate from the fact that this belief reflects stigma against psychiatric illness, it is not based on empirical evidence, but rather reflects a conceptual assumption. For that reason, the scientific evidence supporting spectrum concepts in mood disorders was rejected in the DSM-5 process.

Any future change likely will await a move away from the DSM process of diagnostic criteria towards something different, such as new research-based clinical criteria for diagnosis.

Differential diagnosis

The differential diagnosis of mood conditions involves distinctions within the mood dichotomy (bipolar vs unipolar) and distinctions with other conditions based on overlapping symptoms such as personality changes (borderline, antisocial, narcissistic personality disorders), delusions or hallucinations (schizophrenia and/or

Unspecified BP is DSM terminology for bipolar aspects of a case that do not meet mania or hypomania criteria, such as recurrent depressive episodes with underlying hyperthymia, or recurrent depressive episodes with a first-degree relative with bipolar illness.

Fig. 66.2 The manic-depressive spectrum.

schizoaffective illness), and cognition (ADD). An important aspect to approaching differential diagnosis is the concept of a diagnostic hierarchy, which has been rejected by DSM nosology. In the hierarchy approach, diagnoses with multiple symptoms should be diagnosed preferentially to diagnoses with fewer symptoms [47]. Thus, pneumonia would be the only diagnosis in a case of fever with lung infection, as opposed to 'fever disorder' comorbidity. Since mood disorders cause personality changes, delusions, and cognitive effects, they should be diagnosed, instead of assuming the presence of personality disorders, schizophrenia, and/or ADD. Further, the assumption of 'comorbidity', which is encouraged by the DSM approach, would be challenged by a hierarchy concept. Multiple diagnoses would not be made, unless other symptoms could be shown to exist, independent of the mood condition.

Within the mood dichotomy: unipolar vs bipolar

In the DSM polarity-based nosology of mood disorder, the differential diagnosis of unipolar vs bipolar illness rests completely on the identification of manic or hypomanic episodes. Most patients present for treatment in the depressive phase; thus, the differential diagnosis rests entirely on past manic/hypomanic episodes. As noted, patients deny having manic episodes about half the time, due to lack of insight. Such impaired insight is even worse in hypomania. Thus, in most cases, patients will deny manic/hypomanic episodes, leading to underdiagnosis of bipolar illness and overdiagnosis of MDD, which has been shown empirically [17]. Interviewing should include family and friends, who report manic symptoms more accurately than patients, to correct for this diagnostic bias. Patient self-report is not sufficient to rule out past manic/hypomanic episodes.

A non-DSM-based approach would emphasize all diagnostic validators, including the course of illness and genetics, and not just symptoms, to differentiate bipolar vs unipolar depression. The

depressive states themselves are somewhat different, with more melancholia, mixed states, and delusions/hallucinations in bipolar than unipolar depression [48]. Family genetics of bipolar illness would argue against the legitimacy of diagnosing MDD in a depressed person. A course of illness with early age of onset (that is, 20 years or earlier), brief depressive episodes (3–6 months or less), and high recurrence (multiple depressive episodes yearly) all would argue for the diagnosis of bipolar illness and against unipolar depression [26].

The therapeutic relevance of this distinction is that antidepressants appear to be mostly ineffective in acute bipolar depression [49] and in prophylaxis [50]. They also can cause acute manic/hypomanic episodes [51] and, more importantly, have been shown to worsen the long-term course of bipolar illness in some subjects, especially those with a rapid-cycling course [52]. In rapid-cycling cases, randomized data show that more mood episodes, including depressive states, occur over time with antidepressants than if those agents are discontinued or foregone altogether [53].

Personality disorders

Borderline, narcissistic, and antisocial personality disorders

Bipolar illness and borderline personality share some features and differ in others. Shared features include rapid mood swings, unstable interpersonal relationships, impulsive sexual behaviour, and suicidality. DSM-III through 5 criteria for borderline personality are met with the four criteria described, along with one more out of nine total criteria. Thus, using DSM definitions, most persons with bipolar illness would meet borderline criteria automatically. This apparent 'comorbidity' is questionable due to overlapping diagnostic definitions. As examined in a review [54], true comorbidity would be definable with the other five borderline criteria which are less common in bipolar illness, especially dissociative states and self-mutilations. If sexual trauma is added, which is not even one of the DSM criteria for borderline personality, then it has been shown that specific differentiation of bipolar illness from borderline personality is feasible. Further, the presence of bipolar family genetics would strongly argue for bipolar illness and against borderline personality, with the former being about twice as heritable genetically than the latter.

When manic, or as part of hyperthymic or cyclothymic temperament, persons with bipolar illness have high self-esteem, which can get reflected in lack of empathy towards others and a range of selfish behaviours. If seen through a Freudian and DSM-based lens, many clinicians misdiagnose such persons as having narcissistic personality disorder (NPD), characterized by a pervasive pattern of grandiosity, a need for admiration, and low empathy. This approach would ignore the diagnostic validators that would support mood illness,

Fig. 66.3 The major depressive disorder (MSD) spectrum.

such as family bipolar genetics, and other manic symptoms that are irrelevant to NPD such as high energy levels and decreased need for sleep. It is relevant that NPD has been invalidated by research with diagnostic validators, being unable to be distinguished from multiple other personality disorders (that is, borderline, histrionic, dependent, antisocial) [55]. The DSM-5 Personality Disorders Task Force recommended the removal of NPD, but this recommendation was rejected by the APA Board of Trustees. Thus, the scientific legitimacy of NPD as a diagnosis is questionable.

In contrast, antisocial personality has been diagnosed and validated for a century or more in psychiatry. Again, there is overlap with manic behaviours, which can be aggressive and impulsive, leading to legal troubles. If those behaviours are viewed solely from a social perspective, the antisocial diagnosis may seem relevant. Such an approach would be corrected if other diagnostic validators were taken into account, again emphasizing family bipolar genetics, but also the course of illness with different behaviours in and out of mood episodes, as well as the presence of other manic symptoms that are irrelevant to antisocial personality such as high energy levels and decreased need for sleep.

Schizophrenia/schizoaffective illness

When delusions or hallucinations are present, the differential diagnosis of mood conditions includes schizophrenia and schizoaffective illness. Delusions or hallucinations occur in about one-half of manic states and in about 10% of depressive states, somewhat more in bipolar than unipolar illness [56]. When present, such symptoms are qualitatively similar to the delusions or hallucinations of schizophrenia and thus can be mistaken for the latter. Further, negative symptoms of schizophrenia like apathy, lack of affect, low energy, and social isolation can appear like symptoms of depression episode. In both conditions, cognitive impairment is present. This misdiagnosis was common throughout the twentieth century, when schizophrenia was diagnosed cross-sectionally by the presence of delusions/hallucinations (as Eugen Bleuler popularized), as opposed to longitudinally by a chronic declining course (as Emil Kraepelin taught). This course was key, in the Kraepelinian view—dementia praecox was chronic and MDI was episodic. The Bleulerian view was disproved by the seminal United States–U.K diagnostic project and other research, which led to the return to the Kraepelinian course criterion with DSM-III in 1980 [57].

Some recent genetics studies indicate common genetic aetiologies for schizophrenia and affective illness, which some interpret as challenging the nosological dichotomy. Other genetic studies differentiate the two basic diagnostic groupings, as do other diagnostic validators such as course and neuroimaging [58, 59].

Some patients share features of both conditions, defined in the DSM system as schizoaffective disorder. Various studies of the classic diagnostic validators suggest that schizoaffective illness does not breed true and does not appear to represent a valid third psychotic disease [60]. Instead, it likely is sometimes a more severe variant of affective illness and sometimes a less severe variant of schizophrenia. In some cases, it could represent the chance comorbidity of schizophrenia and affective illness in the same person.

Attention deficit disorder

Depressive and manic states are characterized by impaired concentration, as well as executive function impairment, and

abnormal working and short-term memory [61]. These cognitive states are also present in ADD, leading to the diagnosis of ADD in persons who have manic and depressive symptoms. This misdiagnosis would be common, especially in hyperthymia and cyclothymia, where chronic problems with attention are present due to constant manic and depressive symptoms. Using the hierarchy concept, such persons would be diagnosed preferentially as having mood conditions; using DSM definitions, the comorbidity of both diagnoses would be asserted. In contrast to bipolar illness definitions, which have remained restrictive, DSM-5 broadened the diagnosis of childhood ADD, requiring fewer criteria to be met and extending the age of onset range from a maximum of 6 years to 12 years. DSM-5 also formalized a definition of ADD in adulthood as well.

Again differential diagnosis would be assisted by attention to all diagnostic validators, not just symptoms; thus, family genetics of bipolar illness would argue against the ADD diagnosis, as would recurrent depressive episodes. Since amphetamines are used to treat ADD and they have been associated with worsening of manic states [62], as well neurotoxicity in animal studies [63], the differential diagnosis has important practical implications.

Epidemiology of mood disorders

Lars Vedel Kessing

Introduction

Unipolar depressive disorder and bipolar disorder are common mental diseases that impose a very high societal burden in terms of morbidity, mortality, lost productivity, and costs [1]. The Global Burden of Disease study, which is a comprehensive assessment of disability and mortality from diseases and injuries from 1990 and projected to 2020, highlights the importance of mood disorders for the world. Using the measure of disability-adjusted life years (DALYs), the World Health Organization (WHO) revealed that depressive disorder was the fourth leading cause of disease burden and bipolar disorder was the sixth leading cause in the world in 1990, and it was projected that, in the year 2020, depressive disorder would be the second leading cause of disease burden. In 2010, mental and substance abuse disorders accounted for 7% all DALYs worldwide, and within mental and substance abuse disorders, depressive disorder accounted for 40% and bipolar disorder for 7% of DALYs [2]. Together, mood disorders burden society with the highest health care costs of all psychiatric and neurological disorders [3]. One DALY represents the loss of a healthy year of life and aggregates the years of life lived with disability (YLDs) with the years of life lost (YLLs) due to premature mortality. In 2010, depressive disorders were the second leading cause of YLDs due to population growth and ageing [4]. These estimations have contributed to shifting international focus towards mood disorders as a leading cause of burden in its own right and also in comparison to more recognized physical disorders.

Mood disorders have received considerable attention in psychiatric epidemiology over the last 25 years. These received particular attention in the five-site United States National Institutes of Mental Health Epidemiologic Catchment Area Study (ECA), as well as in epidemiological studies in other countries around the world that used the ECA methodology. Mood disorders also received particular attention in the National Comorbidity Survey (NCS) in the United States, in the National Psychiatric Morbidity Survey of Great Britain, and most recently in the World Mental Health Survey (WMH) across many countries. Thus, there are substantial data from around the world on the epidemiology of these disorders. In addition, many of the population-based case registers and twin registries have also paid particular interest in mood disorders, and

some of these registers have the additional advantage of being able to consider genetic, as well as environmental, risk factors.

Depressive disorder and bipolar disorder hold large similarities in pathogenesis, course of illness, and outcomes, and it is estimated that approximately 1% of patients convert from depressive disorder to bipolar disorder per year as patients develop hypomanic or manic episodes [5, 6], approximating 20–40% during the lifetime course.

Bipolar disorders

Diagnostic issues

While classical bipolar disorder, with episodes of euphoric mania interspersed with episodes of depression, is one of the clearest clinical syndromes in psychiatry, the boundaries of bipolar disorder remain contested. As case definition is central to epidemiology, all the contested boundaries of bipolar disorder could influence prevalence rates and our understanding of risk factors. Some of the major boundary issues for bipolar disorder include the overlap of bipolar disorder with psychotic features with schizoaffective disorder and schizophrenia, and the overlap of bipolar disorder with unipolar depressive disorder when patients who present primarily with depression have brief or mild episodes of hypomania. There is also an overlap of bipolar disorder with apparent personality disorder, especially Cluster B personality disorders such as borderline and narcissism, and the issue of when hyperthymic personality merges into bipolar disorder. When bipolar disorder is comorbid with alcohol or substance abuse, there are also important diagnostic issues.

Another important issue in determining caseness of bipolar disorder for epidemiological surveys is symptom pattern and duration. A number of the diagnostic instruments for assessing bipolarity in population surveys limit the questions on mania to a type of symptom profile characterized by euphoria, grandiosity, increased energy, and decreased sleep. Whether the commonly used epidemiology interviews adequately detect those individuals who have manic episodes, characterized by irritability, anger, and activation, is very debatable. The other key diagnostic issue is what criteria are used to categorize the minimum duration for hypomania; are 4 days too long? Are even 2 days too long? Furthermore, as insight is sometimes impaired in hypomania and mania, and as these are low-prevalence disorders,

the accuracy of case detection of bipolar disorders in populations remains an issue for further research.

Prevalence

Prior population studies, such as the ECA and its related cross-national studies and the NCS, reported that the lifetime prevalence of bipolar I disorder varied from 0.3% to 1.5% [7, 8]. More recent studies, such as the NCS replication study [9], reported data on both bipolar I and bipolar II disorders and found lifetime (and 12-month) prevalence estimates of 1.0% (0.6%) for bipolar I, 1.1% (0.8%) for bipolar II, and 2.4% (1.4%) for subthreshold bipolar disorder. Broader definitions of mania/hypomania have resulted in lifetime prevalence rates increasing to about 4% or even higher [10].

In bipolar I disorder, the prevalence in males and females is similar. This is in contrast to the reasonably consistent female excess found in bipolar II disorder and depressive disorder.

The incidence of bipolar I and II disorders is estimated to be 10–30 per 100,000 year (0.01–0.03% per year).

Comorbidity

In the NCS, all identified bipolar I individuals suffered from at least one, and often up to three or more, comorbid disorder. The most common comorbid disorders included the full range of anxiety disorders, alcohol and drug dependence, and antisocial behaviours.

Alcohol and drug abuse and/or dependence are commonly comorbid with bipolar disorder. Clinical studies find that bipolar patients with comorbid substance dependence are less adherent to prescribed mood stabilizers and have more frequent hospital readmissions. Stimulant abuse/dependence rates are especially increased in bipolar disorder.

Individuals with bipolar disorder have the full range of anxiety disorders, including phobias, panic disorder, and obsessive-compulsive disorder.

A controversial area of comorbidity with bipolar disorder is that of childhood attention deficit disorder. Early studies have suggested high comorbidity between attention deficit disorder and child and adolescent mania/bipolar disorder [11, 12], whereas longitudinal data [13–15], as well as studies with more careful diagnostic sorting of symptoms [16], have revealed lower comorbidity and supported the differentiation of child and adolescent mania/bipolar disorder from hyperkinetic disorder/attention deficit disorder. As argued by Arnold and colleagues, ‘Indeed, if one automatically count such symptoms as hyperactivity and impaired attention towards both disorders without noting association with mood episodes, and especially if one does not require episodicity for bipolar disorder it may artificially inflate the comorbidity rate’ [16]. In this way, longitudinal results seem to confirm the observation that even though the symptoms may not be so different between mania and attention-deficit/hyperactivity disorder (ADHD), the clinical presentation and illness course with an episodic course in bipolar disorder and a more chronic course in ADHD differ between the disorders [15, 17].

Risk factors for bipolar disorders

In considering the risk factors for bipolar disorder, it is useful to separate risk factors into those that are risk factors for lifetime vulnerability (for example, genetic factors) and those that are risk factors for the onset of an episode of depression or mania (for example, life

events). Thus, in determining the risk factors for lifetime vulnerability, genetic factors constitute the largest single risk factor. Bipolar disorder is one of the psychiatric disorders with the highest heritability at about 70–80%.

However, if one is considering who is vulnerable to an episode of mania over the next 6 months, genetic factors will play a relatively smaller part and predictions may be best based on other factors such as past history, childbirth, the presence of subsyndromal affective symptoms and cognitive deviances, being treated for depression with antidepressant medication, and the approach of spring or summer.

Although organic factors, such as some types of central nervous system damage, are unusual risk factors in young adults, in late-onset bipolar disorder (age of onset more than 50 years), organic disease of the central nervous system is an increasing factor for the development of mania.

Age of onset and course of illness

Early-onset bipolar I disorder is more familial and is associated with a higher genetic load. Different population studies show that the mean age of onset of bipolar disorder varies from 17 to 30 years, but there seems to be differences between Europe and the United States. European data suggest a mean age in the late twenties, whereas United States data suggest a mean age in the early twenties. Reasons for these substantial differences are not known but may include greater genetic loading due to a higher risk of affective illness in those who migrated from Europe to the United States, a higher rate of assortative mating in the United States, as well as various genetic mechanisms, including anticipation and gene–environment interactions that may also differ in importance between the United States and Europe. Further, increasing overweight among children and adolescents has been suggested as a contributing factor being more prevalent in the United States.

Nevertheless, as age of onset is not normally distributed, the mean is a slightly misleading variable, while the mean age of onset may be in the twenties; for a large proportion of patients, the age of onset are the teenage years.

The majority of first episodes in bipolar I disorder are depressive; approximately 85% of patients have a depressive first episode, 10% a manic episode, and 3–5% a mixed episode. Typically, the duration of depressive episodes is between 2 and 5 months, although longer durations are often seen. The duration of manic episodes averages around 2 months.

Long-term studies suggest that the vast majority of patients with bipolar I disorder, approximating 90–100%, will develop more episodes after the first manic episode. The course of illness is heterogenous—some will develop few episodes, and some many—but, on average, the risk of recurrence increases with the number of prior affective episodes, suggesting a clinical progression of the illness [18, 19]. Long-term studies also show that despite treatment, patients with bipolar disorder type I or II suffer from affective symptoms of some severity approximately half of their lifetime. Over the course of illness, 80% of affective episodes are of the depressive type and 20% of the manic or mixed type. The presence of even milder affective symptoms is associated with decreased quality of life and functional and cognitive problems.

Social, functional, and cognitive outcomes

Approximately 40–60% of patients with bipolar disorder present with persistent cognitive deficits in the remitted state and across several cognitive domains, including attention, verbal learning, and executive function [20, 21]. Such cognitive deficits may be prevalent even among healthy relatives of patients with bipolar disorder or early in the course of illness. There is robust evidence from several studies that patients' persistent cognitive dysfunction is a key contributor to their socio-occupational disability, independent of mood symptoms [22–24]. Functional impairment is prevalent in bipolar disorder, with unemployment rates 4- and 10-fold higher than in the general population [25, 26]. Approximately two-thirds of the patients are unable to regain premorbid levels of social and vocational functioning following a single episode [25], and verbal memory and executive function seem moderately related to employment outcome [27].

Patients with bipolar disorder have 2–3 times increased risk of developing dementia in the long run [28–32], and there are some suggestions that the risk of developing dementia may increase with the number of episodes in patients with depressive disorder and those with bipolar disorder [33]. Long-term treatment with lithium may decrease the risk of developing dementia [34–36], further supporting a link between bipolar disorder and dementia.

Undiagnosed bipolar disorder and use of health services

There is often an interval between the onset of mood episodes and seeking help (on average 8–10 years), and it may take a decade for a bipolar patient to receive both the correct diagnosis and be prescribed mood-stabilizing medication, resulting in an extended period of untreated illness [37].

Receiving a correct bipolar diagnosis at initial assessment is complicated by few depressed patients seeking help for hypomanic/manic episodes and more seeking assistance only for their depressive episodes, while viewing any hypomanic/manic episodes as neither harmful or problematic nor particularly pathological. In combination with assessment nuances, this leads to an estimated 20–40% of bipolar patients being misdiagnosed as having a unipolar depressive disorder and administered antidepressant medication that can worsen the longitudinal course of bipolar disorder, principally by causing more switching or more mixed states [37]. Further, the proportion of undiagnosed bipolar disorder in epidemiological samples diagnosed with depressive disorder is high, quantified as up to half of identified depressive cases, depending on the sensitivity of the criteria from which bipolar disorder can be accurately recognized, as well as practice and referral nuances [37].

In the ECA study, 39% of those with bipolar I or bipolar II disorder received outpatient psychiatric treatment within 1 year and about 10% would receive inpatient treatment within a 6-month period. In the NCS study, 45% of those with bipolar disorder had received psychiatric treatment in the previous 12 months, although 93% reported lifetime treatment for their bipolar disorder. However, both of these studies suggest that more than half of individuals with bipolar disorder are not currently in psychiatric treatment.

Misdiagnosis or delayed help-seeking has been considered as a major contributor to poor outcome in bipolar disorder, with 80% of undiagnosed patients experiencing psychosocial problems impacting on their relationships, employment, finances, and health.

Further consequences of inappropriately treated bipolar disorder include an increased risk of suicide, longer hospitalizations, poorer social functioning, and general deterioration of the condition.

Use of pharmacotherapy
