Preface

This is the third edition of the textbook. We decided to rethink the size and content completely when planning this edition. Our sense was that a larger and larger archive of accumulated knowledge is no longer feasible or desirable in the digital age. We wanted to produce a single volume with a more defined point of view, that better reflects the challenge of the future.

Psychiatry is a medical specialty. Medicine took its origins in simple observation and classification and the serendipitous discovery of palliative treatments. The application of science has transformed much of medicine by providing an understanding of mechanisms of pathology. The scientific method provides the only way to reliable knowledge, and medical science is slowly developing rational treatments that are potentially curative. However, aside from treatable infections, we have a long way to go. The trajectory of medical advance in the practice of psychiatry has been slower than for other disease areas in recent years, but neuroscience is difficult. What underwrites our confidence in what is sometimes disparagingly described as the medical model is the fact that psychiatric disorders, especially severe disorders, have a genetic basis. Genetic risks are largely unidirectional and they are biological. They guarantee some kind of future biological explanation for the phenomena they describe. So if you decide that schizophrenia is a myth, a social construct, or a plot by psychiatrists to enhance their social status, you have to explain why its inheritance is what it is.

If, like us, you find the genetic data compelling, then you accept the grand challenge of working out the neurobiology of psychiatric disorder. We cannot know how quickly it will translate into improved treatments, but we think there are already promising developments from molecular biology and neuroimaging. Imaging has been particularly important because it has stimulated the development of a completely brain-based cognitive neuroscience. This is a major intellectual shift. Forty years ago, an experimental psychologist would have said that the brain was unimportant for the study of mental mechanisms and even less important for the development of psychological treatments. As this view changes, so the advances of neuroscience can be translated into patient benefit as scientifically guided psychotherapy.

Our authors are drawn from all over the world, and they illustrate the simple truth that science is universal. We thank them most sincerely for their efforts in bringing the project to completion.

The layout of the book

The content of chapters was not highly pre-specified, and the chapters themselves have not been edited for conformity with the editors'

views. They can be read as free-standing contributions. Accordingly, there is both overlap and divergence in how topics are covered, which will reflect the writers' priorities and interests.

In the previous edition of the textbook, the editors identified convergence as an important theme of the book. We are not convinced further convergence has occurred since 2001. Instead we have seen a surprising amount of divergence in the claims made about psychiatry. Our section on approaches to psychiatry reflects some of the key issues relating to the patient's perspective, stigma, the global challenge of mental disorder, practical ethics, and the foundations of psychiatry as phenomenology and a medical discipline. It further sets the scene for current controversies around diagnosis, psychopathology, evidence, and drug terminology.

The chapters in the section on the scientific basis of psychiatric aetiology and treatment provide simple introductions to the relevant disciplines that underpin our scientific understanding.

Individual disorders are covered in sections that follow the structure of the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5). DSM-5 was published in 2013. It had been envisaged that it would be possible to make major changes to the approach of DSM-IV. Thus, major advances in genetics, imaging, and neurobiology were widely expected to transform psychiatry, following the success of the human genome project and the decade of the brain. This transformation has not yet happened. Hence, DSM-5 (and the International Classification of Diseases, eleventh revision) follow a much more conventional, clinically led summary of how patients present with psychiatric disorder. We see no reason to deny the utility of symptom-based diagnoses and the consensus that created the current categories. However, the project of applying neuroscience to psychiatry has not failed, as has sometimes been implied by criticism of DSM-5. For these reasons, we have included chapters on genetics, neurobiological targets, and imaging in the sections of the book focused on specific disorders.

We have also included sections on service provision and forensic psychiatry because these are critical to the context in which psychiatric disorder is managed.

We thank the staff of OUP for their support and encouragement and Andy Richford who has been our project manager sans pareil.

Professor Michael Gelder (1929–2018)

Michael Gelder, one of the founding editors of the New Oxford Textbook of Psychiatry, sadly died in 2018. We dedicate this new edition of the book to Michael's memory.

Michael was the first WA Handley Professor of Psychiatry at the University of Oxford and founded the Department of Psychiatry in 1969. He led the Department for 27 years until he retired in 1996. Before arriving in Oxford, at the Institute of Psychiatry, Michael developed a treatment for anxiety based on desensitization, in which gradual exposure to the feared stimulus was coupled with physical relaxation. He described the first controlled trial of this psychological therapy in patients with severe agoraphobia in his seminal 1966 publication with Isaac Marks.

Michael possessed remarkable organizational abilities and leadership skills and he built a thriving Department of Psychiatry in Oxford with a particular focus on developing both psychological and physical treatments. This departmental focus continues into the present. When JRG interviewed him in 2018, very shortly before he died, Michael admitted to being particularly proud of the Department's development of cognitive behaviour therapy (CBT) under his leadership. These treatments include highly effective forms of CBT for anxiety disorders, post-traumatic stress disorder, chronic fatigue syndrome, and eating disorders. All have been widely adopted in clinical practice and have benefited enormous numbers of people worldwide. Michael also developed a psychopharmacology research unit based on powerful cross-departmental collaboration within the University. The unit has a strong track record of investigating the mechanisms of action of antidepressants and anxiolytics and its work has fundamentally shaped our understanding of the biology underlying psychiatric disorder.

Michael was also a committed and inspirational teacher and the driving force behind a successful series of psychiatry textbooks. The first, in 1983, was the *Oxford Textbook of Psychiatry* (now in its seventh edition). Translated into six languages, this became the standard textbook for psychiatric trainees. Then came the *Concise Textbook* (aimed at medical students and now in its fifth edition) and the current *New Oxford Textbook of Psychiatry* (targeted at postgraduates—this is the third edition).

As he passed the age of 80, Michael had finally retired from editing textbooks (although he was delighted that his colleagues continue to revise them!), but he closely followed the development of the Department. He will be greatly missed. Michael was a truly remarkable clinical academic, inspirational in his ability to combine research with clinical practice, teaching, and leadership.

Contents

Abbreviations xv

Contributors xxvii

SECTION 1

The subject matter and approach to psychiatry

1. **The patient's perspective** 3
Kay Redfield Jamison and Adam Ian Kaplin
2. **Public attitudes and the challenge of stigma** 6
Nicole Votruba, Mirja Koschorke, and Graham Thornicroft
3. **Global mental health** 12
Crick Lund, Dörte Bemme, and Judy Bass
4. **The history of psychiatry as a medical specialty** 23
Pierre Pichot and Guy M. Goodwin
5. **New ethics for twenty-first century psychiatry** 34
Matthew L. Baum, Julian Savulescu, and Ilina Singh
6. **Foundations of phenomenology/descriptive psychopathology** 42
Hans-Jürgen Möller
7. **DSM-5 and ICD-11 classifications** 51
Darrel A. Regier, David P. Goldberg, Bedirhan T. Üstün, and Geoffrey M. Reed
8. **The National Institute of Mental Health Research Domain Criteria: an alternative framework to guide psychopathology research** 62
Charles A. Sanislow, Sarah E. Morris, Jennifer Pacheco, and Bruce N. Cuthbert
9. **Application of research evidence in clinical practice** 73
Andrea Cipriani, Stefan Leucht, and John R. Geddes
10. **A neuroscience-based nomenclature for psychotropic drugs** 80
Guy M. Goodwin, Joseph Zohar, and David J. Kupfer

SECTION 2

The scientific basis of psychiatric aetiology and treatment

11. **Neurodevelopment** 91
Karl Zilles and Nicola Palomero-Gallagher
12. **Neuroimaging technologies** 101
Mark Woolrich, Mark Jenkinson, and Clare Mackay
13. **The connectome** 113
Olaf Sporns
14. **Neurotransmitters and signalling** 122
Trevor Sharp
15. **Psychoneuroimmunology** 135
Juan C. Leza, Javier R. Caso, and Borja García-Bueno
16. **Functional genomics** 144
Caleb Webber
17. **Cognitive neuroscience: principles and methods** 154
Anna Christina Nobre
18. **Ageing and the human brain** 170
Verena Heise, Enikő Zsoldos, and Klaus P. Ebmeier
19. **Development of brain stimulation** 183
Andrea Crowell, Patricio Riva-Posse, and Helen S. Mayberg
20. **Adherence to treatment in psychiatry** 193
Amy Chan and Rob Horne

SECTION 3

Intellectual disabilities

21. **Core dimensions of intellectual disabilities** 207
Anthony J. Holland
22. **Epidemiology and course of intellectual disabilities** 216
Sally-Ann Cooper

23. **Aetiology of intellectual disability and its clinical features** 223
Judith L. Rapoport, Dale Zhou, and Kwangmi Ahn
24. **Management and treatment of intellectual disability** 231
José L. Ayuso-Mateos and Cary S. Kogan

SECTION 4

Autism spectrum disorders

25. **Core dimensions of autism spectrum disorders** 239
Fred R. Volkmar and Scott L. J. Jackson
26. **Basic mechanisms and treatment targets for autism spectrum disorders** 246
Emily J. H. Jones
27. **Epidemiology of autism** 260
Charles R. Newton
28. **Genetics of autism spectrum disorders** 270
Abha R. Gupta, Thomas V. Fernandez, and Ellen J. Hoffman
29. **Imaging of autism spectrum disorders** 279
Christine Ecker and Declan Murphy
30. **Management and treatment of autism spectrum disorders** 289
Emily Simonoff

SECTION 5

Attention-deficit/hyperactivity disorder

31. **Core dimensions of attention-deficit/hyperactivity disorder** 301
Eric Taylor
32. **Basic mechanisms and treatment planning/targets for attention-deficit/hyperactivity disorder** 309
Barbara Franke and Jan K. Buitelaar
33. **Epidemiology of attention-deficit/hyperactivity disorder and the implications for its prevention** 318
Guilherme V. Polanczyk
34. **Genetics of attention-deficit/hyperactivity disorder** 327
Kate Langley and Anita Thapar

35. **Insights from neuroanatomical imaging into attention-deficit/hyperactivity disorder throughout the lifespan** 335
Philip Shaw and Eszter Szekely
36. **Management and treatment of attention-deficit/hyperactivity disorder** 344
Alessandro Zuddas and Sara Carucci

SECTION 6

Motor disorders

37. **Neurodevelopmental motor disorders** 357
Davide Martino and Antonella Macerollo

SECTION 7

Delirium, dementia, and other cognitive disorders

38. **Pathways of neurodegeneration underlying dementia** 373
Noel J. Buckley and George K. Tofaris
39. **Delirium** 382
Ravi S. Bhat and Kenneth Rockwood
40. **Alzheimer's disease** 395
Ivan Koychev and John Gallacher
41. **Frontotemporal dementias** 405
Akitoshi Takeda and Bruce Miller
42. **Prion disease** 414
Akin Nihat, TzeHow Mok, and John Collinge
43. **Dementia with Lewy bodies** 424
Anto P. Rajkumar and Dag Aarsland
44. **Dementia in Parkinson's disease** 435
Michele Hu and Fahd Baig
45. **Dementia due to Huntington's disease** 448
Russell L. Margolis
46. **Vascular cognitive impairment** 454
Joanne A. Byars and Ricardo E. Jorge
47. **Traumatic brain injury** 464
Christian Lepage, Inga K. Koerte, Vivian Schultz, Michael J. Coleman, and Martha E. Shenton

SECTION 8

Substance use disorders

48. **Substance use disorders and the mechanisms of drug addiction** 477
Trevor W. Robbins and Barry J. Everitt
49. **Genetics of substance use disorders** 492
Yann Le Strat, Nicolas Ramoz, and Philip Gorwood
50. **Alcohol use disorder** 498
Wim van den Brink and Falk Kiefer
51. **Opioids: heroin, methadone, and buprenorphine** 507
Michael Farrell, Briony Larance, and Courtney Breen
52. **Cannabis and mental illness** 519
David J. Castle
53. **Stimulants, ecstasy, and other 'party drugs'** 525
Adam R. Winstock and Remy Flechais
54. **Psychedelics and dissociative substances** 539
Adam R. Winstock and James Rucker
55. **Tobacco addiction** 546
Marcus Munafò and Meryem Grabski
56. **Co-morbidity of substance use and psychiatric disorders** 555
Julia M. A. Sinclair and Anne Lingford-Hughes

SECTION 9

Schizophrenia and psychotic disorders

57. **The core dimensions of schizophrenia** 565
Nancy C. Andreasen
58. **Epidemiology and course of schizophrenia** 574
Assen Jablensky
59. **Genetics of schizophrenia** 587
Kimberley M. Kendall, James T. R. Walters, and Michael C. O'Donovan
60. **Structural and functional neuroimaging of schizophrenia** 597
Andreea O. Diaconescu, Sandra Iglesias, and Klaas E. Stephan
61. **Schizoaffective and schizotypal disorders/acute and transient psychotic disorders** 609
William S. Stone, Stephen V. Faraone, and Ming T. Tsuang

62. **Delusional disorders** 619
Andreas Marneros
63. **Prevention and early intervention in psychotic disorders** 628
Emre Bora, Mahesh Jayaram, and Christos Pantelis
64. **Antipsychotic and anticholinergic drugs** 639
Herbert Y. Meltzer and William V. Bobo
65. **The treatment and management of patients with schizophrenia** 668
Joseph P. McEvoy, Kammarauche Asuzu, Daniel W. Bradford, Oliver Freudenreich, and Katherine H. Moyer

SECTION 10

Mood disorders

66. **Diagnosis, classification, and differential diagnosis of mood disorders** 681
S. Nassir Ghaemi and Sivan Mauer
67. **Epidemiology of mood disorders** 691
Lars Vedel Kessing
68. **Primary prevention of mood disorders: building a target for prevention strategies** 700
Gin S. Malhi

SECTION 11

Bipolar disorder

69. **Basic mechanisms of and treatment targets for bipolar disorder** 721
Grant C. Churchill, Nisha Singh, and Michael J. Berridge
70. **Genetics of bipolar disorder** 735
Francis J. McMahon and Sevilla Detera-Wadleigh
71. **Neuroimaging of bipolar disorder** 744
Mary L. Phillips and Wayne C. Drevets
72. **Management and treatment of bipolar disorder** 757
Eduard Vieta, Isabella Pacchiarotti, and David J. Miklowitz
73. **Perinatal psychiatry** 767
Ian Jones and Arianna Di Florio

SECTION 12

Depressive disorders

74. **Basic mechanisms of and treatment targets for depressive disorders** 779
Marcela Pereira, Roberto Andreatini, and Per Svenningsson
75. **Genetic epidemiology of depression in the molecular era** 789
Alison K. Merikangas and Kathleen R. Merikangas
76. **Imaging of depressive disorders** 797
Guy M. Goodwin and Michael Browning
77. **Management and treatment of depressive disorders** 807
Philip J. Cowen

SECTION 13

Trauma- and stress-related and adjustment disorders

78. **Classification and descriptive psychopathology of post-traumatic stress disorder and other stressor-related disorders** 819
Dean G. Kilpatrick, Matthew J. Friedman, and Amanda K. Gilmore
79. **Basic mechanisms of, and treatment targets for, stress-related disorders** 829
Bruce S. McEwen
80. **Genetics of stress-related disorders** 840
Michael G. Gottschalk and Katharina Domschke
81. **Imaging of stress-related disorders** 850
Navneet Kaur, Cecilia A. Hinojosa, Julia Russell, Michael B. VanElzakker, and Lisa M. Shin
82. **Primary prevention and epidemiology of trauma- and stress-related disorders** 860
Maria Bragesjö, Emily A. Holmes, Filip K. Arnberg, and Erik M. Andersson
83. **Management and treatment of stress-related disorders** 869
Leigh van den Heuvel and Soraya Seedat
84. **Bereavement** 879
Beverley Raphael, Sally Wooding, and Julie Dunsmore
85. **Recovered memories and false memories** 884
Deborah Davis and Elizabeth F. Loftus

SECTION 14

Anxiety disorders

86. **Core dimensions of anxiety disorders** 897
Nastassja Koen and Dan J. Stein
87. **Basic mechanisms, genetics, targets, and animal models for anxiety disorders** 905
Martien J. Kas and Berend Olivier
88. **Epidemiology of anxiety disorders** 917
Hans-Ulrich Wittchen and Katja Beesdo-Baum
89. **Genetics of anxiety disorders** 928
Michael G. Gottschalk and Katharina Domschke
90. **Neuroimaging of anxiety disorders** 938
Gregor Leicht and Christoph Mulert
91. **The primary prevention of anxiety disorders** 948
Aliza Werner-Seidler, Jennifer L. Hudson, and Helen Christensen
92. **Treatment of anxiety disorders** 961
David S. Baldwin and Nathan T. M. Huneke

SECTION 15

Obsessive-compulsive and related disorders

93. **Core dimensions of obsessive-compulsive disorder** 969
Sophie C. Schneider, Eric A. Storch, and Wayne K. Goodman
94. **Basic mechanisms of, and treatment/planning targets for obsessive-compulsive disorder** 976
Eric Burquière and Luc Mallet
95. **Obsessive-compulsive disorder** 987
Lior Carmi, Naomi A. Fineberg, Oded Ben Arush, and Joseph Zohar
96. **Genetics of obsessive-compulsive disorder** 995
Gerald Nestadt and Jack Samuels
97. **Imaging of obsessive-compulsive disorder** 1003
Rebbia Shahab and Emily R. Stern
98. **Management and treatment of obsessive-compulsive disorder** 1011
Naomi A. Fineberg, Lynne M. Drummond, Jemma Reid, Eduardo Cinosi, Lior Carmi, and Davis N. Mpavaenda
99. **Hoarding disorder** 1023
Lorena Fernández de la Cruz and David Mataix-Cols

100. **Body dysmorphic disorder** 1031
Megan M. Kelly and Katharine A. Phillips

SECTION 16

Feeding, eating, and metabolic disorders

101. **The eating disorders** 1045
Christopher G. Fairburn and Rebecca Murphy
102. **Basic mechanisms and potential for treatment of weight and eating disorders** 1048
Johannes Hebebrand, Jochen Antel, and Beate Herpertz-Dahlmann
103. **Epidemiology and primary prevention of feeding and eating disorders** 1059
Katherine A Halmi
104. **Genetics of feeding and eating disorders** 1065
Christopher Hübel, Cynthia M. Bulik, and Gerome Breen
105. **Imaging of feeding and eating disorders** 1075
Natalie Kurniadi, Christina E. Wierenga, Laura A. Berner, and Walter H. Kaye
106. **Management and treatment of feeding and eating disorders** 1087
Susan L. McElroy, Anna I. Guerdjikova, Nicole Mori, Paul L. Houser, and Paul E. Keck, Jr.
107. **Aetiology and management of obesity** 1096
Jamie Hartmann-Boyce, Nerys M. Astbury, and Susan A. Jebb
108. **Elimination disorders in children and adolescents** 1105
Alexander von Gontard

SECTION 17

Sleep-wake disorders

109. **Basic mechanisms of, and possible treatment targets for, sleep-wake disorders** 1115
David Pritchett, Angus S. Fisk, Russell G. Foster, and Stuart N. Peirson
110. **Diagnosis of sleep and circadian rhythm disorder** 1124
Kirstie N. Anderson
111. **Epidemiology of sleep-wake and primary prevention of its disorders** 1137
Lena Katharina Keller, Eva C. Winnebeck, and Till Roenneberg

112. **Genetics of sleep-wake disorders** 1148
Diego R. Mazzotti, Allan I. Pack, and Philip R. Gehrman

113. **Multimodal imaging of sleep-wake disorders** 1156
Umberto Moretto, Dylan Smith, Liliana Dell'Oso, and Thien Thanh Dang-Vu

114. **Management of insomnia and circadian rhythm sleep-wake disorders** 1167
Simon D. Kyle, Alasdair L. Henry, and Colin A. Espie

SECTION 18

Gender dysphoria and sexual dysfunction

115. **The sexual dysfunctions and paraphilias** 1181
Cynthia A. Graham and John Bancroft
116. **Gender dysphoria** 1191
Els Elaut and Gunter Heylens

SECTION 19

Personality disorders

117. **Core dimensions of personality pathology** 1201
Andrew E. Skodol and Leslie C. Morey
118. **Basic mechanisms of, and treatment planning/targets for, personality disorders** 1211
Kate E. A. Saunders and Steve Pearce
119. **Personality disorders: epidemiology and clinical course** 1218
Renato D. Alarcón and Brian A. Palmer
120. **Genetics of personality disorders** 1229
C. Robert Cloninger
121. **Imaging of personality disorders** 1239
Christian Paret and Christian Schmahl
122. **Treatment and management of personality disorder** 1247
Giles Newton-Howes and Roger Mulder

SECTION 20

Impulse-control and conduct disorders

123. **Impulse-control and its disorders, including pathological gambling** 1257
Donald W. Black

124. **Conduct disorders and antisocial personality disorder in childhood and adolescence** 1265
Stephen Scott and Melanie Palmer

SECTION 21

Suicide

125. **Epidemiology and causes of suicide** 1279
Merete Nordentoft, Trine Madsen, and Annette Erlangsen
126. **Self-harm: epidemiology and risk factors** 1289
Nav Kapur, Sarah Steeg, and Adam Moreton
127. **Biological aspects of suicidal behaviour** 1296
J. John Mann and Dianne Currier
128. **Prevention of suicide and treatment following self-harm** 1303
Keith Hawton, Kate E. A. Saunders, and Alexandra Pitman

SECTION 22

Somatic symptoms and related disorders

129. **Deconstructing dualism: the interface between physical and mental illness** 1317
Michael Sharpe and Jane Walker
130. **Neural mechanisms in chronic pain relevant for psychiatric interventions** 1320
Chantal Bena and Irene Tracey
131. **Treatment of fibromyalgia (chronic widespread pain) and chronic fatigue syndrome** 1330
Jonathan Price
132. **Factitious disorder and malingering** 1342
Thomas Merten and Harald Merckelbach
133. **Functional neurological symptom disorder (conversion disorder)** 1350
Jon Stone and Michael Sharpe

SECTION 23

Service provision

134. **Public policy and service needs in mental health** 1363
Martin Knapp

135. **Planning and providing mental health services for a community** 1372
Tom Burns and Tony Kendrick

136. **Health economic analysis of service provision** 1384
Judit Simon

137. **Organization of psychiatric services for general hospital departments: proactive and preventive interventions in psychiatry** 1392
William H. Sledge and Julianne Dorset

138. **Refugees and populations exposed to mass conflict** 1401
Mina Fazel, Susan Rees, and Derrick Silove

SECTION 24

Forensic psychiatry

139. **Associations between psychiatric disorder and offending** 1415
Seena Fazel and Mark Toynbee
140. **Developmental approach to understanding the needs of young people in contact with the criminal justice system** 1423
Sue Bailey and Prathiba Chitsabesan
141. **Child molesters and other sexual offenders** 1433
Stephen J. Hucker
142. **Stalking and querulous behaviour** 1442
Rosemary Purcell and Paul E. Mullen
143. **Domestic violence and abuse and mental health** 1451
Louise M. Howard and Deirdre MacManus
144. **Assessing and managing the risk of violence to others** 1461
Alec Buchanan
145. **The expert witness in the criminal and civil courts** 1469
John O'Grady
146. **Homicide** 1478
Matthew Large and Olav Nielssen

Index 1487

Abbreviations

α -MSH	alpha-melanocyte-stimulating hormone	AIMS	Abnormal Involuntary Movement Scale
G \times E	gene and environment	AL	allostatic load
μ g	microgram	ALDH	acetaldehyde dehydrogenase
AA	arachidonic acid	ALIC	anterior limb of the internal capsule
AAO	age at onset	ALFF	amplitude of low-frequency fluctuations
AAS	ascending arousal system	ALS	amyotrophic lateral sclerosis
AASM	American Academy of Sleep Medicine	AMBIT	adolescent mentalization-based integrative therapy
ABA	applied behavioural analysis; activity-based anorexia	AMDP	Association for Methodology and Documentation in Psychiatry; alternative DSM-5 model for personality disorders
Abeta	amyloid beta		
AC	adenyl cyclase		
ACC	anterior cingulate cortex	AMP	adenosine monophosphate-activated protein; amphetamine
ACE	angiotensin-converting enzyme; adverse childhood experience	AMPA	α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
ACE(R)	Addenbrooke Cognitive Examination (Revised)	AMTS	Abbreviated Mental Test Score
aCGH	array-comparative genomic hybridization	AN	anorexia nervosa
ACh	acetylcholine	ANA	antinuclear antibody
ACMG	American College of Medical Genetics and Genomics	ANP	atrial natriuretic peptide
ACQ	Agoraphobia Cognition Questionnaire	AN-R	restrictive subtype of anorexia nervosa
ACT	acceptance and commitment therapy; assertive community treatment	AO	assertive outreach
ACTH	adrenocorticotrophic hormone	aOR	adjusted odds ratio
AD	axial diffusivity; Alzheimer's disease; Alzheimer's dementia; adjustment disorder	AOS	apraxia of speech
ADAMHA	US Alcohol, Drug Abuse, and Mental Health Administration	AP	agoraphobia; area postrema
ADAPT	Adaption and Development After Persecution and Trauma (model)	APA	American Psychiatric Association
ADAS-cog	Alzheimer's Disease Assessment Scale-cognitive subscale	APD	antisocial personality disorder
ADD	attention deficit disorder	APOE	apolipoprotein E
ADDUCE	Attention Deficit Hyperactivity Disorder Drugs Use Chronic Effects	APP	amyloid β precursor protein
ADH	alcohol dehydrogenase; antidiuretic hormone	APS	attenuated psychotic symptoms
ADHD	attention-deficit/hyperactivity disorder	ARFID	avoidant restrictive food intake disorder
ADP	adenosine diphosphate	ARID	autosomal recessive forms of intellectual disability
A&E	accident and emergency	ARMS	at-risk mental state
aFTLD-U	atypical fronto-temporal lobar degeneration with ubiquitinated inclusions	ARP	aripiprazole
AGD	argyrophilic grain disease	AS	anxiety sensitivity

		ASN	asenapine
		AsPD	antisocial personality disorder
		ASPD	antisocial personality disorder
		ASPS	advanced sleep phase syndrome
		ASWPD	advanced sleep-wake phase disorder
		ATC	Anatomical Therapeutic Chemical
		ATF6	activating transcription factor 6

ATL	anterior temporal lobe	CADASIL	cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy
ATP	adenosine triphosphate	CAM	Confusion Assessment Method
ATPD	acute and transient psychotic disorder	CAMCOG(R)	Cambridge Cognitive Assessment (Revised)
ATX	atomoxetine	CAMHS	child and adolescent mental health services
AUC	area under the curve	cAMP	cyclic adenosine monophosphate
AUD	alcohol use disorder	CAPA	Child and Adolescent Psychiatric Assessment
AUDADIS-IV	Alcohol Use Disorder and Associated Disabilities Interview Schedule-IV	CAPP	Comprehensive Assessment of Psychopathic Personality Disorder
AVP	vasopressin	CART	cocaine- and amphetamine-related transcript
AvPD	avoidant personality disorder	CAS9	CRISPR-associated protein 9
AVPD	avoidant personality disorder	CAT	cognitive analytic therapy
BBB	blood–brain barrier	CATCH-IT	Competent Adulthood Transition with Cognitive Behavioural and Interpersonal Training
BBV	blood-borne virus	CATIE	Clinical Antipsychotic Trial of Intervention Effectiveness (study)
BD	bipolar disorder	CBA	cost-benefit analysis
BDD	body dysmorphic disorder	CBC	complete blood count
BDI	Beck Depression Inventory	CBCL	Child Behavior Problems Checklist
BDNF	brain-derived neurotrophic factor	CBCM	cognitive behavioural case management
BDSM	bondage, dominance and submission, sadism, and masochism	CBD	cortico-basal degeneration; cannabidiol
BED	binge eating disorder	CBF	cerebral blood flow
BET	brief eclectic therapy	CBG	cortico-basal ganglia
BF	basal forebrain	CBG-GSH	guided self-help cognitive behavioural therapy
BI	behavioural inhibition	CBI	classroom-based intervention
BIA	budget impact analysis	CBIT	Comprehensive Behavioral Intervention for Tics
BIBD	basophilic inclusion body disease	CBO	community-based organization
BIPS	Brief Intermittent Psychotic Symptoms	CBS	cortico-basal syndrome
BIT	behavioural intervention team	CBT	cognitive behavioural therapy
BLA	basolateral amygdala	CBT-E	enhanced cognitive behavioural treatment
BLIPS	Brief Limited Intermittent Psychotic Symptoms	CBTi	cognitive behavioural therapy for insomnia
BMI	body mass index	CBT-PD	cognitive behavioural therapy for personality disorder
BMP	bone morphogenetic protein	CC	collaborative care
BN	bulimia nervosa	CCA	cost-consequences analysis
BNM	biophysical network model	CCK	cholecystokinin
B/NRT	bupropion/nicotine replacement therapy	CCK-4	cholecystokinin tetrapeptide
BOLD	blood oxygen level-dependent	CCL	conventional consultation liaison
BOTMP	Bruininks–Oseretsky Test of Motor Proficiency	CCM	collaborative care management
BP	blood pressure	CD	coeliac disease
BPD	borderline personality disorder; bipolar disorder	CDC	Center for Disease Control and Prevention
BPI	bipolar disorder type I	CDDG	<i>Clinical Descriptions and Diagnostic Guidelines (from ICD-10 Classification of Mental and Behavioral Disorders)</i>
BPII	bipolar disorder type II	CEA	cost-effectiveness analysis
bpm	beats per minute	CEST	chemical exchange saturation transfer
BPRS	Brief Psychiatric Rating Scale	CET	cue-exposure treatment
BPSD	behavioural and psychological symptoms of dementia	CETA	Common Elements Treatment Approach
BS	basic symptoms	CFIR	Consolidated Framework for Implementation Research
BSE	bovine spongiform encephalopathy	CFS	chronic fatigue syndrome
BTSAS	Behavioural Treatment for Substance Abuse in Severe and Persistent Mental Illness	CGAS	Child Global Assessment Scale
bvFTD	behavioural-variant fronto-temporal dementia	CGE	caudal ganglionic eminence
BWLT	behavioural weight loss therapy	CGI-I	Clinical Global Impression of Improvement
BZD	benzodiazepine	cGMP	cyclic guanosine monophosphate
C&A	children and adolescents	CGMV	cortical grey matter volume
Ca ²⁺	calcium	CH	congenital hypothyroidism
CAA	cerebral amyloid angiopathy		
CAARMS	Comprehensive Assessment of At-Risk Mental State		
CAC	Clinical Assessment of Confusion		
CAD	coronary artery disease		

CHARGE	Cohorts for Heart and Aging Research in Genomic Epidemiology	CRISPR	clustered regularly interspaced short palindromic repeat
CHAT	Comprehensive Health Assessment Tool	CRN	correct related negativity
CHMP	Committee for Medicinal Products for Human Use	CRP	C-reactive protein
CHMP2B	charged multivesicular body protein 2b	CrPR	Criminal Procedure Rules
CHOICE	CHOosing Interventions that are Cost-Effective (project)	CRSWD	circadian rhythm sleep–wake disorder
CHOP	Children’s Hospital of Philadelphia	CS	conditioned stimulus; compulsive shopping
CHR	clinical high-risk	CSA	child sexual abuse
CI	confidence interval	CSB	compulsive sexual behaviour
CIDI	Composite International Diagnostic Instrument	CSF	cerebrospinal fluid
CIR	Clutter Image Rating	CSS	chromosomal substitution strain
CJD	Creutzfeldt–Jakob disease	CSTC	cortico-striato-thalamo-cortical
CLiPS	Collaborative Longitudinal Personality Disorders Study	CT	computed tomography
CLP	consultation-liaison psychiatry	CTD	chronic tic disorder
CLPDS	Collaborative Longitudinal Personality Disorders Study	CTE	chronic traumatic encephalopathy
CLPS	Collaborative Longitudinal Personality Study	CTO	community treatment order
cm	centimetre	CU	callous-unemotional
CM	contingency management; crisis management	CUA	cost-utility analysis
CMA	chromosomal microarray analysis; chaperone-mediated autophagy; cost-minimization analysis	CUtLASS	Cost Utility of the Latest Antipsychotic drugs in Schizophrenia Study
CMAT	Changes to the Matrix Council	CVD	cardiovascular disease
CMD	common mental disorder	CVO	circumventricular organ
CMHD	common mental health disorder	CWMV	cerebral white matter volume
CMHT	community mental health team	CY-BOCS	Children’s Yale-Brown Obsessive Compulsive Scale
CMP	comprehensive metabolic panel	DA	dopamine
CMS-R	Comorbidity Survey-Replication	dACC	dorsal anterior cingulate cortex
CNGC	cyclic nucleotide-gated channel	DACCP	Dundee ADHD Clinical Care Pathway
CNS	central nervous system	DAG	diacylglycerol
CNV	copy number variant	DAGK	diacylglycerol kinase
COG	centre of gravity	DALY	disability-adjusted life year
COGA	Collaborative Studies on Genetics of Alcoholism	DAMP	damage-associated molecular pattern
COGEND	Collaborative Genetic Study of Nicotine Dependence	DAPP	Differential Assessment of Personality Pathology
COMT	catechol- <i>O</i> -methyltransferase	DARI	dopamine reuptake inhibitor
CONSORT	Consolidated Standards of Reporting Trial	DAT	dopamine; dopamine transporter
CONVERGE	China, Oxford, and Virginia Commonwealth University Experimental Research on Genetic Epidemiology	DAWS	dopamine agonist withdrawal syndrome
COPC	chronic overlapping pain condition	DBH	dopamine-beta-hydroxylase
C9ORF72	chromosome 9 open reading frame 72	DBS	deep brain stimulation
CoSA	Circles of Support and Accountability	DBT	dialectical behaviour therapy
COX-2	cyclo-oxygenase-2	DCD	developmental co-ordination disorder
CP	choroid plexus	DCM	dynamic causal model
CPA	Care Programme Approach	DCR	Diagnostic Criteria for Research (from <i>ICD-10 Classification of Mental and Behavioral Disorders</i>)
CPES	Collaborative Psychiatric Epidemiological Studies	DCS	d-cycloserine
CPR	Civil Procedure Rules	DD	delay discounting
CPT	cognitive processing therapy	DDA	direct detection assay
Cr	creatine	DDP	dynamic deconstructive psychotherapy
CR	cognitive rehabilitation; conditioned response	DEX	dextroamphetamine
CRA	community reinforcement approach	DFC	dorsolateral prefrontal cortex
CREB	cAMP response element binding protein	2-DG	2-deoxyglucose
CRF	corticotropin-releasing factor	DHA	docosahexaenoic acid
CRF1	corticotropin-releasing factor 1	DHPG	dihydroxyphenylethylene glycol
CRH	corticotropin-releasing hormone	DIAN	Dominantly Inherited Alzheimer Network
CR/HT	crisis resolution/home treatment	DIRT	Danger ideation reduction therapy
		DIRUM	Database of Instruments for Resource Use Measurement
		DIS	Diagnostic Interview Schedule
		DISC	Diagnostic Interview Schedule for Children
		DISC1	Disrupted in Schizophrenia 1

DLB	dementia with Lewy bodies	ED	elimination disorder; emergency department; eating disorder; erectile disorder
DLMO	dim light melatonin onset	EDNOS	eating disorder not otherwise specified
dIPFC	dorsolateral prefrontal cortex	EDSP	Early Developmental Stages of Psychopathology (study)
DLPFC	dorsolateral prefrontal cortex	EEG	electroencephalogram
DM	diabetes mellitus	EFFEKTE-E	Entwicklungsförderung in Familien: Eltern- und Kinder-Training in emotional belasteten Familien
DMH	dorsomedial nucleus of the hypothalamus	EGF	epidermal growth factor
DM-ID	Diagnostic Manual-Intellectual Disabilities	EHS	essential hypersomnia syndrome
DMN	default mode network	EI	early intervention
DMT	dimethyltryptamine	EMA	European Medicines Agency; ecological momentary assessment
DNA	deoxyribonucleic acid	EMDR	eye movement desensitization and reprocessing
DNIC	diffuse noxious inhibitory control	EMG	electromyography
DOMINO	Donepezil and Memantine in Moderate to Severe Alzheimer's Disease (study)	ENCODE	Encyclopedia of DNA Elements
DOMS	delayed onset of muscular soreness	ENIGMA	Enhancing NeuroImaging Genetics through Meta-Analysis (Consortium)
DOR	delta opioid receptor	EOG	electro-oculography
DOSS	Delirium Observation Screening Scale	EOS	endogenous opioid system
DPD	dependent personality disorder	EP	explaining pain
DPMS	descending pain modulatory system	EPA	eicosapentanoic acid
DR	dorsal raphe	EPAD	European Prevention of Alzheimer's Dementia Consortium
DRD4	dopamine receptor type 4	EPDS	Edinburgh Postnatal Depression scale
DRG	diagnosis-related group	EPI	echo planar imaging
DRN	dorsal raphe nuclei	ePREP	Prevention and Relationship Enhancement Programme
DRPLA	dentatorubropallidoluysian atrophy	EPS	extra-pyramidal side effect
DRS-R-98	Delirium Rating Scale-Revised-98	EPSE	extra-pyramidal side effect
DS	dorsal striatum	ER	endoplasmic reticulum
DSED	disinhibited social engagement disorder	ERF	event-related field
DSM	<i>Diagnostic and Statistical Manual of Mental Disorders</i>	ERK	extracellular regulated kinase
DSM-III	Third revision of the Diagnostic and Statistical Manual of Mental Disorders	ERN	error-related negativity
DSM-III-R	DSM-III-Revised	ERP	event-related potential; exposure and response prevention
DSM-IV-TR	DSM-IV 'Text Revision'	ES	effect size
DSM-5	5th edition of the Diagnostic and Statistical Manual of Mental Disorders	ESDM	Early Start Denver Model
DST	daylight saving times; dexamethasone suppression test	ESR	erythrocyte sedimentation rate
DSWPD	delayed sleep-wake phase disorder	ESS	Epworth Sleepiness Scale
DTC	democratic therapeutic community	ESSENCE	Early Symptomatic Syndromes Eliciting Neurodevelopmental Clinical Examination
DTI	diffusion tensor imaging	EU	European Union
DTS	diffusion tensor spectroscopy	EUFEST	European First Episode Schizophrenia Trial
DUB	deubiquitinating enzyme	EULAR	European League Against Rheumatism
DUD	drug use disorders	EUnetHTA	European Network for Health Technology Assessment
DUI	daytime urinary incontinence; duration of untreated illness	FA	fractional anisotropy
DUP	duration of untreated psychosis	FACT	functional assertive community treatment
DURG	Drug Utilisation Research Group	fAD	familial Alzheimer's disease
DVA	domestic violence and abuse	FASD	fetal alcohol spectrum disorders
DWI	diffusion-weighted imaging	fcMRI	functional connectivity magnetic resonance imaging
DXA	dual-energy X-ray absorptiometry	FDA	US Food and Drug Administration
DY-BOCS	Dimensional Yale-Brown Obsessive Compulsive Scale	FDG	fluorodeoxyglucose
DZ	dizygotic	FDOPA	18F-fluorodopa
EAGG	European ADHD Guideline Group	FEP	first-episode psychosis
EAS	euthanasia or assisted suicide	FFI	fatal familial insomnia
EC	enhanced care	FFM	five-factor model of personality
ECA	Epidemiologic Catchment Area (study)		
ECG	electrocardiography		
ECNP	European College of Neuropsychopharmacology		
ECT	electroconvulsive therapy		

FFT	family-focused therapy; functional family therapy	GI	gyrification index; gender incongruence
FGA	first-generation antipsychotic	GID	gender identity disorder
FGCB	Family Group Cognitive-Behavioural	GIDC	gender identity disorder of childhood
FGF	fibroblast growth factor	GIDYQ-AA	Gender Identity/Gender Dysphoria Questionnaire for Adolescents and Adults
FI	faecal incontinence	GIP	G protein-coupled receptor-interacting protein
FINGER	Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (study)	GJ	gap junction
FLAIR	fluid-attenuated inversion recovery	GLM	general linear model
FL-APM	first-line dopamine antagonist medication	GM	grey matter
FM	fibromyalgia	GMV	grey matter volume
fMRI	functional magnetic resonance imaging	GnIH	gonadotrophin-inhibitory hormone
FMRP	fragile X mental retardation protein	GnRH	gonadotrophin-releasing hormone
FMT	6-18F-fluoro-l-m-tyrosine	GnRHa	gonadotrophin-releasing hormone analogue
FNSD	functional neurological symptom disorder	GO	Gene Ontology
FOCUS	Families OverComing Under Stress	GORD	gastro-oesophageal reflux disease
FPN	frontal-parietal network	GPCR	G protein-coupled receptor
FPR	Family Procedure Rules	GPPPD	genito-pelvic pain/penetration disorder
FSCD	Family Study of Cocaine Dependence	GR	glucocorticoid receptor
FSIAD	female sexual interest/arousal disorder	GRADE	Grading of Recommendations, Assessment, Development, and Evaluations
fT	femtotesla	GRDS	genetic risk and deterioration syndrome
FTD	fronto-temporal dementia	GRE	gradient echo
FTDC	International Behavior-variant FTD Criteria Consortium	GREML	genomic-relatedness-matrix restricted maximum likelihood
FTE	full-time equivalent	GRK	G protein-coupled receptor kinase
FTI	family therapeutic intervention	GRML	genomic relationship-matrix restricted maximum likelihood
FTLD	fronto-temporal lobar degeneration	GRN	granulin
FTLD-ni	fronto-temporal lobar degeneration without inclusions	GRS	genetic risk scoring
FTLD-tau	fronto-temporal lobar degeneration with tau-positive inclusions	GSK-3 β	glycogen synthase kinase-3 β
FTLD-UPS	fronto-temporal lobar degeneration with immunohistochemistry against proteins of the ubiquitin proteasomal system	GSS	Gerstmann-Sträussler syndrome
FUS	fused in sarcoma (protein)	GTP	guanosine triphosphate
FXS	fragile X syndrome	GWA	genome-wide association
g	gram; effect size	GWAS	genome-wide association studies
GA	Gamblers Anonymous	GWES	genome-wide exome sequencing
GABA	gamma aminobutyric acid	HAI	health care-associated infection
GAD	generalized anxiety disorder	HAROLD	Hemispheric Asymmetry Reduction in Old Adults (model)
GAF	Global Assessment of Functioning (scale)	HbA1c	glycated haemoglobin
GAPD	General Assessment of Personality Disorder	HBV	hepatitis B virus
GAR	Global Attentiveness Rating	HCR-20	Historical, Clinical Risk Management-20
GBA	glucocerebrosidase	HCV	hepatitis C virus
GBD	Global Burden of Disease (studies)	HD	Huntington's disease; hoarding disorder
GBL	gamma butyrolactone	HDAC	histone deacetylation
GCAN	Genetic Consortium for Anorexia Nervosa	HD-D	Hoarding Disorder Dimensional Scale
GCase	β -glucocerebrosidase 1	HDE	humanitarian device exemption
GCMS	gas chromatography-mass spectrometry	HDL	high-density lipoprotein
GCS	Glasgow Coma Scale	HDRS	Hamilton Depression Rating Scale
GCT	gender-confirming treatment	HF	high frequency
GCTA	genome-wide complex trait analysis	HFS	high-frequency stimulation
GD	gender dysphoria; gambling disorder	5-HIAA	5-hydroxyindoleacetic acid
GDNF	glial cell-derived neurotrophic factor	HIC	high-income country
GDP	guanosine diphosphate; gross domestic product	HiTOP	Hierarchical Taxonomy of Psychopathology
GET	graded exercise therapy	HIV	human immunodeficiency virus
GF	germ-free	HKD	hyperkinetic disorder
GHB	gamma hydroxybutyrate	HLA	human leucocyte antigen
GHRF	growth-hormone releasing factor	HoNOS	Health of the Nation Outcome Scales
		HOT	hyperbaric oxygen therapy

HPA	hypothalamus–pituitary–adrenal	IM	intramuscular
HPD	histrionic personality disorder	ImPACT	Immediate Post-Concussion Assessment and Cognitive Testing
HPLC	high-performance liquid chromatography	IMPase	inositol-1-monophosphatase
HPPD	hallucinogen persisting perceptual disorder	IMPC	International Mouse Phenotyping Consortium
HPRD	human protein reference database	INAHTA	International Network of Agencies for Health Technology Assessment
HR	heart rate; hazard ratio	INN	international non-proprietary name
HRI	high risk index	iNOS	inducible nitric oxide synthase
HR-QoL	health-related quality of life	IOCDF-GC	International OCD Foundation Genetics Collaborative
HRS-I	Hoarding Rating Scale-Interview	IOM	Institute of Medicine
HRS-SR	Hoarding Rating Scale-Self Report	IP ₃	inositol 1,4,5-triphosphate
HRT	habit reversal training; hormone replacement therapy	IPDE	International Personality Disorders Examination
HSP90	heat shock protein 90	IPL	inferior parietal lobe
5-HT	5-hydroxytryptamine	iPSC	induced pluripotent stem cell
HTA	health technology appraisal; health technology assessment	IPSRT	interpersonal and social rhythm therapy
HTAi	Health Technology Assessment international	IPT	interpersonal psychotherapy
HTT	huntingtin	IPV	intimate partner violence
HVA	homovanillic acid	IQ	intelligence quotient
HYE	health year equivalent	IR	immediate release; insulin resistance
Hz	hertz	IRE1	inositol-requiring enzyme 1
IADL	instrumental activity of daily living	IRGC	intermediate radial glia cell
IAPT	Improving Access to Psychological Therapies	IRLSS	International Restless Legs Syndrome Study Group
IBD	inflammatory bowel disease	IRT	item response theory; individual resilience training; imagery relief therapy
IBMPFD	inclusion body myopathy with Paget's disease of bone and fronto-temporal dementia	ISBD	International Society for Bipolar Disorders
IBS	irritable bowel syndrome	ISC	International Schizophrenia Consortium
ICA	independent component analysis	ISoS	International Study of Schizophrenia
ICCS	International Children's Continence Society	isvz	inner subventricular zone
ICD	impulse-control disorder	ISWRD	irregular sleep–wake rhythm disorder
ICD	International Classification of Diseases	ITP	inferior thalamic peduncle
ICD-10	International Classification of Diseases, tenth revision	IUPHAR	International Union of Basic and Clinical Pharmacology
ICD-11	International Classification of Diseases, eleventh revision	IVF	<i>in vitro</i> fertilization
ICECAP	ICEpop CAPability	JASPER	Joint Attention, Symbolic Play, Engagement and Regulation
ICER	incremental cost-effectiveness ratio	K	kelvin
ICF	International Classification of Functioning and Disability	K ⁺	potassium
ICOCs	International College of Obsessive–Compulsive Spectrum Disorders	kb	kilobase
ICSD-3	International Classification of Sleep Disorder, third edition	kDa	kilodalton
ICU	intensive care unit	KEGG	<i>Kyoto Encyclopaedia of Genes and Genomes</i>
ID	intellectual disabilities; insomnia disorder	KFS	Keeping Families Strong
IDD	intellectual developmental disorder	kg	kilogram
IDO	indoleamine 2,3-dioxygenase	KO	knockout
IED	intermittent explosive disorder	KOR	kappa opioid receptor
IFC	inferior frontal cortex	K-SADS	Schedule for Affective Disorders and Schizophrenia for School Age Children
IFG	inferior frontal gyrus	L	litre
IFN	interferon	LAI	long-acting injected
IGF	insulin-like growth factor	LB	Lewy body
IGF-1	insulin-like growth factor 1	LBD	Lewy body dementia
IgG	immunoglobulin G	LC	locus caeruleus
IHSC	interhemispheric spectral coherence	LD	linkage disequilibrium; learning disability
IL	interleukin	L/D	light/dark
IL-2	interleukin 2	LDL	low-density lipoprotein
IL-6	interleukin 6	L-dopa	levodopa
		LDX	lisdexamfetamine

LF	low frequency	MDA	methylenedioxyamphetamine
LFP	local field potential	MDAS	Memorial Delirium Assessment Scale
LGD	likely gene disrupting	MDD	major depressive disorder
LGE	lateral ganglionic eminence	MDI	manic-depressive illness
lGI	local gyrification index	MDMA	3,4-methylenedioxymethamphetamine
LH	lateral hypothalamic	MDMA-AP	MDMA-assisted psychotherapy
LHA	lateral hypothalamus	MDT	mode deactivation therapy
LHb	lateral habenula	ME	myalgic encephalomyelitis
LHRH	luteinizing hormone-releasing hormone	M/EEG	MEG and EEG
LMIC	low- and middle-income country	MEG	magnetoencephalography
lncRNA	long non-coding ribonucleic acid	MET	motivational enhancement therapy
LOC	loss of consciousness	MFB	medial forebrain bundle
LOD	logarithm of the odds	MFC	medial frontal cortical (regions)
LoF	loss of function	MFG	medial frontal gyrus
LOS	length of stay	MGB	microbiota-gut-brain (axis)
LPFS	Level of Personality Functioning Scale	MGD	Mouse Genome Database
LPS	lipopolysaccharide	MGE	medial ganglionic eminence
LSD	lysergic acid diethylamide	mGluR	metabotropic glutamatergic receptor
LTC	long-term care	MGMH	Movement for Global Mental Health
LTD	long-term depression	MHC	major histocompatibility complex
LTG	lamotrigine	mhGAP	Mental Health Gap Action Programme
LTP	long-term potentiation	MHIN	Mental Health Innovation Network
LUR	lurasidone	MHP	mental health professional
LUTS	lower urinary tract symptoms	MHPG	3-methoxy-4-hydroxyphenylglycol
MABC	Movement Assessment Battery for Children	MHRA	Medicines and Healthcare products Regulatory Agency
MADRS	Montgomery-Åsberg Depression Rating Scale	MHS	mental health services
MAM	mitochondria-associated membrane	MI	motivational interviewing
MANTRA	Maudsley Model of Anorexia Nervosa Treatment for Adults	MIBG	¹²³ I-metaiodobenzylguanidine
MAO	monoamine oxidase	MID	monetary incentive delay
MAOA	monoamine oxidase A	MIPS	<i>myo</i> -inositol-3-phosphate synthase
MAOA-H	monoamine oxidase-high (allele)	miRNA	microribonucleic acid
MAOA-L	monoamine oxidase-low (allele)	mm	millimetre
MAOI	monoamine oxidase inhibitor	MMN	mismatch negativity
MAP	mitogen-activated protein; microtubule-associated protein	MMPI	Minnesota Multiphasic Personality Inventory
MAPK	mitogen-activated protein kinase	MMSE	Mini-Mental State Examination
MAPS	Multidisciplinary Association for Psychedelic Studies (project)	MND	motor neuron disease; Malingered Neurocognitive Dysfunction
MAPT	microtubule-associated protein tau	MOA	mechanism of action
MARAC	multi-agency risk assessment conference	MoCA	Montreal Cognitive Assessment
MAYSI-2	Massachusetts Youth Screening Instrument-Version 2	mOFC	medial orbitofrontal cortex
MBCT	mindfulness-based cognitive therapy	MOR	mu-opioid receptor
MBP	myelin basic protein	mPFC	medial prefrontal cortex
MBSR	mindfulness-based stress reduction	MPH	methylphenidate
MBT	mentalization-based treatment	MPP ⁺	1-methyl-4-phenylpyridinium
MBT-A	mentalization-based treatment for adolescents	MPTP	methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MBU	mother and baby unit	MR	mineralocorticoid receptor; magnetic resonance
MCA	middle cerebral artery	mRASS	modified Richmond Agitation and Sedation Scale
MCC	mid cingulate cortex	MRF	modifiable risk factor
MCDA	multi-criteria decision analysis	MRI	magnetic resonance imaging
MC4R	melanocortin-4 receptor	MRN	medial raphe nuclei
MCH	melatonin-concentrating hormone	mRNA	messenger ribonucleic acid
MCI	mild cognitive impairment	MRS	magnetic resonance spectroscopy
MCMI-III	Millon Clinical Multiaxial Inventory-III	MSA	multiple system atrophy
MCTQ	Munich ChronoType Questionnaire	MSAD	McLean Study of Adult Development
MD	mean diffusivity	MSF	mid-sleep on free day
		MSH	melanocyte-stimulating hormone
		MSI-2	Multiphasic Sex Inventory-2

MSLT	multiple sleep latency test	NJRE	Not Just Right Experience
MSR	magnetically shielded room	NK-1	neurokinin 1
MST	multi-systemic therapy	NMDA	<i>N</i> -methyl- <i>D</i> -aspartate
MSW	mid-sleep on workdays	NMDAR	<i>N</i> -methyl- <i>D</i> -aspartate receptor
MT	magnetization transfer	NMR	nuclear magnetic resonance
mTBI	mild traumatic brain injury	NMS	neuroleptic malignant syndrome
mtDNA	mitochondrial DNA	NND	number needed to detain
MTFC	multi-dimensional treatment foster care	NNI	NMDAR-neuromodulator interaction
mTOR	mammalian target of rapamycin	NNP	number needed to prevent
MTR	magnetization transfer ratio	NNT	number needed to treat
MVPC	multivariate pattern classification	NO	nitric oxide
MZ	monozygotic	NOS	not otherwise specified; nitric oxide synthase
Na ⁺	sodium	NPC	neural progenitor cell
NA	noradrenaline	NPD	narcissistic personality disorder
NAA	<i>N</i> -acetyl aspartate	NPI	neuropsychiatric inventory
NAC	nucleus accumbens; <i>N</i> -acetylcysteine	NPS	novel psychoactive substance; neuropeptide S
NAcc	nucleus accumbens	NPY	neuropeptide Y
nAChR	nicotinic acetylcholine receptor	NREM	non-rapid eye movement
NAM	negative allosteric modulation	NRI	selective noradrenergic reuptake inhibitor
NAMHC	National Advisory Mental Health Council	NRT	nicotine replacement therapy
NaSSA	noradrenergic and specific serotonergic antidepressant	NSAID	non-steroidal anti-inflammatory drug
Natsal-3	third National Surveys of Sexual Attitudes and Lifestyles	NSS	neurological soft sign
NB	net benefit	NSSI	non-suicidal self-injury
NbN	Neuroscience-based Nomenclature	NSSID	non-suicidal self-injury disorder
NcAcc	nucleus accumbens	N24SWD	non-24-hour sleep–wake disorder
NCD	neurocognitive disorder	NTD	neurofibrillary tangle dementia
NCDLB	neurocognitive disorder with Lewy bodies	Nu-DESC	Nursing Delirium Screening Scale
NCGS	non-coeliac gluten sensitivity	NVAWS	National Violence Against Women Survey
ncRNA	non-coding RNA	OAB	overactive bladder
NCS	National Comorbidity Survey	OC	obsessive–compulsive
NCS-A	National Comorbidity Survey Adolescent Supplement	OCD	obsessive–compulsive disorder
NCS-R	National Comorbidity Survey-Replication	OCDUS	Obsessive Compulsive Drug Use Scale
NDA	National Institute of Mental Health Data Archive; new drug approval	OCGAS	OCD Collaborative Genetic Association Study
NDD	neurodegenerative disease	OCPD	obsessive–compulsive personality disorder
NDRI	noradrenaline/dopamine reuptake inhibitor	OCRD	obsessive–compulsive and related disorder
NE	nocturnal enuresis	OCSD	obsessive–compulsive spectrum disorder
NEAT	non-exercise activity thermogenesis	ODD	oppositional defiant disorder
NES	night eating syndrome	OECD	Organisation for Economic Co-operation and Development
NESARC	National Epidemiological Survey on Alcohol and Related Conditions	OED	other eating disorder
NET	noradrenaline (norepinephrine) transporter; narrative exposure therapy	OFC	orbitofrontal cortex
NF-κB	nuclear factor κB	OLZ	olanzapine
nfvPPA	non-fluent-variant primary progressive aphasia	ONS	Office of National Statistics
NGF	nerve growth factor	OPD	operational psychodynamic diagnostics
NGO	non-governmental organization	OPM	optically pumped magnetometer
NGS	next-generation sequencing	OPRI	octapeptide repeat insertion
NHMRC	National Health and Medical Research Council	OR	odds ratio
NICE	National Institute for Health and Care Excellence	OSA	obstructive sleep apnoea
NIDA	National Institute of Drug Abuse	OSE	other stressor event
NIFID	neuronal intermediate filament inclusion disease	OSFED	other specified feeding and eating disorders
NIH	National Institutes of Health	OST	opiate substitution therapy
NIMH	National Institute of Mental Health	osvz	outer subventricular zone
NIMH-RGR	NIMH Repository and Genomics Resource	OxCAP-MH	Oxford CAPabilities questionnaire-Mental Health
		OXTR	oxytocin receptor
		PA	periaqueductal
		PACAP	pituitary adenylyl cyclase-activating polypeptide
		PACT	Preschool Autism Communication Trial
		PAF	population-attributable fraction

PAG	periaqueductal grey	PM+	Problem Management Plus
PAI	Personality Assessment Inventory	PMA	paramethoxyamphetamine
PAL	paliperidone	PMDD	premenstrual dysphoric disorder
PAM	positive allosteric inhibitor; positive allosteric modulation	PMMA	paramethoxymethamphetamine
PAMP	pathogen-associated molecular pattern	PND	postnatal depression
PANDAS	Paediatric autoimmune neuropsychiatric disorder associated with streptococcal infections	PoA	preoptic area
PANESS	Physical and Neurological Examination for Soft Signs	POMC	pro-opiomelanocortin
PaPA	Perceptions and Practicalities Approach	PP	post-partum (puerperal) psychosis
PAR	population-attributable risk	PPAR	peroxisome proliferator-activated receptor
PATS	Preschoolers with ADHD Treatment Study	PPD	paranoid personality disorder
PBMC	peripheral blood mononuclear cell	P&PD	DSM-5 Personality and Personality Disorders Work Group
PBP	Parent-Based Prevention	PPG	penile plethysmography
PCBD	persistent complex bereavement disorder	PPI	protein–protein interaction
PCC	posterior cingulate cortex	PPV	positive predictive value
PCL	paracentral lobule	pRGC	photosensitive retinal ganglion cell
PCL-R	Psychopathy Checklist Revised	PRIME	Programme for Improving Mental Health Care (study)
PCL-YV	Psychopathy Checklist: Youth Version	PROM	patient-reported outcome measure
PCP	primary care physician	PrP	prion protein; Penn Resilience Program
PCPA	para-chlorophenylalanine	PrP ^C	cellular prion protein
PCS	post-concussion syndrome	PrP ^{Sc}	scrapie form of prion protein
PD	panic disorder; proton density; Parkinson's disease; personality disorder	PRS	polygenic risk scoring
PDAQ	Penn Daily Activities Questionnaire	PSA	prostate-specific antigen
PD-CFRS	PD-Cognitive Function Rating Scale	PSD	post-synaptic density; post-stroke depression
PDD	pervasive developmental disorder; Parkinson's disease dementia	PSE	Present State Examination
PDE	phosphodiesterase	PSG	polysomnography
PDE-5	phosphodiesterase type 5	PSP	progressive supranuclear palsy
PD-MCI	Parkinson's disease with mild cognitive impairment	PSQI	Pittsburgh Sleep Quality Index
PD-TS	personality disorder–trait specified	PST	problem-solving therapy
PE	prolonged exposure; premature ejaculation	PTA	post-traumatic amnesia; Positive Thoughts and Action Program
PEG	polyethyleneglycol	p-tau	phosphorylated tau
PEPS	psychoeducation with problem-solving	PTE	potentially traumatic event
PERK	protein kinase RNA-like endoplasmic reticulum kinase	PTSD	post-traumatic stress disorder
PET	positron emission tomography	PU	premonitory urge
PET-MR	positron emission tomography–magnetic resonance	PUFA	polyunsaturated fatty acid
PFA	psychological first aid	PVE	partial volume effect
PFC	prefrontal cortex	PVFS	post-viral fatigue syndrome
PGAD	persistent genital arousal disorder	PVN	paraventricular hypothalamic nucleus
PGC	Psychiatric Genetics Consortium	QALY	quality-adjusted life year
PGC-ED	Eating Disorders Working Group of the Psychiatric Genomics Consortium	QOF	quality and outcomes framework
PGE ₂	prostaglandin E ₂	QoL	quality of life
PGRS	polygenic risk score	QTL	quantitative trait locus
PI	phosphoinositide/phosphoinositol; polarity index	QTP	quetiapine
PiB	Pittsburgh compound B	rACC	rostral anterior cingulate cortex
PIGD	postural instability gait disorder	RAD	reactive attachment disorder; Reynolds Adolescent Depression
PIP ₂	phosphatidyl inositol 4,5-bisphosphate	RAID	Rapid Assessment, Interface, and Discharge (model)
piRNA	piwi-interacting ribonucleic acid	RANZP	Royal Australian and New Zealand College of Psychiatrists
PKA	protein kinase A	RAP	Resourceful Adolescent Program
PKC	protein kinase C	RAR	retinoic acid receptor
PKU	phenylketonuria	RBANS	Repeatable Battery for the Assessment of Neuropsychological Status
PLC	phospholipase C	RBD	rapid eye movement sleep behaviour disorder
PLE	psychotic-like experience	rCBF	regional cerebral blood flow
		rCMRglu	regional cerebral metabolic rate for glucose

RCT	randomized controlled trial	SCZ	schizophrenia
RCV	rare coding variant	SD	sleep deprivation
RD	radial diffusivity	SDQ	Strengths and Difficulties Questionnaire
RDC	Research Diagnostic Criteria	SDS	standard deviation score
RDoC	Research Domain Criteria	SEID	systemic exertion intolerance disease
RdoCdb	Research Domain Criteria Database	SERCA	sarco(endo)plasmic reticulum calcium ATPase
REE	resting energy expenditure	SERT	serotonin; serotonin transporter
REM	rapid eye movement	SES	socio-economic status
REMS	risk evaluation and mitigation strategies	SF-36	Short Form Health Survey 36
RESH	Repeated Episodes of Self-Harm (score)	SFO	subfornical organ
REST	RE1-silencing transcription factor	SFT	schema-focused therapy
RF	radiofrequency	SG	somatosensory gating
RFLP	restriction fragment length polymorphism	SGA	second-generation antipsychotic
RGS	G-protein signalling protein	sgACC	subgenual anterior cingulate cortex
RHT	retinohypothalamic tract	sgp130	soluble glycoprotein 130
RLE	real life experience	sgRNA	single-guide ribonucleic acid
RLS	restless legs syndrome	SHA	System of Health Accounts
RNA	ribonucleic acid	SHORT IQ-CODE	short form of the Informant Questionnaire on Cognitive Decline in the Elderly
RNP	ribonucleoprotein	SHQ	Clarke Sex History Questionnaire
ROADMAP	Real world Outcomes across the Alzheimer's Disease spectrum for better care: Multi-modal data Access Platform	SIADH	syndrome of inappropriate antidiuretic hormone
ROI	region of interest	SIDP-IV	Structured Interview for DSM-IV Personality Disorders
ROM	routine outcome measure	SIH	stress-induced hyperthermia
ROS	reactive oxygen species	SIHD	Structured Interview for Hoarding Disorder
ROSE	Reach Out, Stand Strong, Essentials for new mothers (programme)	SIPP	Severity Indices of Personality Problems
RPS	risk profile scoring	SIPS	Structured Interview for Prodromal Syndromes; Structured Interview for Psychosis-Risk Syndromes
RR	relative risk	SI-R	Saving Inventory-Revised
RRBI	restricted and repetitive behaviours and interests	siRNA	short interfering ribonucleic acid
RRT	rapid response team	SIT	stress inoculation training
RS	rumination syndrome	SLC	solute carrier
rsfMRI	resting-state functional magnetic resonance imaging	sLMFB	superolateral branch of the medial forebrain bundle
RSN	resting state network	SMA	supplementary motor area
rTMS	repetitive transcranial magnetic stimulation	SMD	standardized mean difference
RT-QuIC	real-time quaking-induced conversion	SMG	supramarginal gyrus
RVM	rostral ventromedial medulla	SMI	severe mental illness
RYGB	Roux-En-Y gastric bypass	SMIT 1	sodium/ <i>myo</i> -inositol transporter 1
sAD	sporadic Alzheimer's disease	SMOC	second messenger-operated channel
SAD	social anxiety disorder; seasonal affective disorder	SMR	standard mortality ratio; standardized mortality rate
SANS	Scale for the Assessment of Negative Symptoms	SN	substantia nigra
SAPS	Scale for the Assessment of Positive Symptoms	SNAP	Swanson, Nolan, and Pelham (scale); Schedule for Nonadaptive and Adaptive Personality
SAPS-PD	Scale for Assessment of Positive Symptoms in Parkinson's Disease	SNP	single-nucleotide polymorphism
SARI	serotonin antagonist and reuptake inhibitor	SNR	signal-to-noise ratio
SAVRY	Structured Assessment of Violence Risk in Youth	SNRI	serotonin/noradrenaline reuptake inhibitor
SCAN	Schedule for Clinical Assessment in Neuropsychiatry	SNV	single nucleotide variant
SCC	subcallosal cingulate cortex	SOC	store-operated channel
SCD	social (pragmatic) communication disorder	SOC-7	Standards of Care for the Health of Transsexual, Transgender, and Gender-Non-conforming People, Version 7
SCFA	short-chain fatty acid	SOD	superoxide dismutase
SCID-II	Structured Clinical Interview for DSM-IV Axis II personality disorders	SOFA	Social and Occupational Functioning Assessment Scale
sCJD	sporadic Creutzfeldt-Jakob disease	SORAG	Sex Offender Risk Appraisal Guide
SCL-90	Symptom Checklist-90	SOREMP	sleep-onset REM period
SCM	structured clinical management	SP	specific phobia; subplate (zone)
SCN	suprachiasmatic nucleus	SPD	schizotypal personality disorder
SCO	subcommissural organ		
SCRD	sleep and circadian rhythm disruption		

SPECT	single-photon emission computed tomography	TMF	Trzepacz, Meagher, and Franco (research diagnostic criteria)
SPZ	subparaventricular zone	TMN	tuberomammillary nucleus
SQUID	superconducting quantum interference device	TMS	transcranial magnetic stimulation
SRAI	structured risk assessment instrument	TNF	tumour necrosis factor
SRI	serotonin reuptake inhibitor	TOR	target of rapamycin
SRS	sex reassignment surgery	TPD	Tobacco Products Directive
SRT	sleep restriction therapy	TPJ	temporo-parietal junction
SSCM	specialist supportive clinical management	TR	repetition time
SSRI	selective serotonin reuptake inhibitor	TRD	treatment-resistant depression
STAT3	signal transducer and activator of transcription 3	TRH	thyrotropin-releasing hormone
STEP-BD	Systematic Treatment Enhancement Program for Bipolar Disorder	TRN	thalamic reticular nucleus
STEPPS	Systems Training for Emotional Predictability and Problem Solving	TRP	transient receptor potential
STL	superior temporal lobe	TS	Tourette's syndrome
STN	subthalamic nucleus	TSC	tuberous sclerosis complex
StPD	schizotypal personality disorder	TSF	12-step facilitation
STPD	schizotypal personality disorder	TSH	thyroid-stimulating hormone
STPP	short-term psychodynamic psychotherapy	TSO	total sexual outlet
SUD	substance use disorder	TSPO	translocator protein
SUVr	regional standard uptake value	TSST	Trier Social Stress Test
svPPA	semantic-variant primary progressive aphasia	t-tau	total tau
SVT	symptom validity test	TTFL	transcriptional–translational feedback loop
SWAN	Strengths and Weaknesses of ADHD-symptoms and Normal-behavior (scale)	UA	uric acid
SWI	susceptibility-weighted imaging	UDS	urinary drug screen
SWS	slow-wave sleep	UGDS	Utrecht Gender Dysphoria Scale
T	tesla; testosterone	UHR	ultra-high-risk
tACS	transcranial alternating current stimulation	UHSS	UCLA Hoarding Severity Scale
TADS	Treatment for Adolescents with Depression Study	UI	uncertainty interval
TAP-MS	tandem affinity purification and mass spectrometry	UK	United Kingdom cHECK 1-4!!!
TAU	treatment as usual	UN	United Nations
TBARS	thiobarbituric acid reactive substances	UP	Unified Protocol for Transdiagnostic Treatment of Emotional Disorders
TBI	traumatic brain injury	UPD	uniparental disomy
TBK1	TANK-binding kinase 1	UPR	unfolded protein response
TBSS	tract-based spatial statistics	UPS	unspecified prodromal symptoms
TCA	tricarboxylic acid; tricyclic antidepressant	US	unconditioned stimulus; United States
TCI	Temperament and Character Inventory	USD	United States dollar
TD	typically developing; tardive dyskinesia	USI-model	Universal, Selected and Indicated preventive model
tDCS	transcranial direct current stimulation	uVNTR	upstream variable number of tandem repeats
T2DM	type 2 diabetes mellitus	VaD	vascular dementia
TDP	TAR-DNA binding protein	VasD	vascular dementia
TDP43	TAR-DNA binding protein 43	VBM	voxel-based morphometry
tds	three times daily	VCFS	velo-cardio-facial syndrome
TEMPS	Temperament Evaluation scale from Memphis, Pisa, and San Diego	VCI	vascular cognitive impairment
TENS	transcutaneous electrical nerve stimulation	vCJD	variant Creutzfeldt–Jakob disease
TFBS	transcription factor binding site	VCP	valosin-containing protein
TF-CBT	trauma-focused cognitive behavioural therapy	VC/VS	ventral capsule/ventral striatum
TFP	transference-focused psychotherapy	VEGF	vascular endothelial growth factor
TGA	transient global amnesia	VIAAT	vesicular inhibitory amino acid transporter
TGMD	Test for Gross Motor Development, second edition	VIP	vasoactive intestinal peptide
Th2	T helper 2	VLPO	ventrolateral preoptic
THC	tetrahydrocannabinol	VMAT2	vesicular monoamine transporter-2
TIA	transient ischaemic attack	VMHC	voxel-mirrored homotopic connectivity
TIPS	Treatment and Intervention in Psychosis Study	vmPFC	ventromedial prefrontal cortex
TJ	tight junction	VNS	vagal nerve stimulation
TLR	Toll-like receptor	VNTR	variable numbers of tandem repeat
		VNUT	vesicular nucleotide transporter
		VPA	valproate

VPAG	ventral periaqueductal grey	WM	white matter
VR	virtual reality	WMH	World Mental Health; white matter hyperintensity
VRAG	Violence Risk Appraisal Guide	WPA	World Psychiatric Association
VRAG-R	Violence Risk Appraisal Guide-Revised	WTCCC3	Wellcome Trust Case-Control Consortium 3
VRET	virtual reality exposure therapy	XMRV	xenotropic murine leukaemia virus-related virus
VS/NcAcc	ventral striatum/nucleus accumbens	Y-BOCS	Yale-Brown Obsessive Compulsive Scale
VTa	ventral tegmental area	YFAS	Yale Food Addiction Scale
WASO	wake after sleep onset	Y2H	Yeast 2 Hybrid
WCST	Wisconsin Card Sorting Task	YLD	year of life lived with disability
WFSBP	World Federation of Societies of Biological Psychiatry	YLL	year of life lost
WHO	World Health Organization	YSR	Youth Self-Report
WHO-DAS	World Health Organization Disability Assessment Schedule	ZIP	ziprasidone

The patient's perspective

Kay Redfield Jamison and Adam Ian Kaplin

Introduction

It is difficult to be a psychiatric patient, but a good doctor can make it less so. Confusion and fear can be overcome by knowledge and compassion, and resistance to treatment is often, although by no means always, amenable to change by intelligent persuasion that leads to better healing. The devil, as the fiery melancholic Byron knew, is in the details.

Delivering the diagnosis, prognosis, and plan

Patients, when first given a psychiatric diagnosis, are commonly both relieved and frightened—relieved because often they have been overwhelmed by pain, anxiety, and hopelessness for a considerable period of time, and frightened because they do not know what the diagnosis means, what the treatment will entail, and their likelihood of obtaining a meaningful response. They do not know if they will return to the way they once were, whether the treatment they have been prescribed will or will not work, and, even if it does work, at what cost it will be to them in terms of their notions of themselves, potentially unpleasant side effects, and the reactions of their family members, friends, colleagues, and employers. Perhaps most disturbing, they do not know if their depression, psychosis, anxieties, or compulsions will return to become a permanent part of their lives. Caught in a state often characterized by personal anguish, social isolation, and confusion, newly diagnosed patients find themselves on a quest to regain a sense of mastery of themselves and their surroundings. One of the main goals of therapies of all types is to empower the patient and give them some control back over their world and rechart the meaning and purpose of their lives under altered circumstances.

The specifics of what the doctor says and the manner in which he or she says it are critically important from the start and will colour the patient's ongoing treatment course for years to come. Most patients who complain about receiving poor psychiatric care do so on several grounds—their doctors, they feel, spend too little time explaining the nature of their illnesses and treatment; they are reluctant to consult with, or actively involve, family members; they are patronizing and do not adequately listen to what the patient has to say; they do not encourage questions or sufficiently address the

concerns of the patient; they do not discuss alternative treatments, the risks of treatment, and the risks of no treatment; and they do not thoroughly forewarn about side effects of medications.

Most of these complaints are avoidable. Time, although difficult to come by, is well spent early on in the course of treatment when the manifestations of confusion and hopelessness are greatest, the risk of non-adherence is highest, and the possibility of suicide substantially increased. Hope can be realistically extended to patients and family members, and its explicit extension is vital to those whose illnesses have robbed them not only of hope, but also of belief in themselves, their future, and the very meaning of their lives. The hope provided needs to be tempered, however, by an honest and realistic explication of possible difficulties yet to be encountered: unpleasant side effects from medications; a rocky time course to meaningful recovery which will often consist of many discouraging cycles of feeling the progress of marching towards wellness, only to stumble and slide temporarily backwards towards illness again; and the probable personal, professional, and financial repercussions that come in the wake of having a psychiatric illness.

Importance of doctor–patient communication

It is terrifying to lose one's sanity or to be seized by a paralyzing depression. No medication alone can substitute for a good doctor's clinical expertise and the kindness of a doctor who understands both the medical and psychological sides of mental illness. Nor can any medication alone substitute for a good doctor's capacity to listen to the fears and despair of patients trying to come to terms with what has happened to them. A good doctor is a therapeutic optimist who is able to instil hope and confidence to combat bewilderment and despair. Great doctors are able to provide the unwavering care to their patients that they would want a member of their own family to receive, blending empathy and compassion with expertise and confidence.

Doctors need to be direct in answering questions, to acknowledge the limits of their understanding, and to encourage specialist consultations when the clinical situation warrants it. They also need to create a therapeutic climate in which patients and their families feel free, when necessary, to express their concerns about treatment or to request a second opinion. There must also be a willingness by

doctors to collaborate across medical disciplines in the care of their psychiatric patients because of the influence and, likewise, the impact of somatic diseases on mental illness—for example, there is evidence that depression predisposes people to conditions such as myocardial infarction, diabetes, and multiple sclerosis, all of which conversely increase the likelihood of depression. Moreover, persons with major depression and schizophrenia have a 40–60% greater chance of dying prematurely than the general population, due to physical health problems that are often left unattended or exacerbated by the side effects of psychotropic medications. Doctors are also frequently called upon to advocate for their psychiatric patients who are frequently stigmatized and therefore at great risk of being discriminated against by being deprived of their professional, economic, social, and cultural rights. Particular care must be taken by doctors to prevent their patients from receiving substandard care by refusing to share, against their patient's better judgement, important aspects of their mental illness with non-mental health medical practitioners.

Treatment non-adherence, one of the major causes of unnecessary suffering, relapse, hospitalization, and suicide must be addressed head-on. Unfortunately, doctors are variable in their ability to assess, predict, and facilitate adherence in their patients [1]. Asking directly and often about medication concerns and side effects, scheduling frequent follow-up visits after the initial diagnostic evaluation and treatment recommendation, and encouraging adjunctive psychotherapy or involvement in patient support groups can make a crucial difference in whether or not a patient takes medication in a way that is most effective. Aggressive treatment of unpleasant or intolerable side effects, minimizing the dosage and number of doses, and providing ongoing, frequently repetitive education about the illness and its treatment are likewise essential, if common-sense, ways to avert or minimize non-adherence.

Communication in the digital age

The ever-expanding availability of health information technology, ranging from assistive devices (that permit regular tracking of symptoms and reminders to facilitate treatment adherence such as automated texting and telemedicine) to therapeutic tools (that provide interventions such as online cognitive behavioural therapy), will continue to improve the ease with which care can be delivered. But in the end, it is the therapeutic alliance between patient and clinician, honed and proven over two and a half millennia since the time of Hippocrates, that will and must remain central to the healing process. Technology can assist and enhance, but not replace, the doctor–patient relationship.

Doctor as teacher

Education is, of course, integral to the good treatment of any illness, but this is especially true when the illnesses are chronic and shrouded in the secrecy that is caused by both social and personal stigma. The term 'doctor' derives originally from the Latin word for teacher, and it is in their roles as teachers that doctors provide patients with the knowledge and understanding to combat

the confusion and unpredictability that surround mental illness. Patients and their family members should be encouraged to write down any questions they may have, as many individuals are intimidated once they find themselves in a doctor's office. Any information that is given orally to patients should be repeated as often as necessary (due to the cognitive difficulties experienced by many psychiatric patients, especially when acutely ill or recovering from an acute episode) and, whenever feasible, provided in written form as well. Additional information is available to patients and family members in books and pamphlets obtainable from libraries, bookstores, and patient support groups, but, ever more commonly, information is accessible through the Internet as videos, websites, and online support groups [2, 3]. Visual aids, such as charts portraying the natural course of the treated and untreated illness or the causes and results of sleep deprivation and medication cessation, are also helpful to many [4–6]. Finally, providing the patients with self-report scales to monitor their daily progress, such as mood charts in affective disorder, not only provides invaluable clinical data, but also teaches patients and their physicians to better understand the patient's illnesses and their response to therapeutic interventions and exacerbating stressors. Family members and significant others can, and usually do, play key roles as outside sources of information which can be critically important in ensuring that the proper diagnosis is made at the outset. Patients, when they are well, also often benefit from a meeting with their family members and their doctor that focuses upon drawing up contingency plans in case their illness should recur. These meetings also provide an opportunity to shore up the support system the patient has by educating their caregivers about the nature, cause, manifestations, and treatment of their loved one's mental illness. Such meetings may also include what is to be done in the event that a psychiatric emergency arises and hospitalization is required, a discussion of early warning signs of impending psychotic or depressive episodes, methods for regularizing sleep and activity patterns, techniques to protect patients financially, and ways to manage suicidal behaviour should it occur. Suicide, globally the second leading cause of death in 15- to 29-year olds, is the major cause of premature death in severe psychiatric illnesses [7, 8], and its prevention is of first concern. Those illnesses most likely to result in suicide (mood disorders, comorbid alcohol and drug abuse, and schizophrenia) need to be treated early, aggressively, and often for an indefinite period of time [2, 10]. Lithium, which has demonstrated significant efficacy in preventing suicide, should be considered when appropriate [11]. The increasing evidence that treatment early in psychiatric illness may improve the long-term course needs to be considered in light of the reluctance of many patients to stay in treatment [10, 12, 14].

Conclusions

The ancient proverb *medice, cura te ipsum* (physician, heal thyself) applies most pressingly to mental illness, because the rates of burnout, depression, and suicide among doctors are deeply concerning. A willingness to change the culture of medicine, so that more time, attention, and education is given to the critically important aspects of mental health, routine screening, and treatment of depression to encourage, rather than punish, seeking help.

No one who has treated or suffered from mental illness would minimize the difficulties involved in successful treatment. Modern medicine gives options that did not exist even 10 years ago, and there is every reason to expect that improvements in psychopharmacology, psychotherapy, and diagnostic techniques will continue to develop at a galloping pace. Still, the relationship between the patient and doctor will remain central to the treatment, as Morag Coate wrote more than 40 years ago in *Beyond All Reason* [13]:

'Because the doctors cared, and because one of them still believed in me when I believed in nothing, I have survived to tell the tale. It is not only the doctors who perform hazardous operations or give life-saving drugs in obvious emergencies who hold the scales at times between life and death. To sit quietly in a consulting room and talk to someone would not appear to the general public as a heroic or dramatic thing to do. In medicine there are many different ways of saving lives. This is one of them.'

Public attitudes and the challenge of stigma

Nicole Votruba, Mirja Koschorke, and Graham Thornicroft

Introduction

Stigma can be considered as an overarching term that includes challenges faced by people with mental illness related to knowledge, attitudes, and behaviour [1]. The knowledge domain includes low levels of mental health literacy, for example among the general population (ignorance); the attitudinal domain relates to almost entirely negative affect towards people with experience of mental illness (prejudice), while the behavioural aspects reflect predominantly forces for the social exclusion and diminished citizenship for people with mental illness (discrimination). This chapter considers the evidence of the implications of these elements and also summarizes the literature on what can be done to effectively reduce stigma and discrimination.

The practical implications of stigma and discrimination

The consequences of stigma and discrimination are wide-reaching and severe, and affect people with mental disorders, their family members, mental health staff, institutions, and treatments, as well as society as a whole.

Discrimination, the behavioural consequence of stigma, adds to the disability of persons with mental illness and leads to disadvantages in many aspects of life, including personal relationships, education, and work [1, 2]. It limits the life opportunities of those affected, through loss of income, prolonged unemployment, reduced access to housing or health care, for example, and therefore reduced access to important means of recovery [3]. Commonly, people with mental disorders experience unequal treatment for physical health conditions, leading to rates of morbidity and mortality much beyond what is attributable to their primary mental disorder [4]. Discrimination because of mental illness is pervasive and universal—international studies of mental illness discrimination have shown that rates of both anticipated and experienced discrimination are consistently high across countries among people with mental disorders [5–8].

Yet another form of devaluation takes place when individuals affected by mental illness stigma accept the negative beliefs held against them and lose self-esteem, resulting in self-stigma (or ‘internalized stigma’) [9–11]. Internal consequences of stigma and

discrimination have been the subject of a number of studies and include feelings of shame, a loss of emotional well-being, poor self-efficacy, and negative recovery outcomes [12–19].

What self-stigma can mean is vividly described in a quote by Gallo [20, pp. 407–8] quoted in Angell *et al.* (2005) [21]—a statement from a person with mental illness on how stigma and discrimination have changed the way she feels about herself:

‘I perceive myself, quite accurately, unfortunately, as having a serious mental illness and therefore as having been relegated to what I called “the social garbage heap”, I tortured myself with the persistent and repetitive thought that I would encounter, even total strangers, did not like me and wished that mentally ill people like me did not exist. Thus I would do things such as standing away from others at bus stops and hiding and cringing in the far corners of subway cars. Thinking of myself as garbage, I would even leave the side walk in what I thought of as exhibiting the proper difference to those above me in social class. The latter group, of course, included all other human beings.’ [20]¹

Internal consequences of stigma and discrimination can further lead to hopelessness and depression, social withdrawal, and reduced participation in treatment programmes [3] and act as a stressor that perpetuates ill health and makes recovery more difficult [22, 23]. Coping responses, such as secrecy about the condition and avoidance of others, further feed into the cycle of isolation and alienation [3].

In addition to experiences of direct discrimination from others, persons suffering from mental illness face several forms of structural discrimination, for example manifest in the lack of resources allocated to the care of mental disorders, the location and quality of some treatment facilities, and inadequate attention to the physical health needs of people with mental disorders [24, 25].

Paradoxically, stigmatizing practices and even human rights violations are found within mental health services worldwide [26–28]. Undesirable conditions in mental health institutions, as well as the shame and fear of disclosure associated with attending them, act as a barrier for help-seeking and the effective treatment of mental health

¹ Reproduced from *Schizophr Bull.*, 20(2), Gallo KM, First person account: Self-stigmatization, pp. 407–410, Copyright (1994), with permission from Oxford University Press.

conditions [29]. For example, people with mental disorders may delay seeking treatment or terminate treatment prematurely for fear of being labelled and discriminated against [3, 30].

A statement from Diana on restrained treatment by health-care professionals in a psychiatric hospital:

‘There were between six and eight staff members, I am not sure, I can’t remember too much. I didn’t have a very clear vision. I saw people surrounding me, holding me by the hand, holding me by the legs. I don’t think it was something they had to do. There was no talking. They would have helped better if they would have been more understanding and more talking... more respect. I felt really bad. While I was in hospital I tried to complain but I don’t know if anybody was listening. It was a nightmare.’ [1, p. 87]²

Another very commonly cited source of stigma is family members. Even although many people experience great support from their families, it is family members too who often hold negative attitudes towards people with mental illness and even within their families treat them in a discriminatory way.

‘There I was, the eldest son suffering a sudden deep depression, crying and unable to work. Often threatened by my confused Dad as being “weak”, “a fuck-up”, and a “nutter”. No-one else in the family going back generations had gone “mad like that”. I was told not to tell any of the neighbours what was happening – to stop the gossip. (Paul)’ [1, p. 2]³

In many societies where services are scarce and support systems inadequate, families feel forced to resort to chaining and other practices to restrain relatives with mental illness [28, 31].

Research has shown that mental health professionals themselves hold negative stereotypes and attitudes similar to the general population and even more pessimistic views in the domain of recovery, possibly due to their disproportionate contact with those with poorer outcomes [32]. Service users commonly report lack of empathy and interest from health professionals, diagnoses being given with negative prognosis, and lack of information and involvement in decision-making [33].

‘Some of the worst experiences I have had have been in psychiatric hospitals. I recognise the need to be kept safe but often I have felt that my rights and dignity have been stripped away. Being intimately searched again and again and constantly followed whilst under “close observation” just leaves me feeling singled out and perceived as little more than a nuisance (“there’s to be no trouble on my shift”) [...] I have heard many comments along the lines of “Oh, she’s cut again. Why doesn’t she do it properly and kill herself”. (Sandra) [1], p. 94⁴

Stigma and discrimination do not only affect persons suffering from mental illness, but also families [34–36]. The effect of negative attitudes towards the family members of people with mental illness has been described as ‘stigma by association’ and may lead to

experiences of direct discrimination, as well as feelings of shame and self-blame [1]. In societies where the cohesion of family networks is strong, the impact of stigma by association may be severe and can include economic consequences, as well as impact on work or marital prospects [37].

Contextual factors relevant to stigma and discrimination

The manifestations of stigma and discrimination are subject to the influence of a range of cultural and contextual factors [38]. Key domains through which culture shapes the manifestations of stigma include: (1) notions of ‘mental illness’ and explanatory models (for example, in many settings, psychiatric symptoms may not be seen as indicative of an ‘illness’); (2) cultural meanings of the impairments and manifestations caused by the disorder and its stigma (for example, the impact of stigma on marital prospects may have more severe implications in cultural contexts where marriage is central); and (3) notions of self and personhood (for example, higher levels of family cohesion may offer more support but also go along with a more widespread impact of stigma across family members and generations).

Also socio-economic factors, such as poverty and access to health care, determine the context in which stigma is enacted and experienced [7, 9, 39, 40]. In low- and middle-income countries (LMICs) and other settings where most people with mental illness do not have access to social welfare benefits, the negative economic consequences of stigma, for example, through discrimination in work, may be so severe as to threaten the economic survival of entire families [41].

Global patterns of stigma and discrimination

There are few studies comparing the frequency of experiences of stigma and discrimination in different contexts, and recent research has sought to address this gap in the literature. International surveys of experienced and anticipated discrimination among people with schizophrenia (27 countries) and among people with depression (39 countries), for example, found rates of both outcomes to be consistently high across cultures [5, 7, 8]. Significant between-country variation was found for experienced discrimination, but not for anticipated discrimination reported by people with schizophrenia [7]. A report on the qualitative data collected as part of the same study, however, found few transnational differences [6]. Another study looking at public attitudes across 16 countries identified a ‘backbone’ of certain prejudices that were held across all settings, even where overall stigma was relatively low [42].

On the other hand, some smaller studies suggest stark differences between high-income country (HIC) and LMIC settings, for example, studies from China [43] and India [41], with rates of experienced discrimination much lower than those commonly reported from HIC studies, and qualitative differences in the meaning and appraisal of the experiences made. At first sight, this appears to support the findings of early cross-cultural research on stigma, suggesting that the stigma of mental illness may be less marked in non-industrialized societies due to a more supportive environment with more social cohesion, and

therefore less risk of prolonged rejection, isolation, segregation, and institutionalization [44, 45; 46, 47 cited in 48]. The better prognosis of schizophrenia found in international studies by the World Health Organization (WHO) [49–52] has therefore commonly been attributed to less stigmatization in LMICs [53].

Yet, in contradiction to this, there is now a considerable body of evidence documenting that in many LMIC settings, experiences of stigma, discrimination, and human rights abuses due to mental illness are common and severe [5, 11, 27, 37, 54–62]. One international study using population-wide data from 16 countries found even higher rates of reported stigma among people with mental disorders in developing (31.2%) than in developed (20%) countries [55].

In conclusion, our understanding of global patterns of stigma and discrimination is still rather limited to date, and further high-quality cross-cultural research is needed to throw light on the forces that drive intercultural differences in the manifestation of stigma. Understanding the factors that shape stigma distinctly in different contexts will serve to inform the development of context-specific anti-stigma interventions.

How to measure stigma

Alongside the development of research into stigma, the creation and validation of instruments to measure stigma and discrimination took their beginnings in the 1960s. Early scales focused largely on the measurement of stigmatizing attitudes among the general population. Since, numerous scales have been developed, incorporating a wider range of perspectives on stigma and discrimination, notably the inclusion of the perspectives and experiences of service users and carers [63]. Nevertheless, there continues to be a distinct lack of measures developed or validated in LMIC settings and/or non-Western cultures [64]. Several methods have been put forward which seek to achieve cultural validity of measures of stigma and discrimination, including an approach by Yang *et al.* which proposes to focus on ‘what matters most’ in a given culture [65, 66]. A recent review concluded that future efforts in the domain of measuring stigma and discrimination should focus on: (i) procedures for achieving cultural validity of measurement tools, (ii) indicators for structural stigma and stigmatizing behaviour (underrepresented in current scales), and (iii) targeted or tailored measures for specific subgroups, all with a particular focus on LMIC countries where literature is sparse [63]. This is important as the appropriate measurement of stigma and discrimination is critical to understanding whether and how anti-stigma interventions are effective [63].

How to tackle stigma

The critical question to tackle stigma in mental health is: what interventions work? In the past years, research on anti-stigma interventions to change knowledge, attitudes, and behaviour towards people with mental illness has increased. Most interventions aim at changing one or several of these aspects through education, social contact, or behavioural interventions.

A recent narrative review concluded with the following main findings on the evidence of anti-stigma interventions [64]:

- (1) ‘at the population level there is a fairly consistent pattern of short-term benefits for positive attitude change, and some lesser evidence for knowledge improvement;
- (2) for people with mental illness, some group-level anti-stigma interventions show promise and merit further assessment;
- (3) for specific target groups, such as students, social-contact-based interventions usually achieve short-term (but less clearly long-term) attitudinal improvements, and less often produce knowledge gains;
- (4) this is a heterogeneous field of study with few strong study designs with large sample sizes;
- (5) research from low-income and middle-income countries is conspicuous by its relative absence;
- (6) caution needs to be exercised in not overgeneralising lessons from one target group to another;
- (7) there is a clear need for studies with longer-term follow-up to assess whether initial gains are sustained or attenuated, and whether booster doses of the intervention are needed to maintain progress;
- (8) few studies in any part of the world have focused on either the service user’s perspective of stigma and discrimination or on the behaviour domain of behavioural change, either by people with or without mental illness in the complex processes of stigmatisation.’⁵

It has been found that generally the effectiveness of the interventions depends much on the target group and the time frame of the intervention. However, most studies are short-term effectiveness studies looking at attitudes of the general public towards people with mental disorders in HICs. The most widely evaluated interventions are education/information and social contact [63].

Overall there remains a large knowledge gap for medium- to long-term anti-stigma interventions, and particularly for interventions in low-income countries where evidence is almost absent [63]. There is also a need for: (i) more high-quality interventions based on robust methods and validated measures, (ii) more systematic reviews on long-term effectiveness, (iii) more randomized controlled trials, and (iv) more evidence from LMICs [67].

Social contact-based interventions

Interventions using social contact as a key element have been found to be the most effective type of interventions [68]. At the same time, social contact is also the best evidence-based intervention, particularly in short-term outcomes. Evidence from systematic reviews suggests that social contact is the most effective intervention in terms of achieving short-term improvements in knowledge and attitudes among adults.

An account by a young man who participated in the German school project ‘Crazy? So what!’:

‘Eight years ago I became ill: I developed schizophrenia [...]. I’ve been feeling better now for two years. But I do have to take good care of myself. But hiding because of that? These times are over. I finally want to live now! Talking to the students is exhausting but also really great [...] they discover that there are a lot more commonalities than differences between us, that their images of the ‘crazy ones’ are

⁵ Reproduced from *The Lancet*, 387(10023), Thornicroft G, Mehta N, Clement S, *et al.*, Evidence for effective interventions to reduce mental-health-related stigma and discrimination, pp. 1123–1132, Copyright (2015), with permission from Elsevier.

not true. It feels really good to contribute to achieving that we finally can talk openly about mental illness, and that nobody has to hide because of a mental health problem.' [69]⁶

Social contact is the most effective type of intervention in the short term, but it is not clear whether effectiveness is sustained in the medium to longer term [67]. While social contact has been reported to be the most effective intervention in adults, these evaluations are mostly based on intervention studies from HICs. There is a great need for more evidence from LMICs to assess whether social contact is as effective there and how to implement it to suit local requirements. In addition, more research is needed to investigate the long-term effectiveness of social contact interventions.

Educational interventions

'The [...] practical way to stop stigma and discrimination is by better education of schoolchildren at an early age and to reinforce this message through lifelong learning. Each course or class should not only start with "household" messages about fire escapes, etc., but that bullying or discrimination will not be tolerated whilst on the course.' (Paul) [1]

(Thornicroft, 2006)

While direct social contact interventions have been found to be the most effective intervention in adults, systematic reviews have found that in students, educational interventions are more effective in reducing stigma in students' knowledge and attitudes in the short term. However, the evidence base for effectiveness in the medium to longer term is weak [64]. A meta-analysis found both social contact as well as educational interventions reduce stigma significantly and, importantly, irrespectively if these interventions are delivered face-to-face or via Internet programmes [70]. Moreover, Thornicroft *et al.* have found evidence that education and information seem to be the most effective interventions in the medium and long terms [64]. Evaluations in HICs have found that stigma and discrimination against people with mental illness can be reduced through focused, long-term information campaigns like Time to Change in the United Kingdom (UK) [71]. High-quality effectiveness evaluations for educational interventions are scarce for LMICs. Several national and regional campaigns from LMICs report qualitative changes in attitudes and behaviour; however, these effects lack high-quality evaluation for quantitative efficiency [72].

Behavioural domain

Overall the effect of behavioural therapy and psychotherapy has not been sufficiently researched. In persons with mental illness, psychoeducational therapy, including elements of cognitive behavioural therapy (CBT), seem to be effective in reducing self-stigma

[73]. Yet, CBT has been found not to be effective in reducing stigma in other groups.

For medium- or long-term outcomes, systematic reviews have found there was not sufficient research to believe psychotherapy or entertainment/arts interventions can help to reduce stigma [64].

Conclusions

From this discussion, the authors draw the following conclusions. Stigma and discrimination appear to be universal in their presence and impact, although there are clear local and regional variations in their content and manifestations. Lay stigma by the general public constitutes a powerful force for social exclusion, and in addition there is also strong evidence that stigma among health-care professionals is a powerful barrier to the mental and physical health care needed by people with mental illness. There is now increasingly strong evidence that personal and social contact methods, including filmed/virtual contact, is the most strongly evidence-based method to reduce stigma and discrimination. This evidence is now accumulating at inter-personal, organizational, and national levels. But as yet, there are few longer-term studies to know if such gains are sustainable in the long term. Nearly all the research evidence is from HICs, with a distinct evidence gap from LMICs. For the future, it is clear that service users are the central pioneers/key active ingredients in anti-stigma programmes and that interventions specifically locally and culturally adapted for use in LMICs are a pressing priority.

Global mental health

Crick Lund, Dörte Bemme, and Judy Bass

Introduction

Global health has been defined as ‘an area for study, research and practice that places a priority on improving health and achieving equity in health for all people worldwide’ [1]. In a similar vein, global mental health has emerged in recent years as a field of research, advocacy, and practice that is focused on improving the mental health of populations and reducing inequity in the global burden of mental illness. Because these challenges are multi-faceted, global mental health has been marked from its inception as a multi-disciplinary field, incorporating disciplines of psychiatry, psychology, epidemiology, health economics, anthropology, and implementation science. Although much of the work of global mental health has been focused on the needs of women and men living in low- and middle-income countries (LMICs), there is increasing awareness that many of the mental health challenges faced by populations in LMICs are also encountered in high-income countries (HICs).

Why then is it important to think about mental health in global terms? Firstly, despite the massive and growing global burden of mental illness, mental health has been neglected in global health and international development policy [2]. For example, mental health was excluded from the 2000–2015 Millennium Development Goals, and much of the focus and funding of agencies like the Global Fund and the Bill and Melinda Gates Foundation has been on communicable diseases. Secondly, emerging evidence from the WHO Atlas surveys informs us that the world’s mental health resources are largely concentrated in HICs and in wealthier, largely urban settings of LMICs—in short, there is a global maldistribution of mental health resources [3]. Thirdly, human rights abuses and stigma, especially against people with severe mental illness, are global problems that pervade all cultures of the world [4]. Fourthly, there is strong emerging evidence regarding the links between the global challenge of poverty and mental health—poverty is a key social determinant of population mental health, and mental illness leads to individual and household impoverishment [5]. Finally, there are important links between mental health and many other global development challenges, including gender inequity, violence, forced migration, and climate change. As several have argued, there is no sustainable development without mental health [6].

This chapter sets out to provide an overview of the emerging and dynamic field of global mental health. It starts with a brief history

of the field, noting landmark publications and events. The chapter then introduces key areas of enquiry and action in global mental health, including epidemiology, mental health policy and services, intervention research, implementation science, humanitarian settings, qualitative research, instrument development, and economic evaluation. Finally, it concludes with reflections on critiques of the field and future directions.

Global mental health: a brief history

The emergence of global mental health marks a departure from, but also continuity with, earlier efforts to conceptualize and address mental health problems around the world. While historical accounts have traced the evolution and proliferation of psychiatric knowledge back to antiquity, the rise of institutional care in Europe, and the spread of the psychiatric asylum to many countries during the colonial era [7], global mental health as a specific institutional and programmatic assemblage has emerged out of a more recent post-Second World War history. During this period, mental health became the subject of international public health and psychiatric epidemiology, which rendered mental disorders comparable across regions and other diseases, and allowed for mental health to become visible as a ‘global’ problem.

Post-war History

Initially, after the founding of WHO in 1948, mental health promotion followed a pacifist agenda and conceived of mental health as a vehicle to further ‘harmonious relationships between men’ and ultimately ‘world peace’ [8]. WHO’s initial focus was not on distinct mental illnesses, but on mental health as a positive state of well-being in the tradition of the ‘mental hygiene’ movement, which had advocated for the prevention of mental illness through education since the 1920s [9]. The dual goal of building harmonious ‘world citizenship’ and mental health education also informed the founding of the World Mental Health Federation in 1948, the first non-governmental organization (NGO) with which WHO collaborated on matters of mental health policy [10].

A stronger focus on mental disorders came about with the rise of psychiatric epidemiology in international mental health in the 1970s, which sought to assess the prevalence, distribution, and determinants of mental illness. One key challenge to the

epidemiological approach was the lack of standardization in the classification and interpretation of mental disorders. While the early versions of the WHO International Classification of Diseases (ICD-6) (1948) and ICD-7 (1955) contained sections on mental illness, they were not widely accepted internationally. Comparative studies on diagnostic practice had also shown large differences in the clinical interpretation of disease categories [11]. Comparable data on mental disorders thus depended on the development of standardized instruments and classifications. In 1966, WHO initiated what would become a series of cross-cultural proof-of-concept studies on schizophrenia that demonstrated that the disorder existed around the world, that it could be measured with standardized instruments, and that it had greatly varying outcomes across developed and developing settings [12]. Greater standardization of psychiatric classification and practice was achieved through the publication of the *Diagnostic and Statistical Manual of Mental Disorders*, version 3 (DSM III) in 1980, which abandoned the psychodynamic aetiological model in favour of a symptom-based approach with no aetiological underpinning. The DSM classification subsequently increased its harmonization with WHO's ICD system, and a number of instruments were developed to facilitate the collection of comparable data, including the Present State Examination (PSE), the Schedule for Clinical Assessment in Neuropsychiatry (SCAN), and the Composite International Diagnostic Instrument (CIDI).

Disability and disability-adjusted life years

Another important factor lending mental health increasing importance within international health was the development of disability frameworks beginning in the 1980s and leading up to the creation of a new statistical measure that combined morbidity and mortality into the assessment of the global burden of disease through the disability-adjusted life years (DALYs) measure, as part of the *World Development Report* in 1993. This marked the World Bank's increasing investment in health, based on a 'human capital' logic, and its entrance into 'Global Health' [13]. DALYs laid the foundation for the influential 'Global Burden of Disease (GBD)' studies [14], which fundamentally changed how health was measured on a global scale. For the mental health agenda, this shift towards morbidity had a significant impact as mental and neurological disorders became visible as one of the largest contributors to the GBD [15]. Subsequently, medical anthropologists, including Robert Desjarlais, Leon Eisenberg, Byron Good, and Arthur Kleinman, drew further attention to this enormous burden and formulated a call for international action on mental health in the landmark *World Mental Health Report* [16], which combined global data with local case studies. The report was launched at the United Nations in 1995, and in response, WHO initiated the *Nations for Mental Health* programme a year later, which promoted mental health service delivery for underserved populations [17]. These efforts marked a shift towards service delivery rather than pure epidemiology in international mental health.

World Health Report 2001

The year 2001 was a significant year for global mental health when, with the support of the new WHO Director General Gro Harlem Brundtland, the World Health Day and World Health Report were dedicated in their entirety to mental health. The theme of the day 'Stop exclusion—Dare to care' speaks of this shift towards care

delivery and the human rights agenda. In conjunction, the first WHO *Mental Health Atlas* provided a global overview over the existing mental health care resources [18], marking another important step towards the quantification of the global 'treatment gap'. Parallel to these developments, the wider field of global health consolidated in the early 2000s [13] and mental health advocates sought to emulate its achievements and strategies, especially the enormous success of the HIV/AIDS advocacy movement.

Global mental health

Global mental health as a distinct global health community and programme was officially inaugurated in 2007 when *The Lancet* published a special series on global mental health, edited by Patel and colleagues. This series documented the links between mental health and other health conditions [19], presented a systematic review of the evidence for cost-effective prevention and treatment interventions in LMICs [20], and called for the scaling up of evidence-based mental health care in LMICs [21]. The field of global mental health has since grown significantly, with the creation of a distinct assemblage of institutions and training programmes, including Masters and doctoral programmes and short courses; online networks [the Movement for Global Mental Health (MGMH) and the Mental Health Innovation Network (MHIN)]; specialty journals such as *Journal of Global Mental Health* and *International Journal of Mental Health Systems*; funding streams, for example United States National Institute of Mental Health's Office on Disparity and Global Mental Health, Grand Challenges Canada, United Kingdom's Department for International Development, European Commission, and Wellcome Trust; international agencies (in particular, the WHO Department of Mental Health and Substance Abuse); and international NGOs such as Transcultural Psychosocial Organization and BasicNeeds.

What distinguishes global mental health from earlier international mental health efforts are five particular features—firstly, the strengthened emphasis on the development of research-driven *evidence-based* interventions. Commitment to the production of evidence-based interventions favours randomized controlled trial (RCT) research designs to test innovative interventions, with the subsequent goal of implementation and scaling-up. Evidence-based practice guidelines, such as the WHO's *mhGAP Intervention Guide* that outlines the treatment of eight priority disorders [22] and the Inter-Agency Standing Committee's *Guideline for Mental Health and Psychosocial Support in Emergency Settings* [23], have thus become central tools in organizing this new field of practice.

A second distinguishing feature is the consideration of care *delivery* in low-resource settings, for example through the training and supervision of non-specialist health providers—a strategy referred to as task shifting or task sharing [24]. Global mental health pays particular attention to the modalities and limitations of service delivery in low-resource settings by using task-sharing models and simplified and adapted treatment protocols, with an increasing focus on implementation science [25].

Thirdly, global mental health is characterized by multi-disciplinarity and multi-stakeholder involvement. For example, the landmark research agenda-setting article *Grand challenges in global mental health* was based on an extensive international Delphi stakeholder consultation process [26]. This commitment to multi-disciplinary engagement has built a novel knowledge base, adjacent to academic psychiatry, combining the expertise of public health,

psychology, health economics, development studies, anthropology, and the experience of NGOs.

Fourthly, global mental health is characterized by a strong emphasis on human rights and the need to strengthen legislation and regulatory environments to protect and promote the rights of people living with psychosocial disabilities [27]. This has been exemplified in the WHO QualityRights initiative, which has developed a tool to assess human rights protection in the provision of mental health care and campaigned for the reduction of human rights violations, particularly against people living with severe mental illness, whether in communities or in psychiatric institutions [28].

Fifthly, despite efforts to raise the profile of mental health as a specific global health priority, global mental health is working towards the *integration* of mental health into other agendas, including sustainable development, non-communicable diseases, and maternal and child health. This includes efforts towards the integration of mental health care into primary care [29]. In particular, recent global mental health advocacy and research have highlighted its links with the development agenda by demonstrating the link between mental health and poverty [30] and the economically promising ‘return on investment’ of mental health care [31], and by successfully advocating for the inclusion of mental health into the sustainable development goals.

In 2016, the World Bank Group and WHO hosted a high-level meeting entitled *Out of the shadows: making mental health a global development priority* in Washington DC, which was attended by over 500 delegates from the research, business, clinical, policy, and donor communities. At this meeting, the president of the World Bank Dr Jim Kim and the Director General of WHO Dr Margaret Chan committed themselves and their organizations to giving greater priority to global mental health [32].

Epidemiology

Global burden of mental illness

A major breakthrough in the measurement of the global burden of mental disorders came with the development of the DALY measure, first published in the 1993 World Development Report [33]. The DALY combines a measure of mortality [years of life lost (YLLs)] with a measure of morbidity [years of life lived with disability (YLDs)], to assess the burden of all diseases and injuries using the metric of time. This allows for comparison of a wide variety of conditions, from human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) to cancers and to depression, with the latest 2015 GBD study covering over 300 diseases and injuries. Further details of the assumptions and methods in the latest 2015 GBD study can be found elsewhere [34]. From a health policy perspective, this has been transformative for the field of mental health, because it has moved to the foreground the substantial contribution of mental disorders to the global burden of disease.

Data from the latest available 2015 GBD study show that the total proportion of the global burden of disease attributable to mental, neurological, and substance use disorders has increased substantially from approximately 6.5% in 1990 to over 10% in 2015. For mental and substance use disorders alone, there was a 14.9% increase between 2005 and 2015 [34]. These increases have been

largely driven by demographic factors, chiefly population growth and ageing, with age-standardized DALYs per 100,000 population for mental and substance use disorders showing a 0.3% decrease between 2005 and 2015.

There are important gender differences in the burden of mental and substance use disorders, with women accounting for more DALYs in all disorders, except for childhood mental disorders, substance use disorders, epilepsy, and Parkinson’s disease, which are more prevalent among boys and men. There are also important age variations, with the burden of mental, neurological, and substance use disorders peaking in young adult years (Fig. 3.1). Fig. 3.1 also visually depicts the relative contribution of specific mental and substance use disorders to the total burden of all mental and substance use disorders.

Social determinants of mental health

Along with the growing awareness of the burden of mental illness, social epidemiology in the last 30 years has generated new knowledge on the social determinants of mental health [35]. Social determinants are a wide range of social and economic risk and protective factors that influence population mental health across the life course. These social determinants include five broad domains: demographic, social, economic, neighbourhood, and environmental events [36]. The *demographic domain* includes the effects of age, gender, and ethnicity on mental health. In addition to age and gender differences in the burden of mental illness, members of minority ethnic groups have been found to have an increased risk for psychosis and depression, particularly in the context of migration or as a result of experiences of discrimination or exclusion [37]. In relation to the *social domain*, social capital, particularly cognitive social capital, has been shown to offer protection against common mental disorders such as depression and anxiety disorders [38]. Education is important for adolescent well-being, is highly protective against later-life depression, and improves cognitive reserve that may be protective against dementia [39]. In relation to the *economic domain*, there is robust evidence showing a strong association between poverty, unemployment, and adverse mental health outcomes, including common mental disorders and schizophrenia [5, 40]. The relationship between poverty and mental illness is bidirectional, characterized by social causation and social drift/selection [30, 40]. In relation to the *neighbourhood domain*, the characteristics of a local area or neighbourhood have an important bearing on population mental health, over and above the effects of individual level socio-economic deprivation [41]. Finally, *environmental events*, such as natural disasters, industrial disasters, war, civil conflict, forced migration, and the effects of climate change, have been shown to have a range of negative mental health consequences. These include post-traumatic stress disorder (PTSD), depression, and anxiety among adults [42], and emotional and behavioural disturbances, sleep difficulties, and disturbed play in children [43].

Mental health policy and services

Given the major global burden of mental disorders and the powerful social determinants that influence the mental health of populations, what can governments and civil society do? A key area of global mental health research and advocacy since the World Health Report 2001 has been mental health policy and service development.

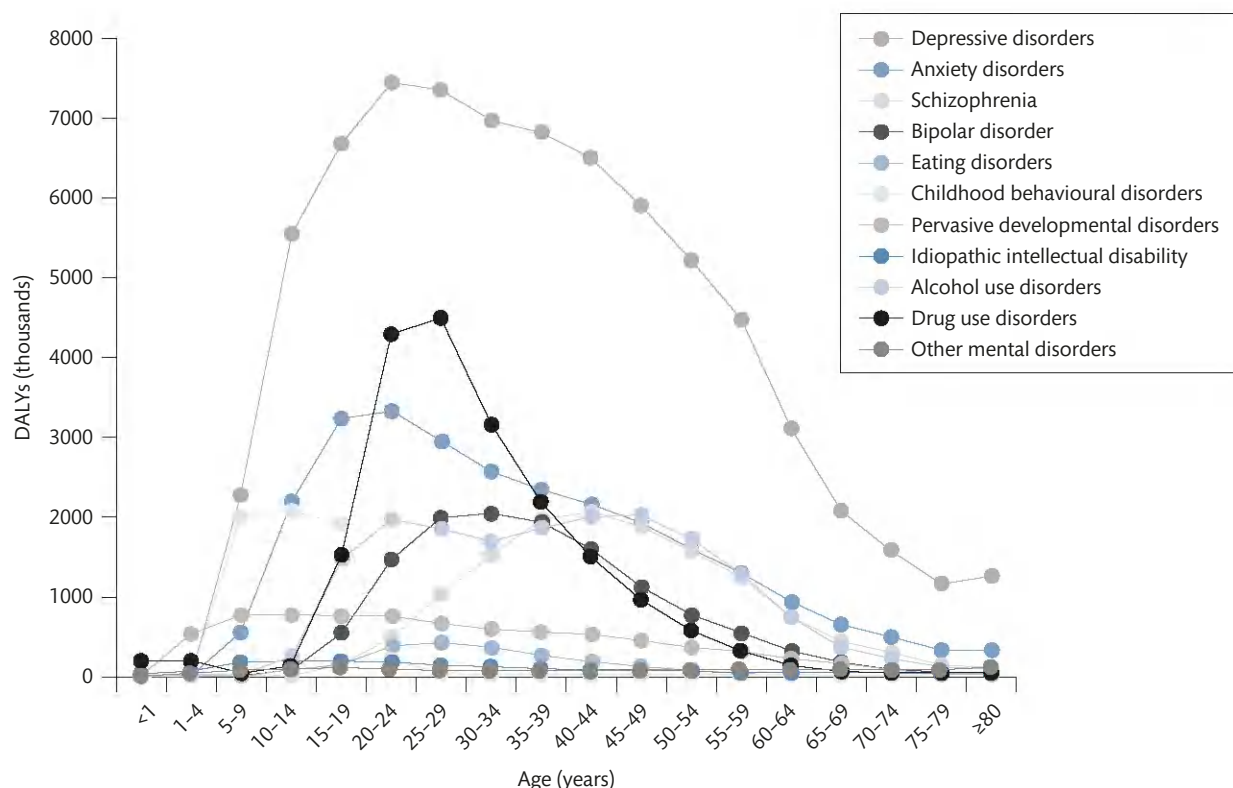

Fig. 3.1 (see Colour Plate section) Disability-adjusted life years (DALYs) for each mental and substance use disorder in 2010, by age.

Reproduced from *The Lancet*, 382(9904), Whiteford HA, Degenhardt L, Rehm J, *et al.*, Global burden of disease attributable to mental and substance use disorders: findings from the Global Burden of Disease Study 2010, pp. 1575–86, Copyright (2013), with permission from Elsevier Ltd.

One of the major WHO recommendations from that report was that countries should develop national mental health policies and plans, and make the most efficient use of their available resources by implementing these policies and plans using cost-effective interventions. From 2001 to 2005, the WHO developed guidelines to assist countries (particularly LMICs) to develop national mental health policies, plans, and programmes. These practical step-by-step guidelines are set out in the WHO Mental Health Policy and Service Guidance Package [44]. Policies and plans are vital for several reasons—a policy provides a roadmap to guide a ministry of health and other relevant ministries; without such a policy, governments do not have a clear mandate or a mechanism to allocate much needed resources; the process of developing a national policy and plan is also an important means of developing consensus among a range of stakeholders; and a clearly articulated policy and plan with the appropriate targets and indicators can facilitate evaluation of the extent to which the mental health needs of populations are being met.

At a global level, these aspirations were subsequently developed and adopted in the WHO Global Mental Health Action Plan (2013–2020), endorsed by all United Nations member states. The objectives of this plan are to: (1) strengthen effective leadership and governance for mental health; (2) provide comprehensive, integrated, and responsive mental health and social care services in community-based settings; (3) implement strategies for promotion and prevention in mental health; and (4) strengthen information systems, evidence, and research for mental health [45].

In relation to the delivery of mental health services, the WHO has recommended an optimal mix of services, which can be depicted

in a pyramid (Fig. 3.2) [46]. This emphasizes the promotion of self-care, the development of primary care and community-based services, the integration of mental health into general health care services, and the provision of a small number of specialist mental health services. Within this overall framework, the Disease Control Priorities initiative has provided a detailed review of the most cost-effective interventions, to be delivered through service platforms, targeting mental health promotion and prevention, treatment, and rehabilitation of mental, neurological, and substance use disorders [47].

Intervention research, trials, and innovations

Much of the intervention research in LMIC settings at the beginning of the twenty-first century has focused on treatments for common mental disorders, specifically depression, anxiety, and trauma-based syndromes. This focus was, in part, due to the high prevalence of these disorders in LMIC populations, as well as a growing recognition of the large treatment gap for accessing any type of mental health services outside of urban psychiatric centres [3]. The predominant model of service provision has used task-sharing models. Evidence is growing that task sharing can be an effective strategy for providing mental health services where few mental health professionals exist [48], though Padmanathan and De Silva [49] identified important barriers to the acceptability and feasibility of task-sharing models if sufficient financial resources are not provided to support these programmes.

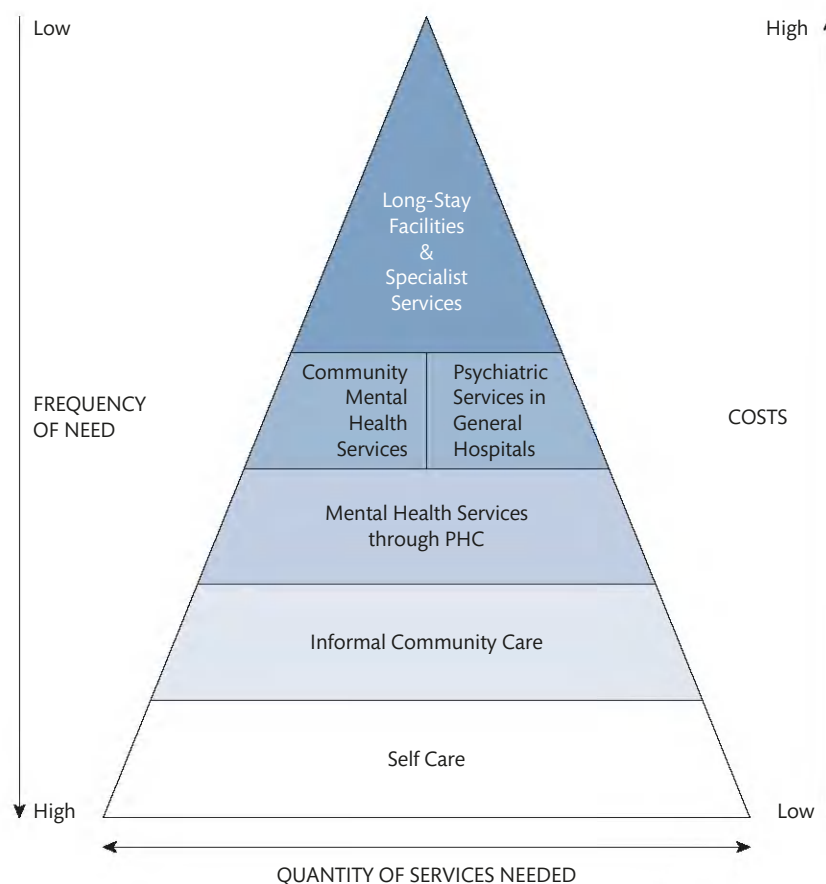

Fig. 3.2 Optimal mix of mental health services.

Numerous randomized trials in LMIC settings across multiple continents have demonstrated the effectiveness of evidence-based psychotherapies, including cognitive behavioural, interpersonal, and cognitive processing therapies, in reducing the burden of common mental disorders [48]. Research has also identified the utility of using these approaches to improve non-mental health outcomes among high-risk populations, with a growing evidence base of the feasibility and impact of treating mental health problems among HIV-infected populations on HIV treatment adherence [50].

Building on task-sharing approaches, intervention research in LMIC settings has also investigated collaborative care and stepped care models, which integrate task-sharing treatment into primary care systems [51].

An area of current innovation in intervention research is the development of cross-diagnostic and trans-diagnostic treatment models. These models are designed to treat multiple common disorders, rather than being disorder-specific (for example, treatments for depression alone). This is an important consideration, as disorder comorbidity is common and being able to train providers in a single treatment, rather than different treatments for each disorder, can improve treatment fidelity, coverage, and quality, particularly for lay providers. Some of these approaches, such as Problem Management Plus (PM+), have a unified treatment protocol that can be applied to individuals with a range of common mental health problems [52].

Current evidence for PM+ indicates that it is acceptable and feasible to implement [53]; impact results are forthcoming. An alternative to a unified treatment approach is the model developed by Murray and colleagues—Common Elements Treatment Approach (CETA)—that includes a set of treatment components that can be delivered in varying combinations to address a range of common mental health problems and comorbidities that present within a population [54]. Two randomized trials of CETA have shown that this model is acceptable, feasible, and effective for reducing the burden of common mental health problems, such as depression, anxiety, and post-traumatic stress, in LMIC populations [55, 56].

Implementation science

A critical finding from existing global implementation research is that, regardless of positive reports of acceptability and feasibility by providers and consumers, evidence-based mental health programming is still not being scaled up or sustained [57]. The field of implementation science is needed to provide evidence for how these interventions can be effectively integrated and sustained into existing care systems through identifying and addressing barriers at the organizational and policy levels that are impeding implementation efforts.

In LMICs, like in many HICs, a range of organizations provide mental health services, including hospitals and primary care clinics, NGOs, educational settings, and social service agencies. Primary care settings provide an important opportunity for integrating mental health care with care for other health conditions under a single system. One large research project that has investigated the integrating and scaling up of mental health care packages in primary and maternal health care contexts in five LMIC settings is the Programme for Improving Mental Health Care (PRIME) study [58]. One of the first steps taken in PRIME was to develop and implement district-level mental health care integration plans in all five country sites at four service levels: health service organization, specialist mental health services, primary care facilities, and the community [59]. While the integration goals, to improve quality and access to mental health services, were common across sites, the system approaches required to achieve these goals were variable, for example in the types of providers used to deliver mental health care (lay and community providers vs more highly qualified and specialist mental health workers). The identified variations mean that different systems approaches will be needed to ensure quality mental health services are provided and sustained over time.

While primary care settings are important for integrating mental health care with other health conditions, for many LMIC populations, accessing mental health services in primary health care settings is neither feasible (because of stigma or logistical barriers) nor preferred (because mental health problems may not be considered to be in the domain of what doctors or health providers treat). NGOs and community-based organizations (CBOs) frequently are direct providers of mental health services, with some at the forefront of investigating how to scale up services through non-health care systems. One example is the international NGO Strong Minds which has been working to scale up interpersonal psychotherapy (IPT), an evidence-based treatment for depression in Uganda [60], through local organizations and community groups [61].

In addition, it is recognized that the health sector often needs to interact with other sectors to improve mental health outcomes—what the WHO defines as ‘intersectoral action for health’ [62]. A qualitative study in South Africa that investigated the challenges and possibilities for intersectoral care for mental health services noted several challenges in this regard, including the lack of systematic strategies for delineating care roles and the lack of communication and referral systems. These limited the success of the multi-system strategies of care, despite the recognition among stakeholders that providing care across multiple systems is necessary [63].

Qualitative research

Global mental health’s emphasis on multi-stakeholder engagement and the recognition that mental health interventions and instruments need to be culturally and linguistically adapted have made qualitative research an important aspect of piloting, implementing, and evaluating mental health interventions. *Ethnographic approaches* have had a strong influence on global mental health, largely due to the anthropologist Arthur Kleinman’s seminal work on the expression of mental distress and somatization in China and Asia [64]. While such long-term, in-depth ethnographic engagement is rare nowadays, global mental health draws extensively on qualitative

health research to tailor interventions and research tools to local contexts and to ensure linguistic and cultural appropriateness [65]. A large body of literature has emerged on ‘*local idioms of distress*’ [66] describing local concepts for mental suffering such as ‘heart–mind’ problems in Nepal [67] and ‘thinking too much’ in Haiti (‘*Reflechi twop*’) [68] and Zimbabwe (‘*Kufungisisa*’) [69], which are similar, but not identical, to the category of ‘depression’.

Another area in which qualitative research has been integrated into the design of global mental health interventions are studies investigating the *acceptability and feasibility* of mental health interventions or barriers to their implementation within specific populations. For example, task-sharing approaches have been assessed through qualitative research in a great number of contexts [70], while other research has explored the barriers to collaboration with traditional healers [71].

Qualitative research has also become increasingly important for *implementation science* [25]. Multi-country consortia like PRIME routinely collect qualitative interview data on the implementation process of their interventions to assess health system bottlenecks, as well as service user and stakeholder perceptions of the service. Qualitative case studies have also been identified as an important tool for *evaluation*, as they allow for the documentation and dissemination of the specific lessons that are learnt on the ground, including processes of delivering interventions [72].

Instrument development

In the measurement of mental health problems globally, it is important to consider the validity, reliability, and utility of measurement tools. In general, a valid instrument is one that measures the construct it is intended to measure and a reliable instrument is one that can consistently measure the construct of interest over time (test–retest reliability) and ensure that this consistency does not vary, based on who administers the instrument (inter-rater reliability). Utility refers to how practical and useful the instrument is for a given problem in a given context.

The development of valid and reliable tools to assess mental health problems across different cultures and contexts has been an area of research for some time. One reason for the importance of focusing on instrument development is that the nature and meaning of mental health symptoms can differ by culture and context [73]. For example, in a review of the qualitative literature on the expression of depression globally, Haroz and colleagues found that many symptoms of depression in non-Western populations are not captured in standard measurement tools based on Western diagnostic criteria and that some of the symptoms that frequently appear in standard depression measures, such as psychomotor agitation or slowing, were infrequently mentioned in non-Western populations [74].

To reconcile local characterization of mental health problems with the desire to use standard instruments that can allow for cross-population comparisons, researchers are now using mixed methods approaches that include qualitative methods to identify symptoms relevant to local populations. For example, Wilk and Bolton’s qualitative study of depressive disorders among HIV-affected Ugandan adults found many of the standard symptoms related to depressive disorders, while also identifying symptoms such as ‘hating the world,’ ‘bad, criminal or reckless behavior,’ and ‘unappreciative of

assistance' as relevant manifestations of locally defined depression [75]. These locally relevant symptoms were added to an existing depression measure to create a more locally valid measure that could still be used to compare the burden of illness with other populations [76]. Similar methods have been used, for example, to develop valid and reliable measures of post-partum depression among women in the Democratic Republic of Congo [77], post-traumatic stress problems among youth in Zambia [78], and disruptive behaviour problems among youth in Nepal [79].

While global mental health researchers have increasingly focused on improving reliability and validity of mental health instruments across contexts, developing tools that are practical and useful for screening and ongoing treatment monitoring and evaluation has been more difficult. And as mental health services are integrated in other care systems and scaled up for delivery, having useful measures becomes increasingly important. In considering utility, two important factors are the length of the measure and the usefulness of individual items to assess different mental disorders, as well as the severity of the disorders. One analytic approach that is currently being used to generate useful measures is item response theory (IRT). IRT is a type of latent variable modelling approach that models the probability of a given response as a function of a respondent's underlying level of a latent trait. IRT can help to refine scales by identifying well-performing items at varying levels of a latent trait, assisting in shortening of a scale for screening or monitoring purposes, preventing floor and ceiling effects [80], and identifying where, along a latent trait, a scale is underperforming and additional items are needed in order to better assess individuals with those levels [81]. Tang and colleagues have used this approach to develop a brief depression measure for older adults in Hong Kong [82], and Haroz and colleagues have used IRT analyses to develop a depression measure that more accurately captures the presentation of depression across cultures [83].

Economic evaluation

Given the severely resource-constrained environment facing mental health systems in most countries, particularly LMICs, it is vital that the available resources are used efficiently. Policymakers face several difficult economic questions in relation to mental health care, namely: (1) what goods and services should a health system produce—for example, should these provide care for infectious diseases, non-communicable diseases, or mental health, and how should these priorities be set?; (2) what is the most efficient and effective way of delivering mental health interventions (for example, through community-based care, primary care services, or hospitals), and who should the key delivery agents be?; and (3) which population groups should be given special attention, for example women, children, older adults, or the economically vulnerable?

A key area of enquiry in global mental health is therefore the economic evaluation of mental health interventions. Economic evaluation has been defined as 'the comparative analysis of alternative courses of action in terms of both their cost and consequences' [84]. Economic evaluations are essential to assist policymakers to set priorities among competing health needs [85]. One of the major concerns of economic evaluation is the relationship between allocated inputs (resources) and outcomes (health benefits). An intervention

is considered technically inefficient if the same, or a greater, health benefit could be obtained with less resources.

The three major methods of conducting economic evaluations are cost-effectiveness analysis, cost-utility analysis, and cost-benefit analysis. All three methods are interested in measuring costs but differ in their measurement of outcomes. In the case of cost-effectiveness analysis, the outcome is measured in the appropriate (usually clinical) measure to assess the effect of the intervention, for example reduction in clinical symptoms or improvement in functioning. In the case of cost-utility analysis, the outcome is measured using a standardized comparable measure of utility such as a combination of life years with the quality of life [quality-adjusted life years (QALYs)] or DALYs, allowing for comparison of the health impacts across a range of interventions and health conditions. In the case of a cost-benefit analysis, the outcome is measured in monetary terms. This latter approach allows policymakers to assess the economic gains from a particular set of service costs or the return on investment.

Some examples of economic evaluations in global mental health research have been Patel and colleagues' cost-effectiveness analysis of primary care for common mental disorders in Goa in India [86] and a task-shifting cognitive behavioural therapy delivered by paraprofessionals for alcohol use in Kenya [87].

In a recent publication, to coincide with the historic World Bank/WHO 'Out of the Shadows' meeting in April 2016, Dan Chisholm and colleagues conducted a global return-on-investment analysis for scaling up care for depression and anxiety disorders between 2015 and 2030. They estimated that for every dollar invested, there would be a \$2.3 to \$3 return on investment when economic benefits alone were considered, and a \$3.3 to \$5.7 return on investment when the value of health returns were also included [31].

Gaps in the field and critiques

In the years following *The Lancet* series on global mental health in 2007, the field attracted some critical attention from transcultural psychiatrists and social scientists who questioned the agenda of this emerging field. These criticisms have focused on a number of key issues.

Weak evidence. Critics have drawn attention to the long-standing controversies surrounding the DSM classification system, especially the cross-cultural validity of psychiatric disease models and the efficacy of psychotropic drugs that Western psychiatry promotes [88]. These critics have argued that the evidence base of psychiatry is too weak to be exported to low-resource settings. Existing evidence, they argued, has been predominantly collected in HICs and may not be applicable to other communities. Instead, local idioms of distress and cultural systems of healing should be included in the evidence base and outcome measures of global mental health [89]. Furthermore, scholars have argued that the production of evidence itself is an uneven playing field because RCTs are costly and complex, and require a high degree of technical expertise, which excludes poor countries from the production of formalized evidence [90].

Too medical. Global mental health's focus on evidence-based interventions led some scholars to caution that the distribution of medication may, in practice, be prioritized over the development of complex and context-sensitive psychosocial interventions [89].

Too individualized. Other scholars critiqued that the Western psychiatric disease model only focuses on the individual, based on the assumption of an underlying, universal brain disorder [91]. Instead, they argued human emotions and behaviour cannot be understood without social context and a meaningful engagement of the community [92] and more attention should be paid to the social determinants of mental health [93].

Social determinants of health. Some have argued that the root causes of mental suffering, such as poverty, structural violence, and globalization [93], need to be addressed by tackling the upstream structural determinants of mental health, such as poverty and violence, rather than dedicating most resources to narrower downstream interventions such as mental health treatments [94].

Limitations of economic arguments for investing in mental health care. The economic argument for mental health care has also been challenged for its potential to undermine calls for care, based on equity, justice, and the right to social participation [95]. A sole focus on 'return on investment' may prioritize the treatment of common mental disorders at the expense of severe spectrum disorders, which require more care and resources [94].

Neo-colonial. Some scholars have gone so far as to describe global mental health as a neo-colonial imposition of Western psychiatric knowledge onto populations in LMICs, driven by the pharmaceutical industry, powerful international institutions, and Western psychiatry [96]. Such an imposition of the biomedical model, they argue, risks the replacement of religious, spiritual, and communal systems of meaning, which may themselves be protective for mental health and offer effective strategies of care [91].

Insufficient attention to substance abuse. Much of the focus of global mental health innovations has been on mental illness, and substance abuse has been relatively neglected, despite the evidence for the major burden associated with substance use disorders and cost-effectiveness interventions.

Critique of the critique. In the aftermath of some of these vociferous critiques, a set of counter-arguments have emerged, including an analysis of the assumptions underlying the polarized debates between 'global' vs 'local' conceptions of mental health and highlighting the need and potential avenues of integrating both perspectives [97].

Although the above critiques present an important challenge to the field of global mental health, many who work in the field are acutely aware of these issues. For example, the issue of cross-cultural validity is an ongoing challenge and many of the leaders in global mental health have focused their research attention on trying to understand local idioms of distress and develop culturally valid and reliable instruments [69]. Similarly, global mental health as a field has focused a good deal of its attention on understanding the social determinants of mental health and developing interventions that can address these determinants [30].

Future directions

As a young, rapidly expanding, and dynamic field, global mental health can be said to have 'come of age' [98]. Nevertheless, many challenges remain. In addition to the above critiques, there are ongoing challenges of inadequate policy priority and resources for mental health, particularly in LMICs. There is also a challenging geopolitical environment, with rising income inequality, ongoing

violence, and forced migration in the Middle East and sub-Saharan Africa, and the growing reality of climate change—all of which carry major implications for global mental health.

These challenges require the field of global mental health to expand its focus from the earlier calls to scale up mental health care [21] towards interventions that promote population mental health and prevent mental illness. Given the powerful effects of the social determinants of mental health, it is unlikely that the global burden of mental disorders can be addressed through treatment alone. This requires a more refined understanding of the mechanisms of the social determinants of mental health, for example through larger longitudinal studies, particularly in LMICs. It also requires a greater integration of mental health and well-being into the broader sustainable development agenda of 2015–2030 [6].

The field also requires a greater convergence of approaches, bringing together the fields of genetics and epigenetics with those of social epidemiology and anthropology, to gain a greater understanding of gene–environment interactions and opportunities for interventions across the life course. This implies the need for a more nuanced understanding of the local and the global, and which interventions work for whom, under what circumstances. In this process, greater partnerships are required between people with lived experience of mental illness, their families, clinicians, and researchers.

Finally, the field needs to move away from categorical classifications of mental disorders towards a more dimensional understanding of mental health, on a continuum from disability to well-being. This requires a staged approach to detection and treatment using trans-diagnostic intervention models, with health systems having the capacity to detect problems early and provide care and support in an empowering and collaborative manner. These challenges remain compelling and have managed to galvanize a significant level of international collaboration, funding, and advocacy, to constitute global mental health as a vibrant, dynamic, and growing field.

The history of psychiatry as a medical specialty¹

Pierre Pichot and Guy M. Goodwin

Introduction

In 1918, Emil Kraepelin wrote [2]:

'A hundred years ago, there were practically no alienists. The care of the mental patients was nearly everywhere in the hands of head supervisors, attendants and administrators of the houses for the mentally ill and the role of the physicians was limited to the treatment of the physical illnesses of the patients.'²

He pointed out that, in the first decades of the nineteenth century, many of the books dealing with psychiatric themes were still written by medical doctors, such as Reil (who coined the word psychiatry), who had few contacts with mental patients or even by philosophers and theologians, and that only in the great scientific centres had specialists appeared 'who had decided to spend their life in the study and treatment of mental diseases'.

The history of psychiatry as a medical specialty has to be distinguished from the history of psychiatric medical knowledge which began in ancient Greece with the birth of medicine as a science. For more than 2000 years, only physicians observed and treated mental illnesses, and institutions were created in which the 'lunatics' and the 'insane' were received. But, as rightly pointed out by Kraepelin, the truth is that psychiatry was not really a medical specialty. One can argue about the precise date of the appearance of psychiatry as a specific field of medicine and of the psychiatrist as a specialist, devoting his professional competence exclusively to the care of the mentally ill. Denis Leigh recognizes that 'some degree of specialization occurred [in England] among respectable physicians' in the middle of the eighteenth century when the monopoly of Bethlem was broken and new 'lunatic hospitals', such as St Luke's, were opened [2]. On the other hand, the American historian Jan Goldstein stresses that in

France the language, as an exact reflection of the underlying reality, began to use expressions such as *homme spécial* to describe a physician specializing in a branch of medicine such as psychiatry only around 1830 [3].

Pinel and the birth of psychiatry as a branch of medicine

Despite those divergences, it is generally accepted that the work of Philippe Pinel constitutes a turning point. His role has several aspects. He is known worldwide as the physician who 'liberated the insane from their chains' in a dramatic initiative he started in 1793, at the height of the French revolution, at the Bicêtre asylum and completed 3 years later at the Salpêtrière asylum. However, the reality is more complex.

Pinel, who was born in 1745, had studied medicine, translated Cullen's books into French, and published scientific papers on various subjects. He acted as a physician in a small Parisian 'madhouse'—the Pension Belhomme, in which wealthy lunatics were confined at the request of their families. At that time, most of the Parisian insanes were confined for a few weeks in the general hospital—the Hôtel Dieu. If their state did not rapidly improve, they were considered as incurable and sent to Bicêtre or the Salpêtrière, built a century before, which also received other social deviants like beggars and prostitutes. Pinel, who was known by his politically influential friends for his progressive scientific ideas, was appointed physician to Bicêtre. The division for the insane was under the direction of an overseer (*surveillant*)—Pussin, who had already introduced humanitarian reforms in the care of the patients. Pinel's merit was to approve and systematically develop Pussin's empirical measures and to propose an explicit scientific theory for their mode of action. Inspired by Crichton's views about the nature of the 'passions' by Condillac's psychology and by the ideas of Jean-Jacques Rousseau, he created the *traitement moral*, which he claimed to be effective with patients previously considered as incurably ill.

The improvement of the conditions in which the insane were cared for, supported and expanded by Pinel, was not an isolated

French phenomenon. In Tuscany, Chiarugi in 1789 had already asserted that the basis of the extensive reforms he had introduced in the local asylum for the insane was that 'it is a supreme moral duty and a medical obligation to respect the mental patient as a person'. In England, where the public had been shocked by the inhumane treatment to which King George III had been submitted during his mental illness, and where a pious Quaker—William Tuke—deeply affected by the conditions in which the wife of a member of the Society of Friends had died in York lunatic asylum, decided to set up a special institution under the government of the Friends 'for the care and accommodation of their own members'. At the Retreat, opened in 1796 near York, physical restraints were largely abolished, and religious and moral values were emphasized in relations with the patients.

Chiarugi's reforms did not survive the upheavals caused by subsequent wars and the political divisions of Italy, and Tuke's creation of the Retreat had not been prompted by medical considerations but was the expression of religious humanitarian purposes. The role played by Pinel was decisive, not so much because of the changes he promoted in the conditions of the patients, although they had a profound influence, but because he made the study and treatment of mental disorders a branch of medicine.

In 1801, Pinel published the *Medico-philosophical Treatise on Mental Alienation*. In it, he presented the various clinical manifestations he had observed, proposed a simple nosological system largely borrowed from older authors, examined possible aetiological factors, and described his 'moral treatment' in detail. The book has remained a landmark in the history of psychiatry, even being considered by the philosopher Hegel as a 'moment of capital importance in the history of humanity'. For Pinel, insanity was a disease, and the patient affected by it remained, despite the loss of his reason, a human being. Its study, like the rest of medicine, had to be 'a science which consists of carefully observed facts'. Goldstein [3] has shown that Pinel's main preoccupation was to prove this scientific nature of the new medical specialty by repudiating the previous practices of the 'empirics' and 'charlatans'—the two terms being practically synonymous. He had accepted the method Pussin had developed empirically and transformed it in his moral treatment by providing a scientific theory of its mode of action. A curiously premonitory aspect of his emphasis on the necessity of a scientific methodology is to be found in his *Tables to Determine How Probable is the Curability of Alienation*, published in 1808. He provided statistical data on the efficacy of his therapeutic method according to the types of mental disorders and in comparison with spontaneous evolution, and concluded that medicine can only be a true science through the use of the calculus of probability!

Psychiatry as a profession: Esquirol and the clinical approach

If, because of the international influence of the ideas expressed in his book, Pinel is the founder of psychiatry as a medical discipline, he was not a psychiatric specialist in the strict meaning of the term. Although he retained his position at the Salpêtrière until his death in 1826 and is known today for his contributions to mental medicine, he had many other medical interests which gave him, in his time,

a leading position among the Paris physicians; his *Philosophical Nosology*, published in 1796 and a classical reference for several decades, deals with general pathology. The case of his pupil and successor Esquirol, who became the prototype of the psychiatric specialist, was very different. At the Salpêtrière, he was only in charge of the 'section of the insane'. He was later appointed medical director of the Charenton psychiatric asylum near Paris and owned, in addition, a small clinic, in which he treated his private patients. All his activities were exclusively dedicated to the study and treatment of mental disorders and the teaching of psychiatry. His book *On Mental Diseases*, published in 1838, in which he collected his previous publications, acquired fame as great as Pinel's *Treatise*. In 1913, Karl Jaspers recognized that the later great representatives of German psychiatry, such as Griesinger and Kraepelin, were strongly indebted to Esquirol. He, and the school he founded, effectively developed one of the basic tenets of the new medical specialty. For Esquirol, careful objective observation and analysis of the symptoms and behaviour of the patients were fundamental. He originated the descriptive clinical approach expanded by his pupils. Even more than Pinel, he was suspicious of unproved theories, and when he eventually suggested relations between pathogenic factors and syndromes, he remained extremely cautious in his interpretations. Zilboorg, the psychoanalytically oriented historian of psychiatry, has accused this predominantly descriptive approach of creating 'psychiatry without psychology' because, lacking psychodynamic concepts, its attempted objectivity remained at an allegedly superficial level [4]. The truth is that it laid the foundations of the present description of the mental disorders. The 'atheoretical' descriptive approach adopted in the present nosological systems—both the American *Diagnostic and Statistical Manual* and the *International Classification of Diseases*—of which the proclaimed purpose is to emphasize the medical character of psychiatry is, in this respect, a return to Esquirol's principles.

The social aspects of psychiatry and the asylum system

By the end of the eighteenth century it was recognized that the study of mental alienation was part of medicine. However, mental diseases were of such a nature that it was not possible to treat the insane in the same conditions as patients affected by other diseases. Their most obvious manifestations had social consequences. According to the prevailing philosophical view, the mentally ill were deprived of free will by their illness. In practice, they were unable to participate in the normal life of society and were often considered as potentially dangerous. Because of this, they had generally been confined in mad-houses of various kinds. One of the aspects of the reforms initiated by Pinel had been to make more explicit the difference in nature between the socially deviant behaviour of the insane, which, being the consequence of an illness, belonged exclusively to medicine, and the other deviations which society had to control and eventually to repress. The implementation of this fundamental distinction during the first half of the nineteenth century helped to give psychiatry its specific shape as a profession by being at the origin of forensic psychiatry and by leading to the formulation of precise rules concerning the commitment of the insane to institutions of a strictly medical character.

The legal code promulgated by Napoleon in 1810 stipulated that ‘no crime or delict exists if committed in a state of dementia’, with the old term dementia being used as a synonym of Pinel’s mental alienation. This legal provision, introduced in similar forms in other countries, opened an important domain of activity to the medical profession of the psychiatrist. Because of their now recognized specialized knowledge, the alienists were to help the judges in determining whether the mental state of an individual convicted of a ‘crime or delict’ was normal or pathological, with decisive consequences on the subsequent decision. The title of Esquirol’s *Treatise* mentions explicitly that it describes mental diseases ‘in their medical, hygienic and medico-legal aspects’. The conflict (which still exists) between the judges, usually supported by public opinion, who took a restrictive view of the concept of mental disease, and the psychiatrists, who tended to expand it to include new types of deviant behaviour, is illustrated by the violent controversies provoked by Esquirol’s description of ‘homicidal monomania’. They had an even more famous counterpart in England. J.C. Pritchard, an admirer of Esquirol, had isolated ‘moral insanity’ as a specific mental disorder in two books published in 1837 and 1842; in the second, he examined its ‘relations to jurisprudence’. Half a century later, in 1897, Henry Maudsley, who was in favour of the use of this diagnosis, recognized that this category, although internationally accepted by the psychiatrists, corresponded to:

‘... a form of mental alienation which has so much the look of vice and crime that many persons regard it as an unfounded medical invention. Judges have repeatedly denounced it from the bench as a “most dangerous medical doctrine”, “a dangerous innovation” which, in the interest of society, should be reprobated.’

Henry Maudsley, 1897.

The general acceptance of the new medical concept of mental alienation implied the existence of adequate facilities for the treatment of the patients. The creation of new asylums—the term was retained—and the reorganization of the old ones were the answers. The French law of 1838 that fixed the detailed rules for the expansion of the new system to the whole country and for its functioning and financial support had a model character. Similar results were obtained in, for example, England with the Asylum Act 1828 and the Lunacy Act 1845. Outwardly, the new system was an extension, under more humane conditions, of the previous institutional practices. However, it had radically original features. While recognizing the necessity of protecting society, it stressed the fact that the insane had a fundamental right to be protected and medically treated in a competent way. The deprivation of liberty for the patients, which it still implied, was strictly controlled to prevent possible misuse and was anyway justified, according to Esquirol and most contemporary psychiatrists, not only by the loss of free will, which was a consequence of the illness, but also by the therapeutic value of separation from a pathogenic milieu.

The asylum system became the central element of psychiatric care and was both the consequence and the determining factor of the emergence of psychiatry as a medical specialty to which it gave, until the end of the nineteenth century and even beyond, an original character. The asylums acquired quasi-monopoly in the care of the mentally ill. The few private institutions reserved for the wealthier members of the population, which often belonged to alienists in charge of the asylum, were generally submitted to the same legal

rules. Private practice with ambulatory patients, as existing today, was exceptional or dealt with cases which were not then considered to belong to mental alienation. As a result, the study of mental illness was predominantly restricted to the more severe forms of disorder. Another consequence was that the alienists in charge of patients committed to the asylums had a dual function, a fact that differentiated them from other hospital physicians. In addition to their medical duties, they were involved in legal procedures which determined the conditions of admission, stay, and eventually release of the mentally ill. As superintendents, they also often had economic and financial responsibilities, being in charge of the material, as well as the medical aspects of the functioning of their institutions.

Despite the fact that the laws now strictly differentiated the nature of the limitations of liberty in asylums and in prisons, the participation of the alienist in a form of social control was eventually perceived negatively by the public, and often by other physicians, and contributed to accentuating the specificity of psychiatry inside medicine. During the third and fourth decades of the nineteenth century, which saw the birth of the asylum system, psychiatrists became really conscious of their identity as a professional group. In England, France, Germany, and the United States, they founded societies and began to publish journals with specialized scientific goals. Such a description oversimplifies an evolution which was progressive and, in some cases, took different directions. The creation and extension of the asylum system took many years; it did not reach its classical form until the last part of the century, as testified by the famous campaign conducted in the United States during the 1840s by Dorothea Dix who complained that many of the mentally ill were still incarcerated in almshouses and prisons. The moral treatment practised in the institutions was eventually used to justify brutal measures, alleged to be therapeutic, and the behaviour of the attendants, who were not usually medically trained (significantly, they were known as *surveillants* in France), was too often of a purely repressive character. It was a long time before the proposals made in 1856 by the British psychiatrist John Conolly in his book *The Treatment of the Insane Without Mechanical Restraints* were put into practice everywhere.

The biological and the psychological model

The clinical orientation of Pinel, Esquirol, and their followers was basically empirical. By concentrating on describing observable symptoms and abnormal behaviours, it avoided theoretical controversies. However, many believed that if psychiatry was to become a branch of the medical sciences and to progress, it had to adopt models similar to those accepted by the rest of medicine. According to the anatomoclinical perspective, which was now dominant, diseases were distinct entities. Each disease was defined by a characteristic pattern of symptoms provoked by a lesion or eventually a dysfunction of an organ to be discovered at autopsy. In 1821, Bayle, following this scheme, described the typical clinical symptoms and lesions of the brain in the general paralysis of the insane. Despite the disappointing results of further anatomopathological studies (brain lesions were observed in only a small proportion of cases), there was increasing conviction that, with better investigation methods, mental disorders, like other diseases, could be explained by somatic causes. The degeneration theory, proposed in 1857 by Morel, which attributed many forms of insanity to the hereditary transmission of

dysfunction of the nervous system produced by the noxious effects of environmental factors, and whose influence lasted until Kraepelin, is another expression of this biological orientation, the aim of which was to give psychiatry an undisputed medical status.

The biological and the purely clinical approaches were concerned with different conceptual levels—the discovery of the causes of insanity and the description of its manifestations, respectively. Therefore, they could easily coexist. Even when the followers of Pinel and Esquirol expressed reservations about the applicability of the biological model to every type of mental disorder, they still believed in the medical nature of psychiatry. The situation created in the German-speaking countries by the school of the ‘mentalists’ (the term *Psychiker* by which they were known means ‘psychologically oriented’), who were predominant during the first half of the nineteenth century, was very different. Influenced by philosophical, religious, and romantic trends, these psychiatrists took a radical dualistic position, postulating the absolute difference between the physical body and the spiritual soul. The soul was the source of the whole psychic life and hence eventually of its abnormal aspect—insanity. A term such as disease, appropriate for the somatic illness, could only be used metaphorically in psychiatry. The sins of the patients were the origin of the mental disorders, and psychiatry belonged more to moral philosophy than to medicine. These ideas were developed in various related forms by the majority of the German psychiatrists of the period (Heinroth, Ideler, Langerman, and many others). Their ideological position had two consequences—scientific relations with other schools, such as the French and the English who saw in the publications of the mentalists obscure philosophical theories devoid of medical character, were largely cut off; and they provoked a violent reaction in Germany itself. The most extreme representatives of the contending group of ‘somatists’ (*Somatiker*), such as Jakobi and Friedreich, saw the mental disorders as symptoms of somatic diseases, not necessarily of the brain. In fact, for them, mental diseases as such did not exist. They defended aggressively their biological and sometimes bizarre hypotheses, such as the aetiological role of intestinal worms, against the mentalists. Finally, around 1850, they gained the upper hand. The publication in 1845 of *Pathology and Therapy of the Nervous Diseases* by Wilhelm Griesinger, an heir to their school who was also influenced by the French alienists, is a landmark in the history of German psychiatry. With his appointment in 1865 as professor of psychiatry in Berlin, where he succeeded the mentalist Ideler, medical psychiatry was definitely established in Germany as a branch of the natural sciences.

Universities acquired considerable power and influence in the second half of the nineteenth century. From the 1850s on, chairs were created for the teaching of the new common discipline, and special institutions—university clinics—were built with hospital beds for psychiatric patients (if their disorders became chronic, they were sent to the nearest asylum), and laboratories for research on neurophysiology and neuroanatomy and special wards for neurological cases were developed. Griesinger's first move when he took over the chair of psychiatry at Berlin was the creation of neurological wards at the Charité. The leading neuropsychiatrists in charge of these institutions often performed research in both fields with equal competence, as shown by the work of Wernicke and Westphal, and later of Kleist and Bonhöffer in Germany and of Meynert in Austria.

The concept of neuropsychiatry, appearing at a period during which the German school was progressively gaining influence, had a deep impact on psychiatric thought and the psychiatric profession, even if its institutional driving force—the university clinic system—was not developed everywhere to the same extent as in Germany. For example, it was conspicuously absent in England, despite the fact that the theoretical position taken by the most important psychiatrist of the time Henry Maudsley was very close to that of Griesinger. The National Hospital in Queen's Square, London, founded in 1860, retained a virtual monopoly on the teaching of neurology for many decades, and psychiatry, taught essentially in hospitals, was not represented at university level until the 1930s. However, in most countries, neuropsychiatric institutions coexisted with asylums where the alienists had the unenviable task of caring for chronic mental patients, often with inadequate means. The concept of neuropsychiatry reflected a basically biological perspective on the aetiology of the mental illnesses, expressed in the creation of a new specialty associating competence in the two previously separated domains of medicine. However, it provoked ideological and professional tension between the ‘pure’ psychiatrists, mainly those in charge of asylums, and the neuropsychiatrists, predominantly involved in teaching and research. In the long term, this conflict was one of the factors which finally led, in the 1960s, to the almost complete administrative and institutional separation of the two specialties in countries such as France where they had been, at least formally, associated. But many traces of the old situation remain. The most influential scientific journal published in German *Nervenarzt* still deals equally with neurology and psychiatry, and the term ‘neuropsychiatric’ survives in the titles of many teaching and research institutions.

The rise of neuropsychiatry

Romberg's *Lehrbuch der Nervenkrankheiten* symbolizes the birth of neurology as an autonomous medical specialty studying and treating the diseases of the nervous system. It was published 5 years after Griesinger's *Textbook* in which, adopting and expanding Bayle's anatomoclinical model, he had affirmed: ‘Mental diseases are diseases of the brain.’ If both psychiatric and neurological symptoms originated in the nervous system, some form of association between the two specialties was a logical step, at least at the conceptual level. One aspect of their complex relationship was the creation of neuropsychiatry which developed its most characteristic aspects in the German-speaking countries.

The neuroses and birth of the psychotherapies

The study of the neuroses, in which the relation between psychiatry and neurology was also involved, resulted in completely different, but equally important, changes to psychiatry as a medical specialty. The term neurosis had been coined in 1769 by Cullen to describe a class of diseases he attributed to a dysfunction of the nervous system. In this very heterogeneous group, two entities of very ancient origin—hysteria and hypochondriasis—had predominantly psychological manifestations. Since the affected patients were not usually committed to asylums, they were not normally studied by alienists, but by specialists in internal medicine such as Briquet, who, in 1859, wrote the classical *Treatise on Hysteria*. Because of the

assumed nature of the neuroses, the new discipline of neurology rapidly took an interest in them.

Charcot, the founder of the French neurological school, was responsible for the internal medicine wards at the Salpêtrière—they were not associated with the ‘divisions of the insane’ at the same hospital, the domain of the alienists. In about 1880, he became interested in hysterical patients who, because of their seizures, were admitted to the same ward as the epileptics. He developed a purely neurological theory of the disease, which he described and studied using hypnosis. This was the former ‘animal magnetism’, long fallen into disrepute, but to which he gave a new scientific status. Charcot’s descriptions of the *grande hystérie*, which he demonstrated on selected patients in his famous public lectures, were justly criticized later, but his international fame attracted students from all over the world. One of them was a young lecturer in neuropathology at the University of Vienna—Sigmund Freud, who, impressed by Charcot’s lectures, decided to devote all his energies to the study and treatment of the neuroses. Another was a French professor of philosophy (psychology was then a branch of philosophy)—Pierre Janet, who had become interested in the psychological aspects of the neuroses. He was later to develop, in parallel with Freud, a psychopathological theory which, despite the traces it has left (the concepts of psychasthenia and the dissociative processes in hysteria), was not to be as internationally successful as Freud’s psychoanalysis. Charcot’s ideas were opposed by Bernheim, the professor of internal medicine at the Nancy Medical School and also an adept of hypnosis. He attacked the neurological interpretations of the Salpêtrière and claimed that suggestion played a central role in the phenomena described by Charcot.

The general interest in the neuroses, which extended beyond medicine to *fin de siècle* literature, was an international phenomenon. In 1880, Beard, an American neurologist, described a new neurosis—neurasthenia, which soon aroused even more interest than Charcot’s hysteria. Psychiatry had played almost no part in this evolution, but this was to change under the influence of three related developments: the changes which took place within the concept of neurosis, the birth of the psychotherapies, and the incorporation in the field of psychiatry of psychopathological manifestations, even if they were of minor intensity.

The transformation of the concept of neurosis is apparent in the position taken by Kraepelin in the 1904 edition of his *Textbook*. He introduced a chapter called ‘The psychogenic neuroses’, on the grounds that ‘among the neuroses, to which belong epilepsy and chorea, one must isolate a sub-group characterized by the purely psychological cause of the apparition of the symptoms’. The disintegration of the old concept left to neurology, which, from now on, abandoned the generic term, diseases (such as epilepsy and chorea) whose somatic manifestations could be shown to express a dysfunction of a precise part of the nervous system. Psychiatry took charge of hysteria, hypochondriasis, neurasthenia, and the related phobic, obsessional, and anxious disorders, which constituted the new neuroses. This concept was justified by the psychological nature of the symptoms and the causes recognized even by a biologically oriented psychiatrist such as Kraepelin. This redrawing of the frontier between the neurological and psychiatric specialties also testified to the extension of the limits of psychiatry. Pinel’s insanity, until then defined by the necessity of commitment to special institutions, was replaced by a broader concept. A new class corresponding to our

present personality disorders had already appeared in the 1894 edition of Kraepelin’s *Textbook*. It had been isolated for the first time in 1872–1874 by the psychiatrist Koch. Like the neuroses, the cases were rarely observed in asylums, but nevertheless, they were now considered as belonging to the psychiatric field of study.

This field was further modified by the birth of the psychotherapies. In fact, they had a long history. In 1803, one of the first German mentalists Reil had described, under the name of ‘psychic therapy’ (*psychische Curmethode*), a number of procedures, including very violent somatic ones, which could influence the ‘perturbed passions of the soul’, and Pinel’s moral therapy contained psychotherapeutic elements. However, psychotherapies, as techniques of which the formal rules were based on an explicit theory about their psychological mechanisms of action, derived mainly from Mesmer’s animal magnetism, as rehabilitated by Charcot. The emergence of the psychotherapies, characteristic of the last decades of the nineteenth century, was intimately related to the renewed study of the neuroses. After he had abandoned hypnosis, Freud developed psychoanalysis, but many other techniques evolved during the same period, which were as well, or even better, known at the time, although they were to have a less lasting success. One of these was the method of Janet, who still occasionally used hypnosis. In 1904, Dubois, a Swiss neuropathologist from Bern, introduced a technique influenced by Bernheim’s theory of suggestion in *The Psychoneuroses and their Moral Treatment*, and claimed to produce ‘psychological re-education’ by a combination of rational and persuasive elements. His international reputation brought him patients from all over the world. The ‘rest cure’, proposed in 1877 by the American neurologist S. Weir Mitchell for the treatment of hysteria and later of neurasthenia, was combined with Dubois’ method by Dejerine, Charcot’s successor as professor of neurology in Paris.

This very incomplete summary illustrates the striking fact that, because of their intimate connections with the neuroses, psychotherapies originated inside neurology. When the study and treatment of the neuroses were incorporated into psychiatry, psychiatrists considered that they were an integral part of their activity and tried to retain the monopoly of their practice. They never completely succeeded. Already Freud had, according to his biographer Jones, ‘warmly welcomed the incursion in the therapeutic field of suitable people from another walk of life than medicine’. The problem of ‘lay analysts’, a source of conflict within the psychoanalytic movement, is only an aspect of a broader question which was later to involve the relations of the medical specialty of psychiatry with the new professional group of clinical psychologists.

From the beginning of the twentieth century to the Second World War

During the first half of the twentieth century, psychiatry developed in many directions. Kraepelin’s monumental synthesis [5] established in around 1900 a nosological system which, in its broad outlines, has remained valid until today. Without being radically altered, it was completed to mention only a few contributions, in 1911, by Bleuler’s description of schizophrenia and in 1913, by Jaspers’ psychopathological perspective, developed by the Heidelberg school and Kurt Schneider and by other psychiatrists working in academic institutions. However, the old conflict between the ‘mentalists’ and

the 'somatists' reappeared in a modified form. The mainstream of psychiatry had abandoned the extreme positions of the 'brain pathologists' of the Meynert–Wernicke type but, while recognizing a limited influence of psychological factors, admitted in a general way the biological origin of the more severe mental disorders—the psychoses. The empirical discoveries of biological treatments—of general paralysis by malaria therapy (Wagner von Jauregg in 1917), of schizophrenia by insulin coma (Sakel in 1933) or by chemically induced seizures (von Meduna in 1935), and of depression by electroconvulsive therapy (Cerletti in 1938)—not only helped to dispel the prevailing therapeutic pessimism, but also provided supporting arguments. However, an opposing ideological current represented by psychoanalysis had arisen from the study of the neuroses. Its attention was concentrated on the study of complex psychopathological mechanisms postulated to be at the origin of the neurotic, and later also of the psychotic, symptoms, favoured psychogenetic aetiological theories, and advocated psychotherapy as the fundamental form of treatment. Psychoanalysis expanded steadily during this period and gained enthusiastic adherents in many countries. However, partly because of the suspicion, and even hostility, of many members of the psychiatric establishment, they remained isolated in close-knit groups, with their own teaching system independent of the official medical curriculum, and the use of their therapeutic technique was restricted to a small number of mostly neurotic patients seen in outpatient clinics or, more often, in private practice.

The great majority of patients suffering from mental disorders were still confined in asylums, and the enormous increase in their number, mainly related to the social changes accompanying industrialization and urbanization, although other factors have been invoked, was striking. In Great Britain, it grew from 16,000 in 1860 to 98,000 in 1910, three times more rapidly than the population. A similar phenomenon was observed in all countries and persisted until the end of the 1940s, despite the introduction of the first biological therapies. In the United States, there were already 188,000 patients in mental hospitals in 1910, and by the end of the Second World War, 850,000 were lodged in huge institutions which were overpopulated and understaffed, and could only provide custodial care. This obvious degeneracy of the asylum system, contrasting with the progresses in the scientific field, stimulated efforts to improve the practice of psychiatry and its institutional framework. Most of these improvements took place after 1920 and, although their results remained relatively limited, they were the forerunners of later more drastic changes.

The education of psychiatric specialists, which had varied widely from country to country, was improved and systematized. A convergence of evolution is apparent during this period which can be said, to some extent, to have seen the formal administrative recognition of psychiatry as a medical specialty. Educational programmes and controls of the level of competence were introduced, which extended beyond psychiatrists in academic positions. Limited teaching of psychiatry became compulsory, even in the general medical curriculum. In France, psychiatrists for public asylums and, in some cases, residents in psychiatry were selected by a competitive examination system. In England, the Board of Control recommended in 1918 that a leading position in a psychiatric institution could only be occupied by a physician who had obtained a Diploma in Psychological Medicine awarded by the Royal College of Physicians and by five

universities. In the United States, the moving force behind the reforms was Adolf Meyer, the Director of Henry Phipps Clinic at Johns Hopkins University from 1913 to 1939, who organized a systematic residency system and promoted the creation of the Board of Neurology and Psychiatry. This Board was established in 1936 and awarded a diploma, which it became necessary to hold, to be recognized as a specialist.

The changes were reflected in the vocabulary. The term psychiatry, originating in the German-speaking countries and mostly used there, was adopted everywhere at the beginning of the century. In France, the health authorities officially substituted '*hôpital psychiatrique*' for '*asile d'aliénés*' and '*psychiatre*' for '*aliéniste*' in the 1930s. In England, a Royal Commission used the words 'hospital', 'nurse', and 'patient', instead of 'asylum', 'attendant', and 'lunatic', for the first time between 1924 and 1926. However, efforts were also made to dissociate, when possible, the social protection function of the institutions from their medical role by allowing them to admit patients under the same conditions as the general hospitals. In 1923, a special section was created in the Paris Sainte-Anne asylum which provided treatment to voluntary patients and had both hospital beds and a large outpatient department. In England, the Mental Health Act of 1930 made voluntary admissions to psychiatric hospitals possible; by 1938, they already constituted 35% of all admissions.

Social considerations had always been evident in psychiatry, but their traditional expressions had mainly been of a negative nature, that is the confinement of patients in asylums. The new possibility of free admissions reflected an increase in tolerance towards the disturbing character of mental illness. At the same time, a differently oriented and broader social perspective appeared. The concept of mental hygiene originated in the United States in 1919 with the creation by a former patient Clifford Beers of an organization whose internationally growing influence was manifested by well-attended congresses held in Washington in 1930 and in Paris in 1937. From its beginning, the movement was not purely medical and was influenced by various humanitarian philosophical trends. It emphasized the role of social factors, such as living conditions or educational practices, in the origin of mental disturbances and promoted their prevention and treatment by the close co-operation of psychiatrists and nurses with non-medical groups in the community. One of the institutional consequences of these ideas was the creation of the profession of social worker. They began their activity in Adolf Meyer's clinic (Adolf Meyer had been an early supporter of the mental hygiene movement whose principles converged with his own ideas) at the Sainte-Anne Hospital in Paris, in England where the London School of Economics opened a special training course in 1929, and elsewhere.

Contemporary with the emergence of psychiatric social work was the expansion of clinical psychology. The Binet–Simon scale for the measurement of intelligence, developed in 1905, was the first application to psychiatry of the new discipline of experimental psychology which had originated at the end of the previous century. This initial contribution led to the creation of a professional class of clinical psychologists who were initially concerned with the development and use of psychological assessment instruments and with theoretical research in a few psychiatric centres. Their number initially remained low; in 1945, the United States, where they were the most numerous, had only 200 clinical psychologists.

The expansion of psychiatry after 1945

The Second World War coincided with a major transformation of the psychiatric specialty. The war had vividly demonstrated the frequency of mental disorders in the United States; they had proved to be the leading cause of medical discharges from the military service and the primary cause of almost 40% of selective service rejections. The previously prevailing view that psychiatry was a minor and often somewhat despised medical discipline, concerned primarily with the custodial care of psychologically deviant and potentially troublesome individuals, was progressively dispelled. The preservation and restoration of mental health—an expression from now on often used by national and international institutions—began to be considered by governments as an important task. The fundamental changes which took place after 1945 and shaped psychiatry as we know it today were the result of this new atmosphere and of the emergence of new perspectives in the three traditional domains—the psychological, the social, and the biological. Some appeared in slightly different forms at different times; their relative influence was submitted to variations, and eventually they came into conflict. The result has been an impressive expansion and increase of the efficacy of psychiatry, profound institutional transformations, and successive ideological waves which have had a major impact on the professional position of the psychiatrist.

The demographic data reflect the new importance of psychiatry in medicine. In the United States, the proportion of psychiatrists in the medical profession was 0.7% in 1920, 1.4% in 1940, and 5.5% in 1970, the rate of growth having doubled after the Second World War. In France, at present, there are 18 psychiatrists for 100,000 inhabitants; they constitute 6% of all physicians. Similar levels were reached during the post-war decades in developed countries and remain relatively stable today. Even before this spectacular increase in numbers, psychiatrists had been becoming conscious of the necessity to affirm the identity of their discipline. The First World Congress of Psychiatry, held in Paris in 1950, has been followed by periodic meetings and by the creation of the World Psychiatric Association to which almost every national society of psychiatry belongs. The health authorities of various countries have become conscious of the necessity to provide adequate financial means to support research and training in the discipline. In 1946, the United States government created the National Institutes of Mental Health for such a purpose, and similar efforts were made in many countries, although the structures of the organizations formed were different. To promote the same goals at an international level, the WHO, created immediately after the Second World War, had a Section (later Division) of Mental Health which, among other co-ordinating activities, tried to overcome the difficulties of communication between the national schools by establishing a common nosological language.

While the changes affected almost all countries, they were the most spectacular in the United States. From the end of the nineteenth century until the 1930s, the concepts developed in German-speaking countries had been the most influential. This disappeared with the advent of the National Socialist regime which, under the cover of racist theories, expelled many of the leading psychiatrists from Germany and Austria, introduced compulsory sterilization for several varieties of mental illnesses, and promoted the voluntary killing in psychiatric hospitals of mentally retarded children

and chronic patients. The United States, which had emerged from the Second World War as the most powerful country in the world, began to exert a widespread influence in psychiatry as in the rest of medicine. Because of the prestige of its research and teaching institutions and the worldwide influence of its scientific publications, reinforced by the progressive adoption of English as the language of international scientific communication, American psychiatry became a model in many countries, even though many of the theoretical trends and technical advances it adopted and developed had originated in Europe. However, in the United States, with a local colouring, they took on a special intensity.

The psychodynamic wave

An important factor in the spread of the doctrine of psychoanalysis was the emigration of a relatively large number of German and Austrian psychoanalysts to the United States from 1933 onwards. They had been compelled to leave their home countries for racial reasons—psychoanalysis had been condemned by the National Socialist regime, as Jewish and Freud's books had been publicly burnt. Many of the young psychiatrists trained in large numbers to answer the demands of the armed forces adopted psychoanalysis under the influence of some of those in charge of the programmes. For a generation, until the end of the 1960s, psychoanalysis became the dominant ideology in American psychiatry.

The American form of psychodynamism often deviated from Freudian orthodoxy, but it emphasized the role of psychogenetic factors, the value of the study of intrapsychic mechanisms, and the basic importance of psychotherapy, while giving little consideration to the traditional clinical approach and to nosology. The domination of this essentially psychological orientation, sometimes compared with the success of the German mentalist school during the first half of the nineteenth century, had important consequences. Although the disorders of hospitalized psychotics were eventually interpreted according to the psychoanalytic theory, psychotherapy was mostly used, as it has been since its beginning, for ambulatory neurotic patients. As early as 1951–1952, three out of every seven American psychiatrists identified private practice as their main activity, and in 1954, the number of private psychiatrists exceeded that of their salaried colleagues for the first time, with a quarter of the former devoted exclusively to psychotherapy. However, with the initial encouragement of official institutions such as the Veterans Administration, clinical psychologists began to engage in psychotherapeutic activities. The number of members of the Clinical Psychology Section of the American Psychological Association reached 20,000 in 1980, at a time when they were 26,000 psychiatrists in the United States. In public opinion, and to a certain extent in general medical opinion also, psychiatry was assumed to consist only of psychotherapy and psychology.

In most other countries, the developments that occurred in the United States were not as intense, generally appeared later, and were modified by local traditions and influences. In German-speaking countries, they were delayed by the still powerful neuropsychiatric perspective and the temporary vogue for existential phenomenology. In the United Kingdom, the eclectic current fostered by the influential Institute of Psychiatry in London during the decades following the war restricted the advance of psychodynamism; in 1956, *Time Magazine* could affirm, as a conclusion of a survey, that 'all of Great Britain [had] half as many analysts as New York City'. In

France, the psychoanalyst Jacques Lacan gave the doctrine a special colouring. On the whole, however, the rise of psychodynamism was a general phenomenon, except in communist countries where Freud's doctrine had been condemned on ideological grounds.

A reaction began in the 1960s with the successes of the new pharmacotherapies. Clinical psychologists had developed alternative radically different psychotherapeutic methods based on learning theories, especially the behaviour therapy introduced in 1958 by Wolpe, supported in the United Kingdom by Eysenck, and the cognitive therapy often associated with it. These methods competed successfully with the psychodynamic techniques and conquered a large part of the field. Psychodynamism did not disappear; many of its concepts retained their place in psychiatry, and psychotherapeutic methods continued to be practised, but it lost its predominant ideological position. In addition to its theoretical contributions, when its influence on the professional aspect of psychiatry is considered from a historical perspective, it has been an important factor in the further expansion of the activity of psychiatrists in the treatment of relatively minor disorders and has also encouraged clinical psychologists to play an active and independent role in this field.

The social wave

At the end of the Second World War, there was a great desire for social change; one of its aspects was the belief that everyone had a 'right to health' or at least the right to receive adequate medical care, regardless of the ability to pay. This resulted in the creation of the National Health Service in the United Kingdom in 1948 and the Social Security system in France, together with similar developments in other countries. The social perspective, which was one of the basic principles underlying these developments, initiated major institutional changes in psychiatry. They were the result of a number of factors—the necessity to give to the whole population easy access to psychiatric care, and also the belief that social elements played an important role in the aetiology of mental disorders and that they could greatly contribute to the healing process, with the aim of progressively reintegrating the patient in the community.

The most spectacular aspect of the new policy was the decline of the asylum system, still in a dominant position in psychiatry; in fact, the number of patients in psychiatric hospitals in developed countries reached its peak in 1955. The criticisms of the 'degeneration' of the functioning of psychiatric hospitals and the segregation of patients in institutions, often located far from their homes and families, were not new. However, the previous partial improvements, such as the decrease in the number of compulsory commitments or the creation of outpatient departments, were replaced by the creation of completely new structures. Ideally, the country would be divided into geographical zones or sectors with a population of about 100,000, and each zone would have a multi-disciplinary team of psychiatrists, nurses, clinical psychologists, social workers, and occupational therapists responsible for mental health. Visits and therapeutic interventions in the patient's home and easily accessible outpatient departments were to play an increasingly important role. If hospitalization was necessary, it should be, as far as possible, in small units located in a general hospital where the time of stay was to be reduced to the absolute minimum. Special institutions, such as day hospitals, night hospitals, and specially adapted workshops, would contribute to the progressive readaptation of the patient to life in the community. The introduction of this 'community

care', which was expected to work in close co-operation with general practitioners and various public and private institutions, would result in the disappearance of the traditional psychiatric hospital and 'deinstitutionalizing' psychiatry. The new system was introduced in various forms in most countries after 1969. In the United States, the Community Mental Health Center Act was promulgated in 1967. In the United Kingdom, which had strong traditions of social psychiatry, plans for the implementation of community care were discussed in the 1960s, and in 1975, the Government White Paper *Better Services for the Mentally Ill* encouraged the formation of multi-disciplinary 'primary care teams', which also included general practitioners. In France, an official directive in 1960 created the *psychiatrie de secteur*, which was expected to result in the progressive elimination of *hospitalocentrisme*. The WHO encouraged all its member countries to adopt similar practices.

Although, in the last 40 years, community care has become the official doctrine everywhere, except in Japan where the rate of hospitalization in mostly private hospitals has grown continuously, its implementation has not been easy despite the major therapeutic improvements brought about by pharmacotherapy. In some parts of the United States, the sudden closure of public psychiatric hospitals, combined with the inadequacies of the community mental health centers, was for a time at the origin of an appalling lack of care for a number of mentally ill people. The expected 'fading out' of hospitalization has been slow. According to the WHO, in 1976, the number of mental health beds (including beds for the mentally retarded) per 100 population was 6.5 in Sweden, 5.5 in the United Kingdom, 3 in France, and 2 in Germany. These figures have since decreased, and the types of hospitalization have changed. In 1955, 77% of 'psychiatric care episodes' in the United States occurred in public psychiatric hospitals, compared with 20% in 1990. In 1994, 1.4 million mental patients were hospitalized, but only 35% in public psychiatric hospitals, compared with 43% in general hospitals and 11% in private psychiatric hospitals, which increased in number from 150 in 1970 to 444 in 1988. In France, where the total number of psychiatric patients treated in public institutions (including children) is now about a million, 60% are seen exclusively on an ambulatory basis, but the number of hospital beds has only been reduced by half.

Reflecting the increasing influence of social perspectives, the organizational changes modified psychiatry as a profession. The increase in the number of psychiatrists in private practice was paralleled, in general to a lesser extent, by an increase in the public sector where their role was modified. In the traditional asylum, the authority of the psychiatrist was unchallenged and limited only by the legal provisions related to the procedures of commitment. Nurses, and later clinical psychologists, social workers, and occupational therapists, were 'paramedical auxiliaries' in a subordinate position. The creation of multi-disciplinary teams, working in various settings, gave the psychiatrist a function of co-ordination, made increasingly complex by the claims of professional autonomy made by the former auxiliaries. In some cases, such as in American mental health centres, psychiatrists, who were a small minority in the team and had less and less control over its functioning, resented what they considered to be the loss of their medical status.

The importance given to social factors was not limited to the system by which care was delivered. Sometimes, combined with radical ideological and political attitudes, it took more extreme forms.

The criticisms, which first centred on the inadequacies of the existing institutions, extended to the concept of mental disease itself. The antipsychiatry movement claimed that mental diseases were artificial constructs which were not related to diseases in the medical meaning of the term. The allegedly pathological behaviours, such as those conceptualized as schizophrenia, were in fact normal reactions to an inadequate social system. The so-called treatments were techniques used by the ruling classes to preserve the social order of which they were the beneficiaries. The only solution was a drastic reform of society. Such theses varied in their content and in the arguments used. They were developed by authors such as Szasz, Laing, and Cooper in the English-speaking world, the philosopher Foucault in France, and the psychiatrist Basaglia in Italy. They reached their greatest influence in the 1960s, and a few attempts were made to put their ideological principles into practice. Although they attracted much attention at the time, they were very limited and short-lived. One of the few countries where this movement had a practical impact was Italy. Basaglia's strongly politically oriented theories were influential in the later legal reform of the antiquated asylum system, but, despite the apparently revolutionary character of some of the new administrative provisions, the changes made (notably the closure of large institutions) were very similar to those taking place in other countries.

The biological wave

Psychotropic drugs, such as opium, had been used since the origin of medical treatment of psychiatric patients. During the nineteenth century and the first half of the twentieth century, synthetic drugs such as the bromides, the barbiturates, and the amphetamines were developed. Some of them, especially the sedatives and hypnotics, had a real, but in practice marginal, value in alleviating some symptoms. They had never constituted an effective treatment of mental disorders. Modern psychopharmacology not only initiated what has been rightly called a therapeutic revolution in psychiatry, but also gave a powerful new impulse to the biological perspective. Its date of birth is usually considered to be 1952, when the remarkable activity of chlorpromazine on the symptoms of schizophrenia and mania was discovered. This had been preceded in 1949 by the demonstration of the value of lithium salts in manic states. A few years later, it was shown that the continuous administration of lithium salts prevented the recurrence of manic and depressive phases in the mood disorders. This was followed by the introduction of drugs acting on depressive manifestations (imipramine and monoamine oxidase inhibitors in 1957) and on anxiety (including chlordiazepoxide, the prototype of benzodiazepines, in 1960). In one decade, clinicians had empirically discovered the fields of application of the main classes of psychoactive drugs—the neuroleptics, the antidepressants, the anxiolytics, and the mood stabilizers—which had been synthesized by biochemists and previously tested by pharmacologists on animal models. The scale and rapidity of the spread of their use had major repercussions.

The first was a modification of the image of psychiatry. The layman generally expected a physician to prescribe drugs to treat the disease from which he suffered. In part, because it did not conform to the expected therapeutic behaviour, psychiatry had been seen as an atypical and almost non-medical specialty. In addition to the specificity of the institutions in which it was generally practised, psychological techniques were unknown in the rest of medicine, and even

the recently introduced biological techniques (the shock therapies and the lobotomy) had a somewhat strange and frightening character. The establishment of pharmacotherapy contributed strongly to modifying this perception, even if it did not completely remove the traditional prejudices.

The second consequence was even more important. There were, at least initially, controversies about the roles of pharmacotherapy and of the new social perspectives in the restructuring of the mental health care system. In fact, the number of inpatients in psychiatric hospitals began to decrease from 1955 on, and it seems obvious that the main cause was the therapeutic efficacy of the drugs. They reduced the mean length of hospitalization and eventually even made it unnecessary. Although some types of patients did not benefit from them and the mental state of others was only improved, many who had previously been condemned to long stays in the hospital were able to return to the community, with their treatment eventually being continued in rehabilitation settings and often on an ambulatory basis. Pharmacotherapy had made possible the practical implementation of social trends. In addition to this basic contribution to the 'deinstitutionalization' movement, pharmacotherapy was an essential factor in the growth of private practice. The success of psychotherapy had been one contribution to this, but the complexity of its techniques, the length of the treatment, its applicability to only a few types of disorders, and the uncertainty of the results limited its use to a relatively small number of selected patients, even in the United States during the period of the greatest popularity of psychodynamism. Pharmacotherapy could be used much more easily, on a much larger number of patients, and did not require long and complex training. Some of the drugs, such as the anxiolytics, had an immediate symptomatic effect, and others (the antidepressants and the neuroleptics) could attenuate or suppress the pathological manifestations in a few weeks and, outside the acute phase requiring hospitalization, could be used on an ambulatory basis. It was not only private psychiatrists who were able to treat many of their patients successfully; general practitioners also began to prescribe psychotropic drugs on a large scale.

The third consequence was the explosive development of biological research in psychiatry. The first therapeutic discoveries were largely empirical, but new biochemical techniques allowed some of the modes of action of the drugs to be elucidated. From 1960 on, studies of the influence of these drugs on various aspects of neurotransmission in the brain stimulated hypotheses about the abnormal biochemical mechanisms considered to be the physical substrate of the mental disorders. Meanwhile new methods had been introduced for the examination of morphological modifications of the living brain and even of the nature and localization of the biochemical processes taking place in its different parts. The discovery by Watson and Crick in 1953 of the chemical basis of heredity and the subsequent spectacular advances in molecular biology gave a fresh impulse to psychiatric genetics, which had been partly discredited by their misuse by the National Socialist regime. Under the name of neurosciences, these new fields of enquiry progressively acquired a dominant role in psychiatric research at the same time as the introduction of an ever increasing number of drugs, eventually more potent, usually with less inconvenient side effects, and sometimes with new therapeutic indications.

'Remedicalization' of psychiatry

In 1983, Melvin Sabshin, the director of the American Psychiatric Association, summarized the overlapping chronologies of the psychodynamic, biological, and social waves as follows [6]:

'Psychoanalysis surged through the United States during the 1940s and the 1950s. During the 1950s, a new psychopharmacological approach emerged which had great impact on psychiatric practice generally ... The 1960s saw the dawning of a community psychiatric approach which attempted to accomplish a massive desinstitutionalization of patients from public psychiatric hospitals.'

Although less radical and not strictly identical, the general picture was similar in other countries. The 1960s saw an often uneasy coexistence of three schools. 'During that decade,' wrote Sabshin, 'American psychiatry enlarged its boundaries and its practices so broadly that many critics grew increasingly concerned with the 'bottomless pit' of the field. The extension of the practice of psychotherapy, frequently to cases with no clear pathological character, tended to blur the limits of the mental disease concept and to neglect the traditional diagnostic approach. Social work was also tempted to concern itself with problems with no obvious medical nature, such as those still described in 1978 in the United States by the President's Commission of Mental Health, which asserted that 'American mental health cannot be defined only in terms of disabling mental illness and identified mental disorders' and identified as a domain of concern for workers in the field 'unrelenting poverty and unemployment and the institutionalized discrimination that occurs on the basis of race, sex, class, age ...' In sharp contrast, the new biological psychiatry recognized only a strictly medical model, stressing the necessity of an accurate diagnosis for the prescription of drugs and for the testing of their efficacy, and advocated restrictive limits in the definition of mental diseases.

In around 1970, a profound change took place. Although the institutional modifications of the care system favoured by the generalization of drug therapy continued and expanded under its various forms everywhere, the influence of psychodynamism began to decline within the psychiatric profession. According to the director of the National Institutes for Mental Health, 'it was nearly impossible in 1945 for a non-psychoanalyst to become Chairman of a Department of Psychiatry (in the United States)', but by the mid 1970s, the situation was reversed. The publication by the American Psychiatric Association of the Third Revision of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) is often considered as the symbolic expression of the change. This took place in 1980, but its origins were more than a decade previously, and it was significantly presented by its apologists, such as Klerman, as 'a decisive turning point in the history of American psychiatry ... an affirmation of its medical identity'. The new nosology, which was categorical in nature and introduced diagnostic criteria borrowed from experimental psychology in the delimitation of the categories, did not allow any reference to 'unproven' aetiological factors or pathogenic mechanisms, unless 'scientifically demonstrated'. It claimed to be purely descriptive and therefore acceptable as a means of communication by all psychiatrists, whatever their individual orientation may be. It was, in fact, perceived, not only in its country of origin as a reaction against the extreme socio-psychological positions—the deletion of the term neurosis because of its usual association

with the psychoanalytic theory of intrapsychic conflicts raised violent controversies—but, despite its proclaimed 'a-theorism', also as favouring the biological medical model. Although initially exclusively devised for the use of American psychiatrists, to the surprise of its authors, it was rapidly accepted in all countries, and the WHO adopted finally its principles in its own nosological system—the International Classification of Diseases. Originally, the result of a brutal reversal of trends in American psychiatry, it expressed a general change of direction in the psychiatric way of thinking towards affirmation, against the forces believed to threaten it of the medical character of psychiatry.

Crisis in psychiatry?

At first glance, the new status of psychiatry seems to have taken firm root in the last four decades. It rests on the general acceptance of the medical definition of the concept of mental disease and of the progressive realization of a diversified, but co-ordinated, institutional system of mental health care. The biological perspective, even if it has taken a prominent place in research and therapy, is now combined with psychological and social approaches in the bio-psychosocial model. The psychiatrist, in accordance with his medical professional responsibilities, occupies a central position in a multi-disciplinary team whose members contribute their special competences to the common goal.

This idyllic picture is far from a reflection of reality, even in developed countries, and the existence of a crisis in psychiatry is evoked with increasing frequency. Under the pressure of economic constraints, efforts are made everywhere to control the rising burden of medical care. They have taken different forms according to the country—from the managed care system in the United States to the *numerus clausus* system in France, in which the number of internships available is determined by the government—but their common aim is to limit the number of psychiatrists and the cost of their activities. In the United Kingdom, the most socialized top-down health care system in the world, managers are now responsible for clinical governance, rather than doctors themselves. This has already resulted in a complete system failure at one general hospital. Psychiatry has proved particularly vulnerable to management edict, and recruitment of competent consultant psychiatrists has become increasingly difficult. Paradoxically, the recognition of the frequency of mental disorders and the growing demand for psychiatric treatments has been associated with a reduction in the domain of action of psychiatrists, who are now often vastly outnumbered by clinical psychologists and social workers. In the United States, by 1990, 80,000 'clinical' social workers were active in the psychiatric socio-psychological domain, a quarter of them in part- or full-time private practice. The claims of these powerful professional groups are not limited to a completely autonomous status but, in the case of clinical psychologists, extend to the demand for a legal recognition of such typical 'medical privileges' as the right to hospitalize patients and to prescribe drugs. The most impressive change has been in the proportion of mental disorders being now treated by general practitioners as a result of the availability of psychotropic drugs with fewer side effects; in France, 60% of antidepressants are now prescribed by general practitioners. Professional jealousies also wax and wane but undoubtedly affect the attractiveness of psychiatry as a profession.

These examples may not be a fair representation of the global picture, but there is undoubtedly a movement towards a limitation of the psychiatric specialty to the care of the most severe cases—in practice, the psychotic cases. This reached its most extreme expression in the United Kingdom with the development of the National Service Framework in 1997. This, in effect, refocused secondary care on ‘psychosis’. Some neuroscientists raise doubts about the usefulness of maintaining psychiatry as a specialty, even in this field. Influential, biologically oriented psychiatrists have recently proposed, on theoretical and practical grounds, that psychiatry should be absorbed into a new medical discipline, akin to former neuropsychiatry, and all or most of its socio-psychological aspects should be left to non-medical professions.

In the last decade, medicine in general, but psychiatry in particular, has been accused of selling out to the pharmaceutical industry. This has been based on the high profitability of patented drugs prescribed for psychiatric problems and the fact that large marketing budgets were devoted to the education and entertainment of prescribers. Individual doctors undoubtedly profited from their involvement with companies, and companies obviously influenced how information about new treatments was delivered. However, companies are highly regulated, and indeed off-label promotion, to take one example, has been heavily penalized. The idea that anyone with a so-called conflict of interest (that is, has been paid for professional work by a company) forfeits the right to make a scientific judgement about a treatment is too extreme to be useful. For most doctors, it is their time that is for sale, not their integrity. Suspicion about relationships with big pharma is, however, set to decline with the virtual withdrawal of companies from neuroscience research in the last 10 years.

Conclusions

Since psychiatry has emerged as a specialty, it has been submitted to conflicting forces. The demands of society, changes in the concept of mental disorder and of its limits, variations in the role played by

different theoretical perspectives, and successive scientific discoveries have been responsible for an evolution reflected in the professional status and role of the psychiatrist. Displacements of the centre of gravity of a complex structure in which biological, psychological, and social factors interact have modified the image of psychiatry. The threat of being incorporated in other medical specialties or of being deprived of its medical character is but another transitory episode in its history.

New ethics for twenty-first-century psychiatry

Matthew L. Baum, Julian Savulescu, and Ilina Singh

Introduction

We need new ethics for twenty-first-century psychiatry. Twenty-first-century psychiatry will not be grounded in categorical diagnosis, office-based therapy, medicalization, and use of drugs. It will be oriented around a view of mental health as a continuum; it will bring novel therapeutics, alternative sites of clinical practice, and new targets of intervention (for example, not patients, but the prodrome; not the individual, but the family). In some ways, it may be a return to the bio-psychosocial formulation of the patient as an agent in an embedded social context, with interventions aimed at promoting well-being, rather than the treatment of psychiatric disorder.

In this chapter, we consider a set of innovations in psychiatry that either raise new ethical questions for psychiatrists and for the psychiatric profession or require a revision of prior understanding of what constitutes ethical behaviour in a psychiatric context. We examine two novel neurointerventions at opposite poles—as an example of neuroengineering efforts for increasingly specific interventions at the level of neural circuits, we highlight deep brain stimulation (DBS), and perhaps as an example of an intervention at the other end of the ‘specificity’ spectrum, we highlight the therapeutic use of placebos. We spend the remainder of the chapter discussing ethical and philosophical issues spurred by endeavours to enable a future in which psychiatry is increasingly preventative. The discussion is intended to be exemplary, rather than comprehensive; we hope to prompt sustained reflection and debate on these topics in the profession and, in particular, as part of psychiatric training.

Novel neurointerventions in psychiatry

The case of deep brain stimulation for the treatment of anorexia nervosa

Perhaps the greatest challenges for psychiatric ethics have arrived in the form of technologies that allow for strategic interventions directly into neural circuits and mental processes. Examples include gamma knife surgery and invasive and non-invasive brain stimulation, including optogenetics. As a case study of this trend

in neurointerventions, we consider the use of DBS to treat anorexia nervosa.

DBS is a non-ablative neurosurgical procedure that has been used with great success to ameliorate motor symptoms in treatment-refractory patients suffering from Parkinson’s disease. While the use of the procedure in this context was supported by the UK’s National Institute for Health and Care Excellence (NICE) in 2003, DBS is being increasingly considered as an experimental therapy for a wide range of neurological and psychiatric conditions, including (among others) chronic pain, depression, epilepsy, and anorexia nervosa. Preliminary evidence from the experimental use of DBS in these contexts suggests that the procedure may be used to achieve highly beneficial treatment outcomes for treatment-refractory patients suffering from these conditions [1, 2]. Furthermore, DBS has advantages over existing treatment methods since levels of stimulation can be tailored to the needs of the individual patient and it is reversible—treatment can be stopped and electrodes even removed at the request of the patient [3, 4].

The ethically challenging properties of DBS emerge from the technology’s ability to specifically interfere with neural activity in the brain and modify brain states. Of course, it is true that any intervention affecting feeling, experience, motivation, and behaviour ultimately modifies neural activity. This is true of indirect psychological interventions such as psychotherapy, as well as direct interventions such as drugs, surgery, or DBS; in some sense, they all involve the modification of brain states, so ethical issues raised by one potentially apply to others. That said, the ‘holy grail’ of neurointervention is *precise* control of the activation of neurons in specific circuits to produce targeted effects. Perhaps the most controversial application of this kind of precision in neurointervention would be to bring desire under close cognitive control. Choosing what to desire to do, and being able to do that, is an enormous power with implications for freedom, autonomy, and well-being. Although we are not yet at the stage where agents are enabled to simply will a desire into existence, such that it motivates them sufficiently to act, DBS moves us much closer to this than we have ever been before.

In the context of anorexia nervosa (AN), DBS could be used to impose a motivating desire to eat or to give patients the cognitive control required to resist compulsive motivation to engage in dangerous weight loss behaviour. However, other mechanisms, such as the use of this technology to alter first-order motivating desires or the patient's emotional traits, may confer significant harms as well as potential benefits. For example, amplification of first-order desires to eat without higher-level endorsement may undermine, rather than promote, autonomy [5]. The various ways in which different mechanisms are likely to affect AN patients' experiences of themselves and their ability to be self-governing must be borne in mind in research and clinical development protocols for DBS treatment. Furthermore, practitioners should be wary of the new ways in which the use (and indeed, mere prospect) of DBS treatment could introduce new avenues of perceived coercion and new problems regarding the authenticity of AN patients' desires regarding their continued treatment and eating behaviours [5].

The case of placebo for the treatment of depression

In 2008, Irving Kirsch published the results of a meta-analysis that, for the first time, included unpublished trials of modern antidepressant drugs that were logged with the Food and Drug Administration. Across 47 clinical trials, these antidepressants failed to perform significantly better than placebo in mildly depressed patients and performed only somewhat better than placebo in severely depressed patients. Furthermore, while antidepressants did perform better than placebo for severely depressed patients, the data suggested that as patients became more severely depressed, the group who were given the drug did not fare any better; rather, the control group who were taking placebo fared worse [6, 7]. If these findings are correct, it would seem that severely depressed patients do not respond as strongly to the placebo effect. Consequently, although there is a larger difference between the drug group and the placebo group among severely depressed patients, the drug is no more effective.

Such studies raise the important issue of the extent of the placebo effect in psychiatric treatment and the moral status of such an effect. Since depression, like pain, is a subjective experience, what matters is subjective improvement, and not how it is brought about. That is, two challenges facing psychiatry are to properly ascertain the treatment effect, excluding publication bias, and to better utilize the placebo effect in modern psychiatric practice. Many doctors are forbidden by law or by professional codes of ethics from prescribing placebos without revealing them to their patients [7, 8], but the moral status quo is under pressure as evidence mounts showing that placebos have substantial subjective benefits and that they may even form a larger component of existing popular therapies than was previously thought [9, 10, 11].

Early intervention and prevention in psychiatry

Efforts in predictive biomarker development

'A young man presents to a clinic concerned that people are talking about him on the public bus on his way to school. He knows that they are probably not, but he is troubled by the disconcerting feeling and

it is starting to make him dread the idea of taking public transport. He takes a clinical assessment designed in part to detect other sorts of "attenuated" psychotic symptoms; approximately one third of the individuals who scored as highly as he does go on to have a full psychotic break within two years, one third maintain the current level of troubling attenuated symptoms, one third get better. What should the clinician do with this information? Does the young man have a disorder or is he "merely" at risk of a disorder?'

[Case adapted from Baum 2016]

In the revision of DSM-IV-TR to DSM-5, a vigorous debate surfaced about whether to include a disorder characterized chiefly by the risk of first psychosis [12]. Clinical tools designed to assay attenuated psychotic symptoms had been shown in multiple clinical sites to be able to delineate a group of help-seeking young people, 20–40% of whom would go on to have a psychotic break in the next 2 years. The main opposition to creating such a category in the DSM-5 was that it was inappropriate to have disorders 'based on risk' and that telling someone like the young man in this case that he is at high risk of psychosis could be needlessly traumatic, as a large portion of individuals did not, in fact, go on to develop the psychosis. Proponents responded by sidestepping the concern about risk—that even those who did not develop psychosis still had troubling symptoms that were deserving of care. In the end, this category was not included in DSM-V [13], but the debate about the proper role of risk in psychiatry should be far from over.

At the laboratory bench and super-computing clusters, neuroscientists and bioinformaticians are hard at work to uncover biomarkers in blood, saliva, brain images, and cerebrospinal fluid for diverse phenotypes in psychiatry from psychosis, suicide, and abuse to PTSD and dementia. Efforts do not stop at individual biomarkers, however, as current thinking suggests that an assemblage of multiple biomarkers, demographics, and patient history into actuarial risk predictor tools could yield more predictive power, as does the fracture risk score (FRAX) for all-cause risk of hip fracture, or the Reynolds risk score for 10-year cardiovascular event. The quest for a better classification is increasingly aided by advances in machine learning and has even spilled beyond the medical world into social media where Facebook is currently developing and deploying machine-learning classifiers to identify posts that may indicate the author is at risk of suicide [14]. What makes matters more complex is that this work is beginning to reveal a risk landscape where biomarkers do not map cleanly onto existing disorders but sometimes indicate cross-disorder risk or risk of *events* like suicide, rather than disorders themselves. As this research progresses, the current lines between disordered and well will be blurred and replaced by differential magnitudes of risk of different harmful symptoms and events. Psychiatry as a field will have an increasing number of debates similar to that about young individuals with a clinical high risk of psychosis, and it will have to grapple with the question of how to incorporate risk into its nosology and, more broadly, how risk should change physicians', patients', and society's obligations to each other (for an extended discussion of the neuroethics of biomarkers, see [15]).

The role of risk in the concept of disorder

So what role should quantitative risk play in psychiatric nosology? Should we have disorders based on risk or on categories of risk of

disorders? Interestingly, if one delves into the (seldom read) first few pages of DSM where it discussed what, broadly, should be thought of as a disorder, one can see a telling evolution of a response to these questions. In DSM-IV-TR, risk is explicitly highlighted in a ‘risk clause’ [16]:

‘[A disorder is a dysfunction in the individual] “Associated with present distress (e.g. a painful symptom) or disability (i.e. impairment in one or more important areas of functioning) or with a significantly increased risk of suffering death, pain, disability, or an important loss of freedom.”

(American Psychiatric Association [APA] 2000) [Our emphasis].

But faced with the prospect of throngs of predictive biomarkers, a proposal was put forward to drop the risk clause entirely, with an explanation that the purpose of doing so was to ‘differentiate more clearly between disorders and risk factors’ [17]. One of us has argued that elevated risk of harmful symptoms or of harmful events is precisely why we care about a disorder [15] and that it is really the combination of an unhelpful idea that human existence is neatly cleaved into two conditions, healthy or sick, with disagreements over the *magnitude* of risk and whether the symptoms/events are indeed *harmful* that undergirds disagreements about whether a risk state should be a disorder or not. To see this intuitively, note that we can have highly painful, but quickly resolving, conditions like cramp, which we are unlikely to think of as a disorder (or at least a serious one) *unless we think it is highly likely to happen again or repeatedly in the future*; similarly, people who have a single, unprovoked seizure, though often harmed during the seizure itself (if only by loss of bodily autonomy), are monitored for biomarkers of future seizure risk [for example, epileptiform activity on an encephalogram (EEG)] that could be suggestive of a disorder of sustained predisposition to seizures, e.g. epilepsy. On the other hand, a predictive biomarker like profoundly thickened heart walls indicates a high risk of sudden cardiac death and is relatively uncontroversially thought of as the disorder of hypertrophic cardiomyopathy.

What *should* be controversial and debated openly is the proper course of action indicated by a particular risk and the *types of risks we should care about*. If the ‘other risk factors’ are indeed of very very low predictive value, this is what matters, not that they are ‘risk factors’; indeed, machine-learning classifiers based on the profile of risk factors may soon have higher predictive value of harms we care about than currently accepted clinical standards; for example, in a recent meta-analysis, all of the currently accepted ways of estimating who is at risk of suicidal ideation and attempt, including the oft held idea that those with disorders such as depression and bipolar disorder are at elevated risk, were found to perform only marginally better than chance [18]; several recent machine-learning classifiers, however, performed astronomically better, with one metric of prediction accuracy—the area under the curve (AUC)—of 0.7–0.9 where AUCs of 1 represent perfect prediction and 0.5 represent chance level [for comparison, an elevated score on a prostate-specific antigen (PSA) test has an AUC of 0.68–0.83 for detecting cancer, depending on the PSA cut-off value and the grade of cancer] [19]. Though these algorithms require validation on independent datasets, presumably if part of the reason we care about some psychiatric disorders is the risk of suicide, should we not be even more concerned for the welfare of those identified by an algorithm to be high risk, even if the individual does not map to a currently named disorder?

One of the benefits of being challenged by the development of predictive biomarkers is that it forces us to recognize, more than is currently the case, that the hard conceptual work in psychiatric nosology should be deciding whether a risk is clinically (or morally) significant, whether something is harmful, and whether harms are due primarily to an unjust organization of society [15]. Because the field of psychiatry is unlikely to abandon current nosology entirely, perhaps an interim solution is to retain traditional psychiatric categories but to think of them as useful heuristics for estimating the likelihood of important point outcomes like suicide, future decreases in well-being, or conversely, resolution of symptoms, which can be supplemented with algorithmic and machine learning—similarly to the way a diagnosis of lung cancer is now supplemented by a range of biomarkers from clinical and anatomical pathology to create a better estimate of prognosis.

The role of welfare in the concept of disorder

A complementary approach has also been put forward—treatment should be primarily about improving well-being, and therefore, disorder categories are useful only in so far as they help us to that end [20, 21]. The debate in psychiatry should be less about whether an individual has a disorder, but how best to improve that individual’s quality of life. Thus, a more fruitful question than ‘does this child have attention-deficit/hyperactivity disorder’ is ‘would stimulants improve this child’s quality of life (with a whole-life view)?’. Coming back to risk, if awareness, medical, environmental, or other intervention to alter that risk can improve the individual’s well-being, then that course of action should be considered. Of course, this sentence should provoke the question ‘under what conditions would a reduction of risk improve well-being?’.

To answer this question, it is helpful to frame it within a welfarist account of disability [20, 21]. According to this account, a person has a disability if they have some stable psychological or biological state that makes it likely that their life will get worse, in terms of their own well-being, in the social and environmental context they inhabit. This conception of disability has several morally relevant properties. Firstly, it makes no reference to normality; as such, it does not invite a distinction between treatments that count as therapy and those that count as enhancement. Secondly, it makes no recommendation about the best way to treat disability. The biological, psychological, social, cultural, and other factors that contribute to a person having a disability are relevant only in so far as they negatively impact that person’s well-being. The disability may be treated by addressing any one or more of these factors. While it may be appropriate to treat disability by addressing the biological factors that contribute to it—by prescribing medication or surgery, for example—it may also be appropriate, instead, to address non-biological factors. Imagine someone whose leg has been amputated and who qualifies by the welfarist account as disabled because the amputation makes it difficult for her to negotiate the stairs to the second-floor flat where she lives. This combination of factors reduces her well-being. (For simplicity, imagine that no other factors combine with her amputation to reduce her well-being.) Her well-being will improve if she is fitted with a prosthetic limb; alternatively, it will also improve if a lift is installed in the building where she lives. The medical route to treating disability, then, is not the only route, nor even the most obvious or appropriate.

We believe that the current approach to mental health and illness would benefit from considering a welfarist approach [22]. Such an approach to the goals of psychiatry requires an account of welfare

or well-being. Measures of well-being have not been widely used in psychiatry until very recently, largely because the criterion of 'impairment' has not been framed in alliance with such epidemiological measures. There is some suggestion that this is changing and that, as quality of life measures enter psychiatry, they may need to be re-normed to take account of the various cognitive, behavioural, and other differences entailed in living life with mental health challenges [22].

In philosophy, three broad theories of well-being have been described: hedonistic, desire fulfilment, and objective list. According to hedonistic theory, what makes someone's life go well are positive experiences such as pleasure. According to desire fulfilment theory, what is good is satisfaction of one's desires, even if one does not gain pleasure from that satisfaction. According to objective theory, certain things are good for people, irrespective of whether they desire them or gain pleasure from them [23].

Psychiatrists routinely encounter cases where these three accounts of well-being come into conflict. A patient may enjoy something he desires not to enjoy or *should not* enjoy, even if he does, e.g. sadistic pleasure. Hedonistic and desire fulfilment theories are both subjective theories of the good or value. In this sense, 'beauty is in the eye of the beholder'. The quality of a life is relative to that individual's own valuation.

This is the kind of view that is often put forward by some disability activists and patient advocacy groups; they claim that because the disabled are as satisfied with the quality of their lives as the non-disabled, the quality of their lives is just as good. In a well-cited study, becoming paraplegic has very negative effects on a person in the short term—it causes a significant decrement in subjective life satisfaction. However, over time, the quality of life returns to nearly normal. Many people with paraplegia adapt to their state [24]. Yet, it could be argued that the loss of independence and mobility are serious disadvantages (though clearly ones whose badness depends on the built environment), even if people are equally satisfied.

There are good reasons to include at least an objective element within an account of well-being, especially within psychiatry. In psychiatry, the subjective perspective is often fundamentally affected by the disorder, and it is important to tether treatment to some objective perspective. It is important to recognize that even within a subjectivist framework, however, a person can be mistaken about what is of value. People can be wrong about the facts, for example believing that they are receiving medical care that is beneficial to them when it is not. Or people could be wrong about whether a particular state of affairs instantiates what they value [25]. For example, suppose someone values empathy but mistakenly applies the value of empathy to support a 'tough love' approach. Anorexia might be one psychiatric condition that involves both factual and evaluative errors about body image and shape. However, the problem with subjectivist accounts of well-being—and more generally of value or reasons—is that such accounts are, at base, unfettered—one can literally desire anything.

Each of the three accounts of well-being—hedonistic, desire fulfilment, and objective list theories—has some plausibility. Parfit concludes that an adequate account of well-being must accord weight to all of valuable mental states, desire satisfaction, and objectively valuable activity [26]. It may be best not only to engage in activities that possess objective value, but to also *want* to engage in such activities and to derive pleasure from them. Thus, a welfarist account

would posit that any changes to features of our genetics or biology that make it more conducive to possessing, desiring, and enjoying the things that are objectively good for us should be furthered as a goal of medicine. And in our utilization of biological or algorithmic technology, it is perhaps equally important to seek better estimations of the likelihood that things will go better for an individual as it is that things will go worse.

Personalized medicine, predictive psychiatry, and enhanced clinician responsibilities

Consider the following hypothetical case.

A young woman with florid first-episode psychosis and cognitive impairment was put on antipsychotic medication and consequently developed neuroleptic malignant syndrome (NMS). A case of negligence was brought against the prescribing psychiatrist; one piece of evidence brought forward by the prosecution was that the physician considered, but did not test the woman for, anti-N-methyl-D-aspartate (NMDA) receptor autoantibodies, which would have provided some probabilistic information on NMS risk (for example, see [27]). If the physician had ordered this serological test, he would have found that the woman had high titres of anti-NMDA antibodies. The prosecution claimed that since this test would have yielded relevant information, the physician should have ordered it; because he did not, his prescription was negligent.

Are liability cases like this one poised to proliferate in psychiatry? A psychiatrist might be expected to ensure that a patient does not carry significant risks of a bad reaction to psychopharmaceuticals. How will the responsibilities of the clinician adapt when the ability to detect risks of bad reactions and to perform other risk assessments greatly expand with the development of other predictive biomarkers and algorithms?

Aristotle posited that for someone to be properly held responsible for a state of affairs, she had to have acted voluntarily and with knowledge of what she was doing [28]. If I were not in control of my actions, or if I were not know what I did (or failed to do) was wrong, I would be excused from blame. If a patient deliberately overdosed on a tricyclic antidepressant, but the psychiatrist did not know that the patient was suicidal, this ignorance might excuse the psychiatrist from blame. Yet the technical ability to foresee, to some extent, clinically significant events in psychiatry is poised to drastically shrink the number of cases where one could validly appeal to the excuse of ignorance.

All the way back to Aristotle, theories of moral responsibility have incorporated something similar to a risk clause that permits an individual to be blamed for harm, even if they were in no control or did not know what they were doing at the time the harm came about. Aristotle considers the case of someone who chooses to drink and because of his drunkenness does wrong; that person is still blameworthy for the wrong, even though he had no control over his actions during the highly drunken state, Aristotle argues, because the person could foresee entering such a state when he decided to drink (those who have had training in the treatment of alcohol and substance abuse disorders may have a more nuanced version of these arguments).

In the case of the young woman, even though the clinician had no meaningful control over the harmful reaction at the time that

the woman developed NMS, it might be argued that he did have some sort of control at an earlier time point in so far as he made a choice about whether to prescribe antipsychotics or another course of therapy and could have foreseen the possibility that she would develop NMS as a result of antipsychotic treatment. The prosecution is arguing that the psychiatrist is therefore blameworthy for the harm to the patient. It is certainly true, however, that there is *always a possibility* that a patient given antipsychotics will develop NMS, and it is hardly true that the prescribing psychiatrist would properly be blameworthy for *every case of NMS*. The validity of the prosecution's claim therefore lies in arguing that the psychiatrist becomes blameworthy because the likelihood of NMS would be elevated if the person had anti-NMDA antibodies, that is, the *magnitude of the probability* makes all the difference between NMS being unfortunate or culpable.

One of us has pointed out, however, that philosophical theories of responsibility and legal structures offer little guidance as to the magnitudes of probabilities necessary for a psychiatrist to be culpable; those theories of moral responsibility that mention risk often do so in a binary fashion (for example, it was foreseen or not foreseen, significant risk or insignificant risk) or even posit that the necessary magnitude of risk is a 'non-zero probability' [15]; indeed by ordering whole-exome sequencing, which is quickly becoming cheaper than ordering several individual genetic tests (and thus being considered for genomic screening of newborns in some countries), a clinician instantly gains knowledge of thousands of foreseeable non-zero probabilities.

Discussion of which risks create liability and which risks can be justifiably ignored is all the more pressing because risk assessments in psychiatry are far from being restricted to estimating bad reactions to pharmaceuticals. Here we consider two further cases: risk of relapse and risk of harm to third parties.

The miniaturization of biosensors has enabled them to be integrated into medications where they can wirelessly report ingestion events [29]. This is designed to aid monitoring of patient compliance with a prescribed drug therapy. In psychiatry, however, one could easily see how such a technology could create new obligations for the psychiatrist. It is common for discontinuation of antipsychotic medication (aka non-compliance) to precede an acute phase of psychosis that sometimes results in traumatic, forced hospitalization. What would be the responsibility of the prescribing psychiatrist who would be notified by the biosensor that a patient might be discontinuing medication? One practical solution might be to involve the patient through an extension of a so-called 'Ulysses Contract' (for example, reference [30]). In Homer's *Odyssey*, Ulysses ordered his men to lash him to the mast so that he could not throw himself into the sea upon hearing the sirens' song, the watery plunge being a foreseeable side effect of carrying out his desire to hear their voices. So too, patients might, when well and in full possession of mental faculties of judgement, pre-emptively give their treatment team permission to intervene and hospitalize early when medication discontinuation is detected, even though the patient at the time of discontinuation would not meet the criteria for involuntary hospitalization.

Overall, the role of patient participation in decision-making may increase as prognostic ability grows through the use of biomarkers and big data algorithms. For example, there have been some cases where people with anorexia in the UK have been allowed to die after a long and protracted course with multiple relapses [31]), while it is more normal to force-feed people with anorexia who have a

dangerously low body weight [32]. Greater prognostication may allow high-risk people with anorexia to be identified, and targeted in-depth discussions undertaken during periods of competence to elicit preferences for what should be done when life-threatening anorexia is reached. In this way, better definition of potential patient pathways makes it possible for patients to better and more empathetically engage with their possible futures, and for clinicians to elicit their values in relation to those futures. In this way, patient autonomy can be enhanced as part of a framing of mental health and illness as continuous and dimensional.

Risk assessment in psychiatry also can include risk of harm to third parties. Already, over 200 different actuarial tools are being used in forensic psychiatry to estimate the risk of violent behaviour [33]. There are also individual behavioural biomarkers that may be informative of the risk of violent behaviour, with one of the most discussed in the bioethics literature being the monoamine oxidase A (MAOA) gene \times environment interaction (reviewed in [34, 35]). Briefly, MAOA, involved in the metabolism of monoamine neurotransmitters, is present in two common genetic alleles, MAOA-low (MAOA-L) and MAOA-high (MAOA-H), named according to their metabolic activity *in vitro*. When raised in an environment where they experienced maltreatment, boys with MAOA-L were found to be at elevated risk of future violent behaviour, while boys with MAOA-H were found to be resilient. There are nuances and remaining controversies about this gene \times environment interaction, but for the purposes of this chapter, we wish to highlight the cross-cutting moral implications of such a biological risk of harm to others. Specifically, we might ask if knowledge of differential susceptibility to the violence-predisposing effects of maltreatment should change how public health programmes and social workers prioritize the use of limited social supports (if there is not enough support for all children, should programmes prioritize aiding boys at highest risk of expressing violent behaviour, even if the differential risk is small), or change how courts should evaluate the blameworthiness of individuals who do commit violence. In regard to the latter, one of us previously argued that such a predisposition would affect culpability only if the risk of violence was increased through a legally relevant mechanism; while most jurisdictions would offer no excuse or mitigation for a predisposition that resulted from decreased impulse control, some would allow a partial defence of provocation if an individual were more likely to react with violence due to an increased perceived gravity of a threat to the individual, a possibility supported by some evidence in the case of the MAOA-L gene \times environment interaction.

One further challenge may arise for the child/adolescent psychiatrist who suspects that a boy in their clinical care may be at high risk of maltreatment [34]. Should the threshold for intervention in the family be lowered if the boy has the MAOA-L variant? Conversely, since disruption of family units is itself not without risk to a young person, should the threshold for intervention be raised if the boy's biomarker profile suggests he might be more resistant to one of the negative effects of possible maltreatment?

We will conclude this section by highlighting that the increased ability to gain probabilistic information about the risks patients pose to themselves or pose to others, and that others pose to the patients begs the question of when an individual *should have* known something; for example, they could have learnt more about the risk of suicide, the risk of bleeding, and the risk of violent behaviour but did

not and, because of that ignorance, did wrong. For example, if I said I did not know that the person was drunk (and therefore at high risk of driving dangerously), someone may rightly counter that perhaps I *should have known*. Being blameworthy for not knowing something is referred to, in the legal-philosophy literature, as ‘culpable ignorance’.

A useful concept from the literature of culpable ignorance is the ‘benighting act’:

‘An initial act, in which the agent fails to improve (or positively impairs) his cognitive position, [followed by] a subsequent act in which he does wrong because of his resulting ignorance.’

(Smith 1983, p. 547).

Smith uses the example of a clinician who fails to do relevant continuing education to keep up with standards in the field and, because of that benighting act, wrongs a patient. We can update the case to consider a physician who fails to use predictive technology and, because they lack that knowledge, wrongs a patient; though we discussed the case where the absence of action by the psychiatrist might harm the patient (by failing to intervene to minimize the risk of suicide), it may be the case that the clinician would actually overestimate the risk of suicide (by relying on traditional risk factors; see [18]) and thus wrong the patient by acting, for example, to deprive them of their liberty, if only for a night, under the supervision of a psychiatric nurse.

Smith (1983) [36] highlights that theorists differ in how they respond to culpable ignorance. Some (for example, see [37]), including Aristotle, hold the person equally blameworthy for the wrong, as if they did it without ignorance. Liberal theorists evaluate the blameworthiness of the individual on the benighting act itself, modulating blame according to the likelihood that the act would lead to a wrong. Regardless of which stance one takes, the proliferation of predictive technologies renders the necessity of taking a stance increasingly likely for psychiatrists in training and practice.

Prediction and distributive justice

Distributive justice permeates every facet of psychiatry. There is a global shortage of psychiatrists (and indeed all mental health workers), for example, with only one psychiatrist per 1,000,000 people in low-income countries (vs. one psychiatrist per 472 people in the UK), and even in countries with larger psychiatric workforces, there is a paucity of psychiatrists per capita in rural, compared to urban, areas [38]. So in this sense, psychiatrists themselves are a limited resource that the academies and governing bodies have some concern about how to fairly distribute. Individual psychiatrists must decide: do I accept only private clients? Do I take public insurance? Do I spend time only with the patients I think will benefit the most from my clinical skills, or do I also take on ‘tough cases’ where the chances of my benefiting the person are lower but the person is more deeply affected by the psychiatric disorder?

If we have a limited supply of goods—time, personnel, funding, etc.—with which to benefit people, how should we go about distributing those goods? What counts as fair, or just, distribution can take many shapes. We might think we should distribute all goods equally among the eligible beneficiaries. But sometimes this strategy can make no one better off and some worse off; if one man

had an overcoat on a cold winter day, it would do no one good to distribute the cloth equally among a throng of cold individuals—no one would receive a large enough piece of cloth to warm themselves, and now the man who used to have the coat would also freeze. To counter such an objection to increasing equality by ‘levelling down’, many theories incorporate some element of distributing in order to do good, to benefit people. However, if one posits that it is better to benefit those who are currently worse off over those who are better off, one endorses some version of the priority principle—that one should give priority to benefiting the worse off, even if this means there is less benefit overall.

If it is important to benefit those who are worse off, however, one must have ways of knowing who is worse off. It would be at best callous and at worst a miscarriage of justice to benefit those who are better off over those who are worse off. Historically in psychiatry, diagnostic categories, clinical interviews, and demographics have been used to identify those who are worse off. This information determines who is given priority on waiting lists for mental health services or publicly supported social supports, who is given the ‘direct line’ to a psychiatrist’s pager or office and who will need to speak with a receptionist for triage, who is directly monitored for suicide risk and who is not, or, in forensic psychiatry, who is let out on parole and who stays incarcerated.

If those at higher risk of harm are actually worse off, not ‘merely at risk of being worse off’ [15], then as they develop, predictive biomarkers and algorithms will increasingly be able to inform us about who is at elevated risk of harm, and thus worse off and deserving of distributive priority. Since many of the goods discussed would benefit someone, regardless of whether their risk is detectable through traditional or novel means, then it could be argued that the utilization of predictive bioinformatics could support fair distribution, regardless of whether the test would change clinical management in the narrower sense. This sort of ‘moral utility’ of predictive testing should be considered, in addition to a test’s ‘clinical utility’. When we consider this in conjunction with the concept of ‘culpable ignorance’ raised earlier in this chapter, it is possible that psychiatric practices could encounter scenarios where it is no longer permissible to allocate certain resources considering traditional clinical information only, without utilizing novel bioinformatics methods.

Just as the development of bioprediction may change what is considered as ethical behaviour of psychiatrists, so too may developments in e-health. Many academies and public health systems have incentives for psychiatrists to practise in underserved areas. Often, such programmes come at considerable monetary cost; the Headspace programme for youth mental health in Australia came under the critical spotlight for the variance in the cost of services in remote communities vs. urban communities, for example [39]. However, it is generally viewed as permissible for psychiatrists to choose to practise in big cities where the population’s access to psychiatric services is much better; the justice claims in these cases might have been judged to have been outweighed by the magnitude of the costs to the psychiatrist of satisfying those claims (perhaps their family or research is in the city).

But does the advent of better telepsychiatry and online-mediated treatments change this calculus? One might argue that access to modern outpatient psychiatric services can largely be accomplished online; indeed, emerging evidence suggests that there is little, if any, enhanced therapeutic value of having bodies in the same room,

especially in the treatment of anxiety and depression [40]. If this is true, psychiatrists living in cities may no longer have the same costs in serving rural or foreign populations. Conversely, academics and public health systems may have less justification in continuing to offer incentives for psychiatrists to physically locate their practices in underserved areas. Extending this line of reasoning, should national health insurance move to save costs (and thus be able to reallocate funds) by eliminating office space for outpatient visits and replacing with a telepsychiatry studio altogether?

Against this possibility, one might raise two objections: (1) even if it does not substantively change outpatient experience, having psychiatric services with a presence in hospitals is important in establishing and maintaining parity between mental health care and the rest of health care; (2) as neurotechnologies and biomarkers improve, psychiatrists will increasingly avail themselves of a hospital's other services, such as molecular pathology, imaging suites, etc., that are currently under-utilized in psychiatric practice. If we accept these objections, psychiatrists will regrettably have to continue to grapple with concerns of geography when evaluating justice regarding access to mental health care.

Another justice-based issue arises in e-health with the rapid expansion of peer-support apps and apps designed to aid in unmediated psychiatric treatment. While there is justified concern that peer-support apps are under-regulated, leading to suboptimal support for those who use it (for example, one peer-support app advises listeners to immediately end the chat if a user mentions suicide or suicidal ideation), it is reasonable to think that this family of apps may soon be able to provide some mental health services currently provided by mental health professionals. Because the time of mental health professionals is a limited resource, should mental health professionals strive to maximally use these unmediated tools, thereby freeing up the time they themselves currently spend providing those services and enabling them to provide to more people the services that are not outsourceable? Such a scenario would be supported by desires to do the most good and increase access to care for more people.

Generalizing the new ethics

The pace of change in therapeutics, diagnostics, and prediction in psychiatry is poised to enter an inflection point. This change raises new ethical challenges for the practice of psychiatry, whether from the precision of neuroengineering-based therapies or the embraced imprecision of placebos, but also challenges the field's ethical frameworks as our ability to gain probabilistic insight into the mental vulnerabilities of ourselves and others. There is much of moral relevance under way that we have not discussed—the Do-It-Yourself movement in brain stimulation and the rapid progress of brain-computer interfaces, to name two examples. We hope, however, to have chosen cases that raise transferrable ethical challenges and, hopefully, places to start in thinking about, and discussing, how the practice of psychiatry *should* change in this rising tide of technology.

Foundations of phenomenology/ descriptive psychopathology

Hans-Jürgen Möller

Introduction

Phenomenology or descriptive psychopathology, that is the knowledge of psychopathological phenomena or symptoms, has a long tradition in psychiatry and is much older than the diagnostic systems commonly used today. Correctly applied, it forms the basis for clinical psychiatry as an empirical science [1]. Because the term phenomenology also has a broader, philosophical meaning, the term ‘descriptive psychopathology’ is much more commonly used nowadays.

In psychiatry the term phenomenology is sometimes used in a wider sense to refer to a method of describing, holistically and hermeneutically, all that is characteristic for a person and his situation, a notion which is used in anthropological or ‘daseins’-analytical psychiatry [2]. This methodological approach, which is not very common in modern psychiatry, is based, among other things, on the philosophical tradition of the philosophers Husserl and, in particular, Heidegger (with components such as ‘essences’, ‘interpretation of senses’, ‘existential interpretation of an individual rational world’, ‘study of structures’, etc.). The approach is characterized by intuitive holistic perception and understanding of the world and the person [3–5]. However, this chapter will not cover this extension of phenomenology but rather review descriptive psychopathology in the stricter sense.

Principles and limitations of descriptive psychopathology

In this context, ‘descriptive’ means that symptoms are recorded as far as possible without any theoretical assumptions, for example with respect to certain disease diagnoses or hypotheses of causes, and as far as possible objectively. In clinical diagnostics, the descriptive psychopathological assessment and the creation of a disease/disorder diagnosis or formulation are ideally performed in two independent stages. Nevertheless, it may be useful later in the further course of diagnosing a particular patient, once a presumed diagnosis

has been established, to explore more closely particular symptoms that may or may not be relevant for a specific diagnosis.

Descriptive psychopathology is based on an assessment of symptoms that is as objective as possible, that is, the abnormalities found in the experience and behaviour of the patient should preferably not depend on the individual examiner, the adherence to a particular psychiatric school, the methodology of exploration, the general theoretical attitude (for example, more neurobiological or more psychological), positive and negative expectations, the psychological interaction with the examinee, etc. Moreover, the assessment should be determined in generally the same way by other professionally competent examiners. For various reasons, for example different definitions of symptoms, the completely independent psychopathological diagnostic assessment is in danger of failing to achieve this ideal. To increase the validity and reliability of the assessment, examiners use aids such as symptom lists with exact symptom definitions or even fully structured interviews, especially in research contexts. The clinical psychopathological diagnostic assessment then moves increasingly towards being a fully standardized diagnostic approach, usually involving the use of scales that no longer only make qualitative, but also quantitative, statements. When applying these standardized assessment methods, the diagnostic concordance of the examiners is often additionally improved by ‘rater training’. This use of scales is a modern variant of descriptive psychopathology [6] that does not have the width and subtle differentiation of classical descriptive psychopathology.

Regardless of efforts to improve inter-observer reliability, every psychopathological diagnostic assessment—the classical clinical one, as well as the standardized one—is threatened by various biases, as described in the field of empirical social psychology. These cannot be completely excluded, but rather limited by careful conscious control of the interview process [7, 8].

Systematic distortion of the assessor’s observations can result from the following factors in particular:

- Rosenthal effect: the assessors expectations influence the result of the assessment; tendency on the side of the assessor to systematically over- or under-rate the degree of disturbance.

- Halo effect: the results of the assessment of one characteristic are influenced by the assessors knowledge of the patient's other characteristics or by the overall impression made by the patient.
- Logical errors: the result of the assessment is influenced by assessors reporting only those detailed observations that make sense to them in the context of their theoretical and logical preconceptions.

Another limiting factor of a diagnostic assessment is the patient him- or herself. The patient may show only limited openness to describing psychopathological changes or may have a distorted perception of them. Besides these main types of self-report distortions, one must consider the following:

- Conscious or unconscious tendencies to exaggerate or conceal symptoms.
- Positive response bias and social desirability effects.

There are several others causes of discrepancy between observer views and patient self-reports. In the field of standardized rating scales, examples of the quality and quantity of such discrepancies can be found by comparing the results of observer rating scales and self-rating scales [7, 8]. The risk of discrepant findings can be reduced by having as optimal an interaction with the patient as possible and using a competent and sensitive interview technique.

Descriptive psychopathology is understood as the description of observable phenomena or those experienced and reported by the patient. It does not mean the phenomena developed under psychodynamic/psychoanalytic reconstruction.

It is a general rule of assessment in the context of descriptive psychopathology that an empathic, understanding attitude based on respect is the essential basis for a careful and patient-oriented assessment of psychopathological findings. To guarantee as objective an assessment as possible, it is also important to find the right balance between empathy-related closeness and objectivity-related distance.

Objective 'description' of psychopathological phenomena as an ideal standard

If we designate a psychopathological procedure as 'descriptive', we require that the symptoms be recorded and named as simply as possible in a way that is verifiable and clearly organized, without letting aetiological assumptions, pathogenetic hypotheses, or interpretative elements about the individual or social 'meaning' of certain symptoms (or their meaning as would be typical for the reference group) be included in this phase of the diagnostic process.

Some experts claim that less attention should be paid to symptoms whose presence cannot be 'determined' but only inferred. This is an echo of the distinction between 'signs' and 'symptoms', which is well established in the English-speaking world, but less known elsewhere. Thus, DSM-IV defines a sign as 'an objective manifestation of a pathological condition' that is 'observed by the examiner rather than reported by the affected individual', and the symptom as 'a subjective manifestation of a pathological condition' that is 'reported by the affected individual rather than observed by the examiner'.

In practice, descriptive psychopathological diagnostic assessment no longer so clearly preserves this distinction, and it is no longer found in this strict version in DSM-5. This is demonstrated in

particular by psychomotor symptoms, which refer to the inseparable binding of subjective experience that relates to mood with objective, directly observable motor behaviour [9].

Without question, the impartial assessment of mental phenomena, that is of what a patient describes and experiences, what they remember, what they plan, and the way they act, is a crucial prerequisite for all careful psychiatric practice and research. However, it would be premature to consider this objective fully achievable by choosing a descriptive approach.

Incidentally, this approach can be applied in the same way at the nosological level. DSM-III, published in 1980, was the first standardized diagnostic manual that placed the focus on the independence of the descriptive from the aetiological level and referred to this approach with the rather prematurely chosen term 'atheoretical'. Since then, a process of differentiation has taken place, which highlights more clearly that freedom from *any* theoretical presupposition—which is basically impossible—was and is not meant. Rather, freedom is sought from implicit assumptions about the cause of each symptom or of the respective disorder. In order to prevent the emergence or strengthening of scientific prejudices during the diagnostic process, recognition of implicit assumptions is of crucial importance, be it on the symptom, syndrome, or nosological level [9]. 'Description' can be easily understood as a sober, factual portrayal of something 'objectively' present, similar to the function of a photographic apparatus used by the examiner. The description of psychopathological symptoms, however, is a communication between the patient and the examiner, that is an interpersonal process [4]. This has a different meaning for different symptoms—a symptom such as 'disoriented to place' can be more clearly and 'objectively' determined than the presence of 'thought broadcasting', for example. However, this does not change the fundamental nature of psychopathological description as a process that is characterized through a relationship, among other things.

In general terms, this means that the description is highly dependent on the nature of the symptom, because observable behaviour can be more easily described than internal experiences. Karl Jaspers attached great importance to the finding that 'mental phenomena' never show themselves directly (and consequently also cannot be directly observed), but only indirectly through language, writing, gestures, facial expressions, artistic expression, or behaviour. Therefore, it is all the more important always to be clear about what is actually being 'described' in the descriptive approach [9], that is about:

- The externally recognizable behaviour of the patient.
- His own statements about the current experience.
- Assumptions about the current subjective experience of the patient that the examiner makes on the basis of certain perceptions and ratings (What? Why this one?), although the patient himself perhaps explains them quite differently or even not at all.
- Information from a third party about the patient's behaviour and experiences.

These examples illustrate that in psychopathology, 'description' refers to a complex field of activity. Besides the recording of psychopathological information, it also includes the critical consideration of the respective sources of the things being described and the respective relational context. The procedure is complicated,

among other things, by the fact that the effort to achieve a descriptive recording of the ‘phenomenon’ cannot, in principle, be entirely separated from a basic understanding of psychopathology and the associated view of human beings. The examiner should be aware that every psychopathological ‘description’ moves necessarily between the poles of the subjective experience of the patient and examiner, their relationship, and the objectifying determination of facts.

Pioneers of descriptive psychopathology

Karl Jaspers

Jaspers’ work *General Psychopathology* [10–12] is still regarded as the standard work of descriptive psychopathology. In it, he not only gave an excellent description of psychopathological phenomena, but also additionally discussed fundamental questions about assessing mental phenomena and, going far beyond a mere description of symptoms, discussed aspects of the relationship and backgrounds of psychopathological phenomena. His distinction between ‘explaining’ and ‘understanding’ has meaning still today.

Thus, Jaspers made a strong distinction between scientific explanation, which is based on causality, and understanding, which aims to recreate the mental thoughts of another person. He also spoke in this context of the ‘phenomenological direction’ in psychopathology, with which he mainly meant the respectful and careful engaging of the examiner with the patient’s self-portrayal; he warned about prematurely following the supposed obligation to objectify and standardize the findings. He would not have favoured check-box approaches to the identification of symptoms in structured interviews.

Jaspers was fully aware of the importance of a clear terminology for psychopathology. His response to the inherent tension, present in each diagnostic assessment, between subjective experience and standardization, was: ‘The envisioning of mental experiences and states, their differentiation and determination, so that one can always mean the same with the terms, is the task of phenomenology’ [12, p. 22 ff]. As the first, indispensable step, however, such a phenomenological approach provides the examiner only with ‘a number of fragments of the real mental experience’, and he envisions ‘individual qualities, individual states viewed as dormant’ and thus practises ‘static understanding’.

‘Genetic understanding’ appeared to be more important to him in the psychopathological assessment. This ‘understanding’ deals with the relationship between individual psychological states—in Jaspers’ words, with the understanding of ‘how mental processes emerge with evidence from mental processes’ [12].

An important aspect for Jaspers was the ‘genetic understanding of biographical contexts’ with psychopathological phenomena. This may seem reminiscent of psychodynamic approaches, but the theoretical context is completely different and makes no psychoanalytic assumptions. It is instead based on a ‘common sense psychology’ of the relevant own life experiences of the examiner. Jaspers described not only clinical–psychopathological phenomena (which he did with impressive conciseness and often supplemented with case reports), but also the basics of a healthy psyche. One could only approach assessing the entirety of the mentally healthy or disturbed person—this is one of the core ideas—via the uniqueness of each patient, which is based on the patient’s biography. However, this entirety is never fully accessible by scientific means.

This brief description will have made clear that he was concerned with far more than describing the specific mental/psychopathological phenomenon, with the holistic assessment of the inner connection of mental phenomena and their relationship to personal experiences.

Kurt Schneider

Like Jaspers, Kurt Schneider is another important representative of the descriptive approach in psychiatry. Unlike Jaspers, he represents a descriptive approach in the narrower sense, and accordingly his remarks are less extensive. In continuation of Jaspers’ perspective, however, he did not split the mental state into unconnected adjoining single elements but preserved an understanding of the overall context. He called this process ‘descriptive-analytic’. Even more so than Jaspers, Schneider was interested in carefully clinically justified and, if possible, highly selective psychopathological terminology that should be the guiding principle for the diagnostic process. He was also interested, among other things, in the question of whether characteristic, or possibly even pathognomonic, symptoms exist for certain diseases. Representative of this approach are his remarks about ‘first-rank symptoms’ and ‘second-rank symptoms’, with which he paved the way for modern operationalized diagnostics. His most famous work *Clinical Psychopathology* was continually developed in individual contributions from the 1920s; the book appeared under this title for the first time in 1950; the fifteenth edition appeared in 2007 [13, 14].

Recently, efforts have been made to assess descriptively and operationally even more theoretically fraught and not directly observable psychopathological conditions, such as aspects of psychodynamic relationships and defensive strategies [15]. They represent attempts supplementary to operational psychodynamic diagnostics (OPD) [16] but go beyond traditional classical descriptive phenomenology.

Descriptive assessment of psychopathological symptoms

The descriptive assessment of psychopathological symptoms which follows is based on the most recent version of the manual by the Association for Methodology and Documentation in Psychiatry (AMDP) [17, 18]. Earlier editions of the AMDP manual, which was originally published in German, have been translated into several languages, including English [19].

The AMDP system was chosen because it reflects most comprehensively the continental European psychopathological tradition. Also, despite all its differentiation, it covers the whole spectrum of psychopathology, with a special focus on productive-psychotic and affective symptoms, and is easy to use both clinically and scientifically. In the recent past, enhancements were made in certain areas that were previously assessed only somewhat or not at all in the AMDP system, such as psychomotor function, basic schizophrenic disorders, personality traits, and some symptoms common in ‘neurotic’ disorders. In order to address these shortcomings, in particular with a view to their use in psychiatric research, additional ‘modules’ for the AMDP system were also developed [20].

Disturbances of consciousness

'Disturbance of consciousness' is the generic term for any changes in the level of consciousness. A distinction is made between quantitative changes in consciousness (reduced awareness in the sense of the sleep-wake scale) and qualitative changes (reduced, limited, and shifted consciousness).

A quantitative disturbance of consciousness (reduction of vigilance) is assumed if a patient appears dazed or drowsy and a reduced perception of external stimuli can be detected. The degrees of impaired consciousness can be described as follows:

- **Decreased clarity:** the patient is very contemplative, slowed down, and restricted in acquiring and processing information.
- **Somnolence:** the patient is abnormally drowsy but is easily woken up.
- **Stupor:** the patient is asleep, and only strong stimuli can wake him.
- **Coma:** the patient is unconscious and cannot be woken up. In a deep coma, the pupillary, corneal, and tendon reflexes are absent.

Qualitative disturbances of consciousness

- **Clouded consciousness:** lack of clarity of awareness of oneself or the environment. The associations of experience are lost, and consciousness is as if fragmented. Thinking and acting are confused. Clouding of consciousness is easily recognizable for anyone who has seen this state.
- **Narrowed consciousness:** narrowing of field of consciousness, for example by focusing on a specific experience (intra-personal or in the environment), mostly combined with reduced response to stimuli (for example, the epileptic semi-conscious state). The experience is changed in a dream-like way. Complicated and outwardly organized actions, such as travel, are nevertheless still possible. The assessment of narrowed consciousness can be problematic precisely because of the ability to perform outwardly organized actions.
- **Changed consciousness:** change in consciousness, compared with the usual daily consciousness. There is a feeling of increased intensity and brightness and of increased awareness regarding alertness and perception of happenings inside or in the outside world and/or a feeling of magnification of the space or depth that can be consciously recognized (expansion of consciousness). This condition is difficult to detect and only possible on the basis of subjective information provided by the person being examined.

Disturbances of orientation

Lack of knowledge about temporal, spatial, situational, and/or personal circumstances. Depending on the intensity of the disturbance, one can differentiate between restricted orientation or loss of orientation.

The following forms are distinguished:

- **Time:** patients do not know the date, day, year, or season.
- **Place:** patients do not know where they are.
- **Situation:** patients are not aware of the situation in which they currently find themselves (for example, examination in the hospital).
- **Self:** patients lack knowledge about their own name, date of birth, and other important personal biographical circumstances.

Disorders of attention and concentration

Disorders of attention and concentration are defined as an impairment in the ability to fully direct the perception mediated by the sensations or perceptions to focus on a particular subject.

- **Attention disorders:** scope and intensity of the assimilation of perceptions, ideas, or thoughts are impaired.
- **Concentration disorders:** ability to maintain attention on a specific activity or a particular object or situation is impaired.

The course of the interview will provide indications of whether patients are restricted in their ability to fully focus their perception on the information mediated by their sensations or in their ability to concentrate on a particular object or situation. Abnormalities in writing, such as omissions or duplication of letters, may also provide clues.

Perception disorders

Perception disorders are defined as an impairment of the ability to understand the relevance of perceptual experiences and to interconnect them. Perception may be wrong, slowed or completely missing.

Retention and memory disorders

These disorders are defined as a reduced ability to recall new and old experiences. Traditional psychopathology differentiates between retention and memory disorders. Modern psychological theories of memory differentiate between ultra-short (seconds), short-term (minutes), and long-term memory.

Disorders of memory functions can be generally assessed during the evaluation interview. Can the patient remember the examiner's questions? Do they know what was discussed in an earlier part of the conversation? They may report spontaneously about subjectively perceived forgetfulness. Perhaps they now have to use written reminders to help with shopping or in other life situations, whereas they previously did not make any such notes. The description of the life history and current life situation often provides clear indications of memory gaps, which are then sometimes filled by confabulations. Time lattice defects, that is the inability to report biographical facts in the correct temporal order, also provide information on memory disorders.

Besides the question of subjectively perceived disorders of retention and memory, such disorders are assessed by a preliminary clinical evaluation. Objectively observable behavioural traits are of greater importance than the patient's self-assessment, which can be marked by affect-related feelings of insufficiency.

- **Retention disorders** refer to a recall period of up to about 10 minutes.
- **Memory disorders** refer to a recall period of longer than about 10 minutes. A distinction is made between recent and remote memory disorders:
 - **Short-term memory disorder:** the reduction or loss of the ability to retain impressions or experiences for up to 60 minutes.
 - **Long-term memory disorder:** the reduction or loss of the ability to retain impressions or experiences that took place longer than 60 minutes ago or even further in the past, including biographical events, for example.

Memory disorders also include amnesia.

Amnesia: memory gaps limited to a particular event or time. With respect to a traumatic event (for example, brain damage), a distinction is made between retrograde amnesia, in which a certain period of time before the event is affected, and anterograde amnesia, in which a certain period of time after the event is affected. In anterograde amnesia, the duration of the memory gap is usually longer than the duration of unconsciousness. With regard to the period affected by the memory gap, one can distinguish between total and lacunar (episodic) amnesia.

- **Confabulations:** memory gaps are filled with ideas that patients themselves view as memories.
- **Paramnesias (delusional memories):** memory disorders with fantasy memories. These also include the so-called false recognition, for example the feeling of having experienced certain situations previously ('déjà vu') or never having experienced them ('jamais vu').
- **Transient global amnesia (TGA):** acute, transient episode of retention and memory disorders of unclear aetiology. Routine actions are possible. Amnesia exists for the duration of the episode.

Disorders of intelligence

Intelligence is a complex ability of people to find their way in unfamiliar situations, to capture meaning and relationship contexts, and to meet new requirements through logical functions. Intellectual impairment disorders can be congenital or acquired later in life.

The main indications of the patient's intellectual level are already apparent from their *life story*, for example the type of school education, being held back a year in school, school-leaving qualification, professional status achieved, recreational interests. Also the style of speaking and thought processes (abstract level) during the interview allow orientating conclusions to be drawn. A decrease in professional standing and a reduction in the intellectual level of leisure activities, compared to the past, may also indicate an acquired mental retardation, after other factors have been excluded.

Formal thought disorders

Formal thought disorders are disorders of thought sequence. They are subjectively perceived by the patient or express themselves in verbal utterances.

The following forms are distinguished:

- **Retarded thinking:** the thought process is slow and delayed, appears to be tedious for the patient and is often experienced subjectively by the patient as inhibited thinking.
- **Circumstantial thinking:** thinking is circuitous; irrelevant thoughts are not separated from relevant ones. The main point is lost in the portrayal of insignificant details.
- **Restricted thinking:** restriction of the substantive scope of thinking, attached to an issue or a few topics.
- **Perseveration:** repetition of the same thought contents and adherence to previous words or information that were used but now no longer make sense.
- **Rumination:** constantly busy with certain, usually unpleasant, thoughts that are not experienced by the patient as foreign and usually are related to the current life situation.

- **Pressured thinking:** the patient feels under excessive pressure from many ideas and also constantly recurring thoughts.
- **Flight of ideas:** excessive imaginative thought. Thinking no longer follows a strict direction but changes or loses the goal because of interruptive associations.
- **Tangential thinking:** the patient does not respond to the question and talks around or past the point, although it is apparent from the response and/or situation that they have understood the question.
- **Thought blocking:** sudden interruption of an otherwise fluent train of thought for no apparent reason.
- **Paralogia:** the sentence structure is grammatically still intact, but the consequence of the intellectual context and/or the level of detail of what is said is reduced.
- **Incoherence:** erratic, dissociated thought process, in which the logical and associative dimensions are missing. In severe forms, the grammatical sentence structure is lacking (paragrammatism), all the way to an incomprehensible mix of words and syllables ('word salad'; schizophasia).
- **Neologisms:** building of new phrases or words that do not meet the usual language conventions and often are not easily understood.

Delusions

A delusion is an *uncorrectable* false assessment of reality that occurs independently of experience and which the patient holds onto with *subjective certainty*. The conviction is therefore contrary to reality and to the conviction of others. Delusional phenomena can occur in different forms and with different content.

Delusions belong to the group of *content thought disorders*. They are often hidden and, if suspected, need to be specifically explored and differentiated from *overvalued ideas*. In the latter, strongly emotional thoughts about experiences dominate thinking in a non-objective and one-sided way, but such ideas are not absolutely incorrigible.

Depending on the type of delusion formation, the following forms are distinguished:

- **Sudden delusional thoughts:** sudden occurrence of delusional beliefs.
- **Delusional perceptions:** a normal perception gives rise to an interpretation of delusional and abnormal importance.
- **Explanatory delusions:** delusional conviction for the explanation of psychotic symptoms (for example, hallucinations).

The following terms are useful for the further characterization of the delusional experience:

- **Delusional mood:** sense of the uncanny, the ambiguous, from which delusional ideas arise. General, unclear feeling that something is wrong and is in the air, and that everything concerns the person. The events in the surroundings seem strange and unusual to the person. Because they do not know what is happening to them and what is going on, they become anxious, perplexed, and bewildered. A delusional mood frequently precedes delusional perception.
- **Delusional dynamics:** affective participation in the delusion; the driving force and strength of the emotions in the delusion.
- **Systematic delusions:** delusional ideas are embellished with logical or paralogical associations to a delusional building.

Depending on the content of the delusion, the following can be distinguished:

- *Delusions of reference*: random events are ascribed particular importance for the self.
- *Delusions of persecution*: patients have delusions of being the target of persecution.
- *Delusions of jealousy*: delusional conviction of being cheated on or deceived by one's partner.
- *Delusions of love*: delusional conviction of being loved by another.
- *Delusions of guilt*: delusional conviction to have defied, for example, God's commandments or a higher moral instance.
- *Delusions of impoverishment*: delusional conviction that the financial basis of life is threatened or lost.
- *Hypochondriacal delusions*: delusional conviction that health is threatened or lost or that one has a specific physical illness.
- *Nihilistic delusions*: delusional conviction that all is lost, everything is forlorn, everything is hopeless.
- *Delusions of grandiosity*: delusional overestimation of self all the way to identification with famous personalities from the past or present.
- *Delusions of memory*: delusional falsification of memories.
- *Doppelgänger delusions*: delusional notion that there is a doppelgänger.

Hallucinations

Hallucinations are perceptual experiences without an appropriate external stimulus, but which are still considered to be real sensations. They are also referred to as false perceptions and can occur in all sensory domains. The degree to which they are convincingly real may differ.

If the unreality of the hallucination is recognized, one refers to *pseudohallucinations*. These are to be differentiated from *illusions*, in which something that really exists is believed to be something else than it actually is (misreading of sensations).

Depending on the sensory area, one differentiates between the following:

- *Auditory hallucinations*: they can range from unformed, elementary acoustic perceptions (acoasmas) to hallucinatory experiences of complicated acoustic phenomena (for example, hearing voices).
- *Optical hallucinations*: they can range from unformed, elementary optical illusions (photomes) to the hallucinatory experience of crafted scenes.
- *Olfactory and gustatory hallucinations*: patients with a delusional fear of poisoning claim, for example, to smell gas.
- *Bodily hallucinations*: bodily perceptions are not perceived as being due to external stimulation.

Hypnagogic hallucinations

These are optical and acoustic hallucinations that occur when people are half asleep, that is when waking up or falling asleep. They can also occur in healthy people without mental illness, as can any hallucinations in various borderline situations (for example, in case of sensory deprivation and meditation).

Other disorders of perception

Unlike hallucinations, these changes in perception are usually much easier to assess because they do not appear to patients as being so far from normal mental experience.

- *Change in the intensity of perceptions*: sensory impressions are more colourful, lively, colourless, or hazy.
- *Micro-/macropsia*: objects are perceived to be smaller, or further away, or closer.
- *Metamorphopsia (dysmorphopsia)*: the colour or shape of objects is perceived to be changed or distorted.

Disorders of ego

Disorders in which the egocentricity of experience is altered (de-realization, depersonalization) or the boundary between self and the environment appears to be porous.

One differentiates between the following:

- *Depersonalization*: the own ego or bodily parts are perceived as being foreign, unreal, or changed.
- *Derealization*: the environment appears to patients as unreal, strange, or spatially altered.
- *Thought broadcasting*: the patient complains that their thoughts no longer belong to them alone and that others are sharing them and know what they think.
- *Thought withdrawal*: patients have the feeling that thoughts are being taken away from them.
- *Thought insertion*: patients are of the opinion that their thoughts and ideas are externally inserted, influenced, guided, and controlled.
- *Other feelings of alien influence*: patients are of the opinion that their feelings, aspirations, will, and actions are externally made, directed, and controlled.

Disorders of affect

The realm of affect includes the usually only brief *emotions* ('waves of emotion', for example, anger, rage, hate, joy) and the longer-lasting *moods* (for example, depression).

- *Affective lability/mood lability*: rapid change in affect or mood.
- *Affective incontinence*: lack of control of expressed emotions.
- *Blunted affect*: state of low affect and emotional responsiveness. Patients appear indifferent, emotionally restrained, listless, and disinterested.
- *Feelings of loss of feeling*: painfully experienced lack or loss of affective emotion.
- *Affective rigidity*: reduction in the ability to modulate affect. Patients remain in certain moods or affects, regardless of the external situation.
- *Inner restlessness*: patients complain that they are emotionally moved and are agitated or tense.
- *Dysphoria*: sullen mood.
- *Irritability*: tendency for aggressive emotional outbursts.

- *Ambivalence*: contradictory feelings towards a particular person, idea, or action exist side-by-side and lead to a tense state.
- *Euphoria*: state of excessive well-being and of pleasure, joy, confidence, and increased vitality.
- *Foolish affect*: silly, empty cheerfulness with a touch of simple-mindedness, foolishness, and immaturity.
- *Depressed mood*: depressed, rather negative state in the sense of dejection, sadness, listlessness, and hopelessness.
- *Loss of vitality*: reduced general feelings of energy and vitality, of physical and mental freshness, and of being unimpaired.
- *Feelings of inadequacy*: feeling of having no value and of being inept and incapable.
- *Exaggerated self-esteem*: the feeling of being particularly valuable and particularly competent.
- *Parathymia*: inappropriate mood; expressions of emotion and experiences do not match.

The prevailing mood and emotions can be evaluated in the course of the interview, as long as the interview is sufficiently long and gives patients the opportunity to talk about their emotions. Through targeted exploration, one can try to obtain a differentiated description from patients about their affective state.

Compulsions, phobias, anxiety, and hypochondriasis

- *Fear*: feeling of threat and danger, usually accompanied by vegetative symptoms such as palpitations, sweating, shortness of breath, tremor, dry mouth, or gastric pressure.
- *Phobias*: fear of an object or situation.
- *Suspiciousness*: fear that one is the object of someone's scheming.
- *Hypochondriasis*: concern about one's own health that cannot be objectively explained but that is tenaciously held on to.
- *Obsessive thoughts*: thoughts that cannot be suppressed and that are either senseless or whose persistence and penetrance are perceived to be meaningless and mostly distressing.
- *Compulsive actions*: actions perceived as meaningless and mostly distressing that usually cannot be suppressed; mostly due to compulsive impulses or compulsive fears.

Disturbances of drive and psychomotility

This term summarizes all disorders that affect the energy, initiative, and activity of a person (*drive*) and the overall movements affected by mental processes (*psychomotility*). These disorders are usually diagnosed by observing the patient.

The following types are distinguished:

- *Lack of drive*: lack of energy and initiative, can be recognized by the scarcity of spontaneous motor activity and lack of activity.
- *Inhibition of drive*: in contrast to lack of drive, patients with inhibited drive do not experience their initiative and energy as reduced, but rather as inhibited. 'Everything is a little harder

than usual; it's as if I'm inhibited, but so far hardly anyone has noticed.'

- *Stuporous*: motor immobility and lack of reactions despite normal neurological findings (in contrast to coma).
- *Mutism*: ranges from taciturnity to not speaking, even though organs of speech and the ability to speak are intact.
- *Logorrhoea*: excessive talkativeness. Because of an insatiable urge to speak, no meaningful communication is possible with the patient. Patients ignore or reject attempts to interrupt them.
- *Increased drive*: increased activity and initiative during organized (targeted) activity. Patients express numerous wishes and plans, which are only partially put into action. They are constantly active, are not impressed by counterarguments and ignore or do not care about personal consequences.
- *Motor restlessness*: aimless and undirected motor activity that can increase up to a frenzy. Patients are constantly moving and can therefore have hardly any or no normal social contacts. During the evaluation they cannot stay sitting on the chair and have to get up and walk up and down.
- *Automatisms*: patients perform automatic actions which they describe as not being intentional. These include negativisms (in response to a request, they automatically perform the opposite or nothing at all), automatic obedience (automatic following of instructions), and echolalia/echopraxia (everything a patient hears or sees is repeated or imitated).
- *Indecisiveness*: simultaneous, contradictory impulses make decisive actions impossible.
- *Stereotypy*: language and motor expressions that are repeated in the same way and seem to be meaningless.
- *Tics*: uniformly recurring, rapid, and involuntary muscle twitches, possibly with expressive content.
- *Paramimic*: Mimicking behaviour and affective experience do not concur.
- *Mannerisms*: strange, unnatural, contrived, posing behavioural traits.
- *Histrionics*: patients give the impression that they are presenting themselves in a way that dramatizes their situation or symptoms.
- *Aggressiveness*: tendency to act violently.
- *Social withdrawal*: reduction in social contacts.
- *Social activity*: expansion of social contacts. Patients approach many people, frequently cling indiscriminately to people, lack distance and are always on the go and querulous. They constantly talk to strangers and do not notice when they annoy others. The environment reacts negatively.

Some of these symptoms are traditionally regarded as *catatonic symptoms*. These symptoms are particularly common in the context of the catatonic subtype of schizophrenia and are divided into:

- *Psychomotor hyperphenomena*: psychomotor agitation, movement and speech stereotypes, automatic obedience (echopraxia, echolalia).
- *Psychomotor hypophenomena*: blocking, stupor and mutism, negativism, catalepsy (remaining in a position with passive bodily posture), stereotypical positions, and flexibilitas cerea (wax-like flexibility when moved passively).

Summarizing psychopathological findings: the psychopathological state (mental state examination)

At the end of the exploration, the symptomatology is summarized as a *psychopathological evaluation*. One tries to create a picture of the patient's current psychopathological condition in an abstract, and yet still concrete enough, manner.

One usually starts with the appearance (*habitus*, external presentation, physiognomy, and also psychomotility and drive), because this is the easiest to assess. Then the specific behaviour and speech (way of speaking, sound of the voice, modulation, spontaneity) during the interview are described. Thereafter (if applicable!), details are given on changes in consciousness, attention, attitude, orientation, memory, affect, and drive (affective contact, intensity and modulation of affective reactions, basic mood, mood swings, compulsive needs, will control, etc.). This is followed by a discussion of disorders of perception (including hallucinations), disturbances of formal thought and thought content (delusions, obsessive thoughts), and disorders of ego.

One should note that the summary is not just a list of psychopathological terms with a note on whether they are not at all present or mild, moderate, or severe. Rather, one must create a true picture of the *current mental state* of the patient.

One should also go beyond these areas and provide information on possible demonstrative traits or simulation/dissimulation tendencies, malaise and illness insight, and special risks.

Conclusions

Descriptive psychopathology, or the knowledge of psychopathological symptoms and abnormal experiences and behaviours, is the basis for clinical diagnosis in psychiatry. The symptoms or syndromes recorded within the descriptive psychopathological assessment can be used in the clinical or scientific context, for example in the sense of a syndrome diagnosis [21]. They can also serve to make a diagnosis at a higher level of diagnostics by using certain traditional nosological entities or modern operationalized disease/disorder concepts such as those defined in ICD-10 or DSM-5, for example. While the criteria for the different diseases/disorders can change with each revision of the classification systems, as happened, for example, in the transition from DSM-IV to DSM-5 [22, 23], the description of the symptoms almost always remains stable. Thus, descriptive psychopathology represents the basis of our practice as clinical psychiatrists, and we should use it in everyday clinical practice, as well as in clinical research. Although knowledge of, and competency in, traditional descriptive psychopathology have tended continuously to decrease as part of the development of the operational diagnosis systems such as ICD-10 and especially DSM-IV and DSM-5 [24], descriptive psychopathology is still an important tool for clinical psychiatry [25].

The Research Domain Criteria (RDoC), developed by the National Institute of Mental Health (NIMH), tend to greatly limit the importance of classical descriptive psychopathology and clinical findings for research approaches [26] (see Chapter 8). The reason is that the RDoC focus more on reductionist dimensions detectable at a neuropsychological level as the target of neurobiological research, rather than on complex psychopathological syndromes. This approach may make it easier to achieve research results, but

the transformation of these results into the more complex constructs (syndromes) of clinical psychopathology is difficult; for example, a 'depressive syndrome' is more than just a score on a 'negative valence system'.

Psychopathological findings represent the core of psychiatric diagnosis. This statement, which, at first glance, appears obvious, is nowadays no longer a general consensus. In particular, other diagnostic procedures, such as neuropsychological, neurophysiological, biochemical, genetic, and imaging procedures, have greatly increased in relevance and authority through the scientific developments of the last decades. We stand at an important historical juncture where these diagnostic methods have increased in importance but have not come close to replacing the psychopathological assessment. Whether they ever will is an intriguing question for the future.

DSM-5 and ICD-11 classifications

Darrel A. Regier, David P. Goldberg, Bedirhan T. Üstün, and Geoffrey M. Reed

Brief history of mental disorder classification

The classification of medical conditions has historically included the naming (nomenclature) and description (nosology) of recognized illnesses, and the placement of all such conditions into an organizational structure (taxonomy—classifications) that recognizes similarities and boundaries among these conditions. Similar efforts have been useful for other scientific areas such as chemistry, with the periodic table of elements, and biology, with the recognition and organization of genera and species in the classification of Linnaeus.

With the establishment of asylums for the mentally ill in the eighteenth and nineteenth centuries, there was an opportunity to systematically observe the course of psychiatric illnesses, conduct medical autopsies, and advance new classification structures. Alzheimer's recognition of pathological changes in brains of patients with dementia at autopsy became a biological standard, but Emil Kraepelin was unable to identify parallel changes for dementia praecox. However, Kraepelin's descriptive classification, based on symptom expression and the course of illness, enabled an important separation of schizophrenia and affective psychoses, and his textbooks were widely influential. For asylum directors in the nineteenth century, there was a need to collect statistical information on the types of disorders affecting their patients, and these rudimentary classifications were then used to collect prevalence data by census takers. However, the earliest nineteenth-century international medical statistical classifications focused primarily on listing causes of death (and later diseases) that could aid in standardizing vital statistics reporting for public health monitoring.

At the end of World War II, the United Nations (UN) was established, including the World Health Organization (WHO) as its specialized agency in health. All member states of the UN, which then became signatories to the WHO, agreed to collect common mortality statistics on the causes of death, and morbidity statistics of known medical and mental disorders to develop comparable national and international health statistics. The sixth revision of the *Manual of International Statistical Classification of Diseases, Injuries, and Causes of Death* (ICD-6) was approved by the World Health Assembly, the WHO's governing body, in 1948. Relatively minor revisions were made in the Seventh Revision in 1955, followed by a more extensive Eighth Revision completed in 1965. The increased use of the classification for medical records resulted in individual

countries, such as the United States, making 'clinical modifications', which involved additional codes for both outpatient and inpatient hospital use. This continued for the ninth edition in 1977 and the tenth edition in 1992 [1].

DSM-I to DSM-IV and ICD-10 mental disorder classification links

Although the American Psychiatric Association (APA) contributed to the ICD-6 mental disorders chapter, it also published a separate *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I) in 1952 that more closely reflected Adolf Meyer's view of mental disorders as psychobiological reactions to critical life and developmental events. In preparation for ICD-8 in 1965, the WHO recognized the wide disparity in different national nomenclatures and lists of mental disorders used throughout the world. The WHO commissioned a British psychiatrist—Erwin Stengel—to survey all the major national and academic classifications available at the time as the basis for proposing a feasible international mental disorder classification in future editions of the ICD. Because of the lack of knowledge and differing opinions regarding the pathology and aetiology, he suggested using 'operationalized definitions' of mental disorders, based on observable syndrome criteria that could be reliably reported. In bypassing disagreements about the aetiology of these syndromes, he suggested that such an approach could lead to a greater measure of agreement about the value of specific treatments and facilitate a broad epidemiological approach to psychiatric research [2].

Unfortunately, the recommendations of Stengel were not followed for ICD-8 in 1965 or the parallel second edition of the DSM published by the APA in 1968. Nonetheless, there were several factors which led to the eventual adoption of Stengel's recommendations. The statistical classification of mental hospital admission diagnoses in the United States and the UK demonstrated marked differences in the prevalence rates of schizophrenia and manic depressive disorder. A study to evaluate the basis for this discrepancy showed that the use of common 'operationalized definitions' of these two disorders and a structured psychiatric interview greatly increased the comparability of prevalence rates for these mental disorders [3]. After this study, the WHO realized that additional guidance was needed to improve

comparable clinical applications of ICD-8 diagnoses and published a glossary of terms in 1974—a glossary that was fully incorporated into ICD-9 in 1977. At about the same time, psychiatrists at Washington University, St Louis embarked on an effort to ‘operationalize’ diagnostic criteria for 16 mental disorders (the Feighner criteria) in what was referred to as a neo-Kraepelinian or descriptive approach to psychiatric diagnosis. The approach was recognized as useful for a proposed NIMH longitudinal study of depressive disorders and was modified to become the Research Diagnostic Criteria (RDC) [4]. When Spitzer was also selected to be Chair of the DSM-III Task Force to prepare an edition comparable to the ninth edition of the ICD, the Task Force decided to go beyond the ICD-9 glossary of terms and introduce explicit symptom criteria for each psychiatric disorder—using the RDC as the model for the entire DSM-III [5].

Following the DSM-III publication in 1980, the WHO Division of Mental Health was contacted by the US Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA) to develop a joint effort to bring greater international agreement on definitions and ‘operationalized criteria’ for mental disorders. A series of international conferences was supported, as was a major international conference of psychiatric leaders from 37 countries held in Copenhagen in 1982 [6]. An agreement was reached at this meeting for these countries to work jointly with the WHO on the development of the Mental and Behavioural Disorders chapter of ICD-10 that would also follow the recommendations of Stengel and the model most fully realized at that time by DSM-III. Subsequently, a co-operative agreement was reached with the WHO and NIMH to support collaboration with the DSM-IV Task Force and the development of three research instruments that would facilitate assessments of both DSM-IV and the newly ‘operationalized’ ICD-10 diagnoses [7]. These included the Composite International Diagnostic Interview (CIDI) for epidemiological studies that was based on the Diagnostic Interview Schedule (DIS) used in the NIMH Epidemiological Catchment Area Study—the first study to realize the epidemiological research potential of operationalized diagnostic criteria (in DSM-III) anticipated by Stengel [8]. The other two instruments included the Schedule for Clinical Assessment in Neuropsychiatry (SCAN), based on the Present State Examination (PSE) used in the United States/UK study, and the International Personality Disorders Examination (IPDE), based on Loranger’s Personality Disorder Examination. The most widely used of these instruments has been the CIDI, which, with some modifications, became the assessment instrument for the extensive World Mental Health Surveys [9]. This work substantially influenced guidance published by the WHO for ICD-10 Mental and Behavioural Disorders, including the *Clinical Descriptions and Diagnostic Guidelines* [10], intended for use in clinical settings, and the *Diagnostic Criteria for Research* [11].

When the co-operative agreement between the NIMH and the WHO for ICD-10 diagnostic instruments was completed in 1992—it was extended to 2001 to develop the WHO Disability Assessment Schedule (WHO-DAS) [12]—an assessment instrument that would support the International Classification of Functioning and Disability (ICF) [13].

DSM-5 and ICD-11 classification development

In 1999, the APA initiated a review of DSM-IV [14] and ICD-10 [1, 10, 11] approaches to mental disorder diagnosis and invited the

WHO, the World Psychiatric Association, and the National Institutes of Health (NIH) to join in this effort. Although the exercise resulted in a monograph entitled *A Research Agenda for DSM-V* [15], it also served as the basis for a co-operative agreement application from the APA and the WHO to three NIH institutes entitled *Developing the Research Base for DSM-V and ICD-11* [16]. From 2004 to 2008, there were 13 conferences, involving about 400 clinicians and scientists from around the world to review the evidence base for major groups of mental disorders and a review of the public health implications of changes in psychiatric classification [17]. The conferences, a list of conference series publications, on ‘developing a research agenda for DSM-5’, are available on the web at <http://www.dsm5.org>.

The DSM-5 Task Force Chair and Vice-Chair were appointed in 2006, with the Task Force that included work group chairs and consultants in 2007, and the 13 diagnostic work groups involving a total of about 160 multi-disciplinary and international members were all vetted for conflict of interest issues by the APA Board of Trustees and fully functioning by 2008. Three drafts of proposed diagnostic criteria were posted on the <http://www.dsm5.org> website in 2010, 2011, and 2012. There were over 13,000 recommendations from clinicians, research investigators, and the general public received on the <http://www.dsm5.org> website in response to these postings. In addition, there was a remarkable level of international media interest in the process, and thousands of petitions, e-mails, and letters were received about proposed changes for selected disorders. Field trials to assess the reliability of diagnoses and dimensional measures were conducted in 11 academic settings [18–20] and in over 600 routine clinical practice settings to assess the clinical utility of the revisions [21]. A multi-level review process was established by the APA Board of Trustees, and DSM-5 was approved by the Board of Trustees in December 2012 and published for release in May 2013 [22].

As with previous editions of the DSM and ICD, it was expected that there would be extensive consultation between the two classifications and that they would be published at about the same time. The ICD-11 revision process was launched in 2007, and a DSM–ICD harmonization co-ordinating group was organized to use the jointly developed research base from the conferences to enhance the consistency of DSM and ICD revisions for clinical guidance. A DSM-5 Task Force initiative to develop a more useful and evidence-based organizational structure of the mental disorder classification was converted into a joint DSM–ICD effort to examine the degree to which individual disorders and groups of disorders had been ‘validated’ in research studies. An expanded set of ‘validity criteria’ from the one proposed in 1970 by Robins and Guze was applied in a series of analyses and papers published in 2009 [23].

It was readily apparent that the alignment of multiple validators was much more meaningful for larger groups or disorder spectra than for individual categorical diagnoses. As a result, there was agreement that both DSM-5 and ICD-11 would—to the extent possible given the different conventions and constituencies of the two systems—share a common organizational structure or ‘metastructure’ that would be reflective of the evidence base accumulated in this exercise. However, since the ICD-11 process continued for more than 6 years after publication of DSM-5, several significant additional structural changes in the mental disorders chapter have been made in the context of the larger ICD-11 revisions.

DSM-5

In the three decades between the publication of DSM-III and DSM-5, there was a remarkable increase in the amount of epidemiologic, clinical, and basic neuroscience research on mental disorders. This research has demonstrated the high levels of mental disorder comorbidity, similarities in pharmacologic and psychosocial treatment effectiveness across diagnostic boundaries, and an increasingly complex set of genetic and pathophysiological correlates with a spectrum of clinical syndromes defined in DSM-III to DSM-IV as separate and distinct disorders. The cumulative effect of this research was to support a reconceptualization of the approach to classifying mental disorders that emphasized developmental similarities, common neurobiological correlates, and common phenomenological features that emerged from factor analyses of clinical symptoms and ‘personality’ traits in both general and clinical populations.

This revised approach appears to be supportive of conceptualizing clinical disorders as central tendencies in more continuous syndromes with multi-causal aetiologies. It acknowledges the heterogeneous nature of current categorical mental disorder diagnoses, such as major depressive disorder, which requires any five out of nine diagnostic criteria for diagnosis and allows up to 256 different combinations with 3–4 different levels of severity. In addition, there are now specifiers for anxiety symptoms and contextual factors such as peri-partum status in females that add to the heterogeneity of this disorder. The inclusion of a ‘clinically significant distress or disability’ threshold criterion for almost all DSM-IV and DSM-5 disorders results in adding mood and anxiety symptoms for virtually all disorders. The overlap of mood and anxiety disorder symptoms with stress-induced disorder criteria for a condition like PTSD further reduces the ability of strict categorical diagnostic criteria boundaries to identify homogenous clinical populations.

Conceptual approach to linking categorical and dimensional diagnostic assessments

The emergence of a new understanding of mental disorders conceptualizes them as the likely result of multiple genetic and environmental exposure factors, rather than discrete causes such as single genes (for example, Down’s syndrome—due to trisomy 21), nutritional or toxic exposures (for example, pellagra—due to niacin deficiency), or single infectious agents [for example, central nervous system (CNS) lues—due to syphilis spirochaete]. This provides an entirely different approach to assessing the validity and reliability of psychiatric diagnoses. It affects how we should conduct field trials of diagnostic criteria and interpret statistical measures of diagnostic reliability such as Kappa—a measure that is greatly affected by the comorbidity of the clinical population from which subjects are recruited and the use of exhaustive research vs usual clinical interviews [19, 24]. If there are perhaps as many as a thousand different genes that contribute some degree of vulnerability to the diagnosis of schizophrenia, and some of these are shared with vulnerability genes for autism spectrum disorders (ASD), attention-deficit/hyperactivity disorder, bipolar disorder, and major depressive disorder [25], the potential for overlapping symptoms and comorbidity

becomes apparent. The emerging appreciation of the influence of psychosocial or physical environmental exposures to the epigenetic switching on or off of any of the vulnerable genes for mental disorders only adds to the aetiological complexity and interpretation of biological ‘validators’.

The tension between the psychoanalytic concept of all mental disorders being on a single continuum from normal to psychosis and that of the neo-Kraepelinians that all disorders are discontinuous, discrete disease entities can now be reinterpreted with a better understanding of aetiological factors and statistical analyses of psychopathological symptoms, traits, and clinical course of illness. From a clinician’s perspective, there is clearly something different about the core clinical expression and clinical course of patients with autism spectrum, schizophrenic spectrum, and bipolar and major depressive disorder diagnoses—even if some of the same vulnerability genes are shared. Although a strict dimensional scoring of all biological and symptomatic domains as continuous variables would undoubtedly provide a more precise description of psychopathology, a hybrid model that contains both categorical diagnoses and dimensional variations is much more useful for clinical practice. As a result, DSM-5 has recommended the following modifications in clinical diagnosis:

1. The assessment of cross-cutting symptom domains for adults that include depression, anger, hypomania, anxiety, somatic, suicide risk, hallucinations, sleep, cognition, obsessive–compulsive, dissociation, personality, substance use, attention, and irritability—the last two for children and adolescents. A Level 1 screening and a Level 2 confirmation of higher symptom levels are recommended, regardless of diagnosis.
2. An assessment of disability using the WHO-DAS that replaces the previous DSM-IV Axis V Global Assessment of Function (GAF) scale.
3. Revised syndrome-based categorical diagnoses with porous boundaries that are organized into larger spectrum groups to facilitate assessments of common comorbidity.
4. Explicit threshold criteria are retained for research and clinical communication about the characteristics of the diagnostic syndrome.
5. Diagnostic severity measures that are freely available for downloading online in English and with select translation editions.
6. Use of ‘Other specified’ and ‘Unspecified’ categorical diagnoses, instead of the ‘Not otherwise specified (NOS)’ convention of previous DSM editions.
7. Associated text on diagnostic features, prevalence, development and course, risk and prognostic factors, culture-related diagnostic issues, suicide risk, functional consequences, gender-related issues, differential diagnosis, and comorbidity.
8. Recommended comprehensive case formulations for clinical assessments.
9. Use of a Cultural Formulation Interview to facilitate understanding of cultural expressions that may be misunderstood as evidence of psychopathology—particularly where there are cultural differences between the clinician and the individual patient.

Table 7.1 Proposed overall ‘metastructure’ or groupings of DSM-5 and ICD-11 mental, behavioural, and neurodevelopmental disorders

DSM-5	ICD-11
Neurodevelopmental disorders	Neurodevelopmental disorders
Schizophrenia spectrum and other psychotic disorders (No ‘General mood disorders’ grouping)	Schizophrenia spectrum and other primary psychotic disorders
Bipolar and related disorders	Mood disorders
Depressive disorders	Bipolar and related disorders
Anxiety disorders	Depressive disorders
Obsessive–compulsive and related disorders	Anxiety and fear-related disorders
Trauma- and stressor-related disorders	Obsessive–compulsive and related disorders
Dissociative disorders	Disorders specifically associated with stress
Somatic symptom and related disorders	Dissociative disorders
Feeding and eating disorders	Bodily distress disorders
Elimination disorders	Feeding and eating disorders
Sleep–wake disorders	Elimination disorders
Sexual dysfunctions	(Separate ICD-11 chapter on ‘Sleep–wake disorders’)
Gender dysphoria	(In separate ICD-11 chapter on ‘Conditions related to sexual health’)
Disruptive, impulse-control, and conduct disorders	(In separate ICD-11 chapter on ‘Conditions related to sexual health’)
	Impulse-control disorders (separate grouping from ‘Disruptive behaviour and dissocial disorders’; different order: appears after ‘Disorders due to substance use and addictive behaviours’)
	Disruptive behaviour and dissocial disorders (separate grouping from ‘Impulse-control disorders’; different order: appears after ‘Disorders due to substance use and addictive behaviours’)
Substance-related and addictive disorders	Disorders due to substance use and addictive behaviours
Paraphilic disorders (Included under ‘Somatic symptom disorders’)	Paraphilic disorders
Neurocognitive disorders	Factitious disorders
Personality disorders	Neurocognitive disorders (different order; appears after ‘Personality disorders’)
Other mental disordersz (Not a grouping in DSM-5)	Personality disorders
(DSM-5 divides these up into the section that corresponds to the expressed symptoms. For example, ‘Depressive disorder associated with another medical condition’ is listed under ‘Depressive disorders’)	(Residual categories for each grouping are included by ICD-11 convention)
Medication-induced movement disorders and other adverse effects of medication	Mental and behavioural disorders associated with pregnancy, childbirth, and the puerperium, not elsewhere classified
Other conditions that may be a focus of clinical attention	Secondary mental and behavioural disorders syndromes
	(In ICD-11 chapter on ‘Diseases of the nervous system’ or chapter on ‘External causes of morbidity or mortality’)
	(Separate ICD-11 chapter on ‘Factors influencing health status and encounters with health services’)

The metastructure of DSM-5 classification of diagnostic categories

The anticipated reorganization of the entire ICD statistical coding system from the ICD-9 numeric (000.00–999.99) and ICD-10 alphanumeric (A00.00–Z99.99) system to an ICD-11 numeric-alphanumeric (01A00–99Z99) system opened the possibility for reconceptualizing the grouping and specifiers for individual diagnoses. The previous hierarchy of ‘organic dementia’, followed by substance-induced disorders and psychoses, could be replaced by a more developmental concept of psychopathology that begins with neurodevelopmental disorders, and place acquired neurocognitive disorders far later in the organizational structure. This structure has

been largely adopted in both DSM-5 and ICD-11 and is shown in [Table 7.1](#).

DSM-5 includes an introductory Section 1 that provides operational definitions and guidance regarding the use of the manual. Section 2 contains the diagnostic criteria and relevant ICD statistical codes within the organizational structure shown in [Table 7.1](#). There is also a very substantive Section 3 that includes the previously mentioned dimensional assessment measures, guidance related to cultural formulation, an alternative ‘hybrid model’ for personality disorders, and conditions for further study.

Embedded within this new organizational arrangement is a much greater appreciation of more continuous diagnostic spectra containing previously described separate and discrete disorders.

Examples of the compression of previous separate disorders into single disorder spectra include ASD, specific learning disorder, several sleep disorders, somatic symptom disorder, and substance use disorders. Altogether, 50 separate disorders in DSM-IV were reduced to 22 spectrum disorders—with the greatest number contributed by merging abuse and dependence disorders for ten substances into mild, moderate, and severe forms of substance use disorders. Several new disorders were added, including social (pragmatic) communication disorder (SCD) and hoarding disorder, that contained more limited symptom domains than were present in other disorders in the related disorder spectra. For example, ASD required deficits in both social communication and restricted, repetitive behaviours and interest domains, whereas some patients who demonstrated deficits only in social communication required a separate SCD diagnosis.

Major changes in the grouping of disorders include the movement of attention-deficit/hyperactivity disorder into the 'Neurodevelopmental disorder' chapter, and gambling disorder into the 'Substance-related and addictive disorders' chapter. There are also new placements of disorders that were previously in other sections of the mental disorder classifications; for example, body dysmorphic disorder from the DSM-IV 'Somatoform disorders' group and trichotillomania (hair pulling disorder) from the DSM-IV 'Impulse-control disorders' group were moved into the DSM-5 'Obsessive-compulsive and related disorders' group, which also added new hoarding disorder and excoriation (skin picking) disorder conditions.

For a more complete description of individual diagnoses in DSM-5, the reader is referred to Section II of DSM-5 (pp. 31–727). Highlights of changes in individual diagnoses from DSM-IV to DSM-5 are contained in the full DSM-5 (pp. 809–16).

Mental and behavioural disorders in ICD-11

ICD-10: the current global standard

The WHO member states agree to use the ICD as the basis for reporting health statistics on mortality and morbidity. The ICD-10 (Tenth Revision) was approved in 1990 and included a listing of all of the health conditions in alphanumeric order, ranging from A00 to Z99, with each chapter corresponding to a major area (for example, neoplasms, diseases of the circulatory system). The 'Mental and behavioural disorders' chapter of ICD-10 was the only chapter to include glossary definitions for each condition. However, the WHO has specifically indicated that these definitions did not provide sufficient information for clinical implementation by mental health professionals. Rather, the statistical version of ICD-10 was intended for use by 'coders or clerical workers and also serves as a reference point for compatibility with other classifications' [1].

For implementation of ICD-10 in mental health service settings, the WHO developed the *ICD-10 Classification of Mental and Behavioral Disorders: Clinical Descriptions and Diagnostic Guidelines* (CDDG) [10], which provided a description of the main clinical and associated features of the disorder, together with diagnostic guidelines designed to assist mental health clinicians in making a confident diagnosis. The diagnostic guidelines in the CDDG differed from DSM diagnostic criteria in offering more flexible, prototypic guidance intended to allow for clinical judgement and global variation, rather than strict criteria.

The WHO also published the *ICD-10 Classification of Mental and Behavioral Disorders: Diagnostic Criteria for Research* (DCR) [11], containing fully operationalized diagnostic criteria. The differences between the CDDG and the DCR reflected their different purposes. The diagnostic guidelines contained in the CDDG were intended to help the clinician identify the category that is most likely to offer relevant information for treatment and management. In this context, false negatives based on arbitrary or overly specified criteria, such as precise duration requirements and symptom counts, were problematic because they offered no guidance to the clinician [26]. In contrast, the DCR were intended primarily for identifying more homogenous research populations such as for clinical trials or epidemiological studies.

Therefore, while the ICD-10 CDDG were substantively quite different from DSM-IV, the ICD-10 DCR were intentionally highly similar to DSM-IV's diagnostic criteria—a similarity that was explicitly permitted by a joint agreement between the WHO and the APA. Still, there were important differences. Of the 176 diagnostic categories the two systems had in common, there were some differences in all but one category (transient tic disorder), with differences judged to be conceptual or substantive in the case of 39 disorders [27].

The largest single source of differences between the ICD-10 DCR and DSM-IV was DSM-IV's 'clinical significance' criterion, which effectively required the presence of distress and/or functional impairment as a part of DSM-IV criteria sets. This difference reflected the WHO's view of distress (other than the specific forms of distress that constitute the symptoms of particular disorders) and changes in functional status—the main components of DSM-IV's clinical significance criterion—as consequences or outcomes of health conditions, rather than their inherent features [28]. The inclusion of these features as a part of specific ICD-10 disorder guidelines or RDC criteria sets was therefore restricted to those conditions in which they were considered necessary for distinguishing disorder from normality. These issues are further discussed in the section on the WHO's ICF.

Finally, the WHO published a version of ICD-10 mental and behavioural disorders intended for use in global primary care settings [29]. The primary care version (ICD-10 PHC) contains only 26 disorder categories and was the predecessor for a similar ICD-11 version.

Development of ICD-11 mental and behavioural disorders

Because the ICD plays such a crucial role in the international health community, it is critical that it is based on the best available scientific knowledge and that it keeps pace with significant advances in health care that have the potential to improve its reliability, validity, and utility. Increasingly, in most countries, the ICD must also be compatible with electronic information infrastructure. ICD-10 was approved by the World Health Assembly in 1990 and published in 1992, prior to the current digital age, making the current period the longest in the history of the ICD without a major revision.

The development of ICD-11 was a huge undertaking that involved a review of necessary changes in the classification of all health conditions, of which mental and behavioural disorders represent only a small part. It was made even more complex by the requirement that ICD-11 must be suitable for a range of different uses by all WHO

member states. Responsibility for co-ordinating the development of the ICD-11 chapter on mental and behavioural disorders was assigned to the WHO Department of Mental Health and Substance Abuse. That department appointed an International Advisory Group in 2007 to provide advice and consultation throughout the process.

The public health focus of the WHO Department of Mental Health and Substance Abuse substantially influenced the priorities and methods for developing diagnostic guidelines for ICD-11. Mental and substance use disorders account for a greater proportion of global disease burden than any other category of non-communicable diseases and are the leading cause of disability worldwide [30]. Yet, they are dramatically undertreated, with up to half of individuals with severe mental disorders in HICs and more than three-quarters in LMICs receiving no treatment at all [31]. Moreover, people with serious mental disorders experience a much higher prevalence of other health conditions, such as cardiovascular, metabolic, and respiratory diseases [32, 33], and disproportionately higher rates of mortality, resulting in a substantial reduction in life expectancy [34].

The WHO therefore saw the development of the ICD-11 as an opportunity to provide WHO member states with a better tool to help them reduce the disease burden of mental, behavioural, and neurodevelopmental disorders and to provide health professionals at various levels of care with better tools for identifying people in need of mental health services and which treatments are most likely to be effective. With very limited exceptions, substantial gains in clinical, neuroscience, and genetic research has not produced validity information on which to base major changes in diagnostic classification [35, 36]. However, current knowledge is amply sufficient to provide vastly more effective and more accessible mental health services than are currently provided at a global level, and the WHO provided a set of specific strategies for doing so in its Comprehensive Mental Health Action Plan 2013–2020 [37]. These considerations have led the WHO to focus particularly on improving the classification's clinical utility and global applicability in developing diagnostic guidelines for ICD-11 mental, behavioural, and neurodevelopmental disorders [38].

The International Advisory Group and all Working Groups for ICD-11 Mental, Behavioural, and Neurodevelopmental disorders included representation from all WHO global regions. Professional surveys [39, 40] and formative studies [41, 42] intended to inform early decisions about the structure of the classification were conducted in multiple languages and with international groups of participants. Diagnostic guidelines for the ICD-11 CDDG include a specific section on cultural issues related to the clinical presentation and diagnosis of each condition.

Clinical utility and global applicability are critical, in part, because the ICD-11 CDDG and primary care versions are intended to function as important interfaces between health encounters and health information [41]. A classification that does not provide clinically and locally useful information to health professionals has little hope of being implemented consistently at the encounter level. In that case, diagnostic data that are aggregated from health encounters at the facility, system, national, and global levels will be unable to provide an optimal basis for global health data or for decision-making such as resource allocation.

To achieve its goal for ICD-11, the WHO took a highly systematic approach to the development of ICD-11 diagnostic guidelines by multi-disciplinary and broadly international expert Working Groups, particularly including substantial representation of experts from LMICs where 80% of the world's population lives. Substantial

improvements, as compared to ICD-10, included the adoption of a lifespan approach and the incorporation of dimensional approaches, particularly for personality disorders and primary psychotic disorders, that are more consistent with current evidence, more compatible with recovery-based approaches, eliminate artificial comorbidity, and more effectively capture changes over time. New categories were added, including bipolar type II disorder, complex post-traumatic stress disorder, prolonged grief disorder, body dysmorphic disorder, olfactory reference disorder, hoarding disorder, binge eating disorder, and compulsive sexual behaviour disorder [43]. In addition, the WHO implemented a systematic global programme of field studies using innovative methodologies specifically intended to examine the clinical utility and global applicability of the ICD-11 diagnostic guidelines [44].

In June 2018 the WHO released a pre-final version of the ICD-11 for mortality and morbidity statistics to its 194 member states, for review and preparation for implementation, including considering how the ICD-11 will be incorporated in policies, laws, health systems, translations, and training of health professionals. The World Health Assembly, comprising the ministers of health of all member states, formally approved the ICD-11 in May 2019. Member states are now beginning a process of transition from the ICD-10 to the ICD-11, with reporting of health statistics to the WHO using the ICD-11 to begin on 1 January 2022. The WHO Department of Mental Health and Substance Abuse will publish Clinical Descriptions and Diagnostic Guidelines (CDDG) and separate guidance for the identification of mental health conditions in primary care settings.

Structure of ICD-11 mental and behavioural disorders and compatibility with DSM-5

The ICD-11 was also developed in the context of full knowledge of DSM-5, both in its formative stages and in its 2013 published version. Working Groups were specifically instructed to consider DSM-5 formulations and their suitability for global application but were not prohibited from departing from them when indicated. Therefore, differences between ICD-11 and DSM-5 are intentional.

The proposed groupings for the ICD-11 chapter on mental and behavioural disorders are listed in [Table 7.1](#), which also includes a comparison with the structure of DSM-5. Generally, the comparability of the structure of the two classifications can be counted as a success of harmonization efforts between the WHO and the APA. Some structural differences reflect ICD-wide conventions related to residual categories and mental disorders associated with other underlying disease. Others are the result of deliberations involving the WHO, the Advisory Group, and the various Working Groups, such as in the diagnostic treatment of chronic irritability and anger in children [45] and somatoform disorders [46]. Another difference is related to the integration of the classifications of 'organic' and 'non-organic' aspects of sleep–wake disorders and conditions related to sexual health and gender identity [47] in new ICD-11 chapters in ways that are more consistent with current evidence and clinical practice.

Structure and content of ICD-11 clinical descriptions and diagnostic guidelines

The structure and information contained for each category of the ICD-11 CDDG are expected to enhance the clinical utility of the manual by providing clearly organized, consistent information across disorders that is flexible enough to allow for cultural variation and the exercise

of clinical judgement. The categories of information to be provided for each category in the CDDG are: Category Name, Brief Description (100–125 words), Essential (Required) Features, Boundary with Normality (Threshold), Boundary with Other Disorders (Differential Diagnosis), Coded Qualifiers/Subtypes, Course Features, Associated Clinical Presentations, Culture-Related Features, Developmental Presentations, and Gender-Related Features.

As noted previously, the utility and effectiveness of this format in producing more consistent clinical judgements in ICD-11, as compared to ICD-10, has been tested in a series of international field studies [48, 49].

ICD-11 mental disorders for primary care

The first version of the ICD classification of mental disorders specifically designed for use in primary care settings (ICD-10 PHC) [29] was produced by the WHO in 1996 and included 26 mental disorders that were either very common in these settings or quite important for primary care professionals to recognize. It had several features that distinguished it from the parent version of ICD-10—for each disorder, common presentations in primary care, distinguishing features, and relevant differential diagnoses were described. Also included was information for the patient and family, response to both psychological and pharmacological treatment, and indications for specialist referral [50].

The most compelling rationale for a version of the ICD designed for primary care is that the spectrum of psychological disorders seen in general medical settings is very different from that seen in specialist mental health settings. These patients in primary care settings commonly present with untidy combinations of somatic, anxious, and depressive symptoms, rather than the more elaborated diagnostic entities that are seen as more prototypic by clinicians working in specialist settings. Many of these patients do not see themselves as psychologically disordered, despite having all the symptoms required for various mental disorders—they are worried about their somatic symptoms and hope that the primary care clinician will exclude a physical cause for their symptoms and offer relief from the pain and distress associated with them.

In specialist mental health settings, the diagnostic task of the mental health professional can be characterized as asking systematically about the full range of known disorders. In contrast, the task of a clinician in primary care is to recognize a range of common mental disorders (CMDs), as well as some other severe mental disorders, and a range of problems associated with sleep, eating, alcohol, and drugs. The boundaries of the various overlapping syndromes of CMDs are of less importance than the existence of psychological distress accompanying any presenting physical disorder. The subtle distinctions between many of the individual disorders separately described by the main classifications are of limited value in primary care where clinicians work with the full range of general medical, behavioural, and social problems. A smaller set of disorders, broadly comparable to the main ICD, reflecting the most common conditions seen in this setting, is required for primary care.

Conceptual developments for the new version of the primary care version of ICD-11

Since ICD-10 PHC was released, there have been a number of developments in knowledge and conceptualizations regarding common psychological disorders occurring in primary care settings. These are

related to the relationship between anxious and depressive symptoms, the importance of recognizing depressive symptoms that commonly accompany chronic physical disorders, and the management of multiple somatic symptoms without any accompanying physical disease.

Both major international classifications recognize that depression and generalized anxiety disorder (GAD) commonly accompany each other, but the diagnostic requirements for depression include a duration of only 2 weeks, while the requirement for GAD is several months. Yet many patients develop anxious symptoms around the time they develop depressive symptoms, so that states of both anxiety and depressive symptoms are very much more common than ‘comorbidity’ between depression and GAD.

If the same duration of illness is used to define both depression and anxiety, those with both sets of symptoms have a much worse course, are more resistant to treatment, and are more likely to commit suicide [51]. The depressive symptoms in episodes of depression accompanied by significant anxiety are more severe than in depressive episodes not accompanied by anxiety [52, 53]. Individuals with episodes of such ‘anxious depression’ are more likely to have harm-avoidant symptoms and to also present with a wide range of family members with other anxiety disorders [54]. Focus groups of primary care physicians (PCPs) and nurses were held in eight countries in order to assess the views of PCPs towards the introduction of a category for anxious depression into ICD-11 PHC—they were uniformly enthusiastic [55].

It is true that both anxious and depressive symptoms can and do occur on their own, and therefore, they must both retain their different names, but anxious depression deserves recognition in its own right [56]. Finally, states of mixed anxiety and depressive symptoms that fall just short of the threshold requirements for either are very common in community settings and indeed account for more sickness absence in the UK than either depression or anxiety [57]. These mild disorders tend either to become formally diagnosable or to resolve within the next few months [58].

These various studies encouraged the Primary Care Consultation Group of the WHO to recommend that when the diagnostic requirements for both anxiety and depression are satisfied, although using a shorter duration requirement for anxiety that matches that of depression, patients are diagnosed as ‘anxious depression’, but when one is at ‘case’ level and the other well short of it, these conditions are diagnosed as ‘depression (non-anxious)’ or ‘current anxiety’. When symptoms of both are present, but both just fail to reach the required severity, the individual may be diagnosed with ‘subclinical anxious depression’.

The use of screening instruments for psychological problems

Even in HICs, primary care professionals have difficulty remembering and implementing the complex diagnostic algorithms used by mental health professionals [59], there is considerable pressure on time and resources, and options for specialist referral for CMDs may be limited. Available written screening questionnaires may be of limited usefulness for reasons of language or literacy, not only in low-resource settings, but also in primary care settings in HICs which serve increasingly diverse populations.

The ICD-11 Primary Care Consultation Group therefore evaluated two brief screening scales for anxiety and depression to assist PCPs in deciding whether a diagnosable psychological problem was likely to be present. These screening questions were derived from an earlier WHO international study, in which it had been possible to compute

sensitivity and specificity values for both sets of questions [60]. Given time and resource pressures and linguistic and literacy issues, these screening scales may be of considerable value, especially in LMICs, but also in HICs, and will be published along with the ICD-11 PHC.

International classification of functioning disability and health

Mental disorders and disability: assessment and classification

Mental disorders are strongly associated with disability—detriments in functioning of the brain, the body, and the person in general. People with mental disorders experience impairments in their body and brain functions, limitations in their personal daily activities, and restrictions in their social lives. These disabilities are part and parcel of the clinical picture of persons with mental disorders. The association between a mental disorder and disability may be causal, consequential, or difficult to disentangle. Disability is usually a key determinant for individuals seeking care and a significant factor for providers in making a clinical case formulation. Yet the form, frequency, and outcome of disabilities in mental disorders are not well defined or studied scientifically. Moreover, their use in formulating diagnoses of mental disorders has been unclear and inconsistent.

The WHO and the APA have used the construct of disability differently in their classification systems until recently. The WHO ICD definitions have, as far as possible, kept disability outside the diagnostic classification, as per the model articulated in the WHO's *International Classification of Functioning, Disability and Health* (ICF) [61]. DSM has kept disability as part of the functional impairment component of the clinical significance criteria. However, in the creation of DSM-5, the clinical significance criteria have been aligned to match the operational disability definition in the ICF. This has been an important step to scientifically disentangle disability from the disease process as much as possible in the formulation of mental disorder diagnoses in both ICD and DSM systems.

Ideally, the scientific definitions of a disease or disorder should be based on the aetiology and the pathological process that takes place in bodily systems. Such definitions do not require any sort of disability such as detriment in work capacity. While the consequences of disease are important clinical factors that trigger the recognition of a case by providers and often determine the types of health services and level of care required, they are not always a part of the diagnostic definition of the disease process itself. For example, people with different levels of general intellectual functioning and education may have similar levels of neuronal loss as a result of a brain injury but display different patterns of limitations in their activities. However, poor self-care and social performance are included as negative symptoms in schizophrenia diagnoses. Hence, although most mental disorders do not have known aetiology and specific pathophysiology, the potential benefits of more explicitly defining disability separately from the other signs and symptoms of mental disorders are similar to those of other diseases and disorders. A common disability metric for GBD estimates associated with all diseases and disorders will be helpful [30].

DSM-IV and DSM-5, contrary to the ICD system, make *clinical significance* an explicit part of the criteria for establishing a diagnosis.

The addition of this criterion to almost all disorders occurred after the National Institute of Mental Health Epidemiologic Catchment Area Program (ECA) study demonstrated that use of the DSM-III diagnostic criteria alone in community population studies led to relatively high prevalence rates of disorders—with some subjects having no evidence of distress or impairment [62]. Clinical significance has two main components: *distress* and *functional impairment*. Distress is expressed by the individual in the form of worry and concern about the condition. It has been operationally defined for epidemiological studies (for example, with the K-6 instrument) as including a combination of anxiety and depressive symptoms [63]. Sometimes it may not be expressed or may be explicitly denied. Functional impairment refers to limitations due to the illness, particularly in the social and occupational spheres of life, given that people with a disease or a disorder may not carry out certain functions in their daily lives. As part of the clinical significance criterion, distress and functional impairment help to establish the threshold for the diagnosis of a disorder. No guidance is given for determining the level of disability that would constitute the threshold for a diagnosis; this is left open to the clinical judgement of the clinician.

Operationally, functional impairment as used in the construct of clinical significance is roughly equivalent to the concept of 'disability' in WHO's ICF. The ICF does not use the term functional impairment. In the ICF, the term *functioning* is a neutral one, encompassing all body functions, activities, and involvement in life situations. The term *disability* means the decrements to these functions, which are known at the body level as impairments, at the person level as activity limitations, and at the societal level as participation restriction.

During the development of DSM-5, an attempt was made to align DSM's use of functional impairment more explicitly with ICF's concept of disability. The DSM's concept of social functioning would include the ICF's interpersonal interactions and relationships but might also include some of the items concerning participation in community, social, and civic life. The DSM's occupational functioning would include the activities listed under the ICF's categories of work and employment.

DSM-5 and ICD-11 now use ICF as an anchor to define and quantify disability. The WHO's Disability Assessment Schedule (WHO-DAS 2.0) has been officially recognized to assess the level of disability in DSM-5 Section 3. In this way, it will be easier to measure and identify levels of disability in terms of activity limitations and participation restrictions.

Disability and severity concepts in classifying mental disorders

Traditionally, both in DSM and ICD systems, the disability and functioning concepts have often been used to determine the level of severity of the diagnosed disorder. Three levels of severity are frequently specified (mild, moderate, and severe), which include either the number or the intensity of symptoms and impairments in social and occupational functioning. Determining the level of severity is a clinical judgement. For example, DSM-5's guidance for 'mild' and 'severe' includes either 'few' or 'many' symptoms over the required number and either 'minor' or 'marked' impairments in social or occupational functioning. 'Moderate' is in between.

The criteria for neurodevelopmental disorders such as ASD are somewhat more explicit. Anchors are provided in DSM-5 for mild, moderate, and severe impairment in specific symptomatic domains

for intellectual disability (disorders of intellectual development in ICD-11) and ASD. These domains include conceptual, social, and practical (occupational) areas of intellectual disability, and social communication and restricted, repetitive behaviours in ASD. In both of these disorders, the ability to engage in social activities and the need for supervision are assessed where the amount of supervision required provides an anchor for severity.

In ICD-11, *functioning properties* are being integrated into the information that is being developed to describe health conditions [64]. These are listings of specific functional domains that are specifically relevant to a given disease or disorder, including mental, behavioural, and neurodevelopmental disorders, and may be important foci of assessment. The explicit identification of functioning properties related to specific health conditions is intended to provide a broader and more meaningful picture of an individual's overall health in order to guide clinical decision-making.

Domains of functioning and disability in ICF and WHODAS 2.0 include the following: (1) understanding and communicating with the world (cognition); (2) moving and getting around (mobility); (3) self-care; (4) getting along with people (interpersonal relationships); (5) domestic life, occupation, school, and leisure; and (6) participation in society [65]. The more explicit descriptions of these six domains are intended to facilitate a clinical focus on reducing specific limitations separately, but in conjunction with reducing the symptoms of mental disorders.

Future of mental disorder classification

At the beginning of the DSM-5 and ICD-11 developmental process, there was a nicely articulated summary of the challenges and obstacles to developing a fully explicated aetiological and pathophysiologically based classification system for mental disorders [66]. An overreliance on DSM-IV and ICD-10 symptom clusters as phenotypes for genetic markers and targets for medication development was noted. Findings such as common genetic markers for multiple disorders and pharmacological and psychosocial treatment effectiveness that did not correspond with DSM or ICD diagnostic boundaries called for new research strategies. Out of this background, the NIMH launched the RDoC strategy to facilitate greater attention to the relationships among multiple biological and phenomenological domains—including negative valence systems, positive valence systems, cognitive systems, systems for social processes, and arousal/modulatory systems—as a basis for future breakthroughs in understanding and treating mental disorders [67]. Although it was fully understood in the field that it would be years, if not decades, before such a fully articulated system could be completed, there was an unfortunate initial juxtaposition of the DSM-5 and RDoC systems as competitive, rather than collaborative, efforts to advance our understanding of these disorders. It is now clear that when genes, molecules, cells, circuits, and physiology emerge that correlate with behavioural and symptomatic syndromes and can be assessed in routine clinical settings, they can be incorporated into future versions of clinical classification systems [68, 69]. Such biological measures must be able to demonstrate the level of sensitivity and specificity needed for clinical decision-making.

From a clinical practice perspective, the increasing concern about the quality of care will require more 'measurement-based outcome' approaches for clinicians, as well as for reassuring health care

administrators of the value received for their organizations and funding. The increasing standardization of medical terminology and the use of dimensional measures of symptomatic and disability domains will be fully operational only in the context of electronic health records. By providing more detailed information about clinical status, these measures will have a major impact on risk adjustment for severely ill patients and on outcome assessment for value-based reimbursement to clinicians. In primary care and low-resource settings, use of simple screening methods to identify mental disorders and to monitor treatment response will be important next steps. With the current DSM-5 and ICD-11 classification structures in place, it is expected that more iterative revisions that can be integrated more seamlessly into health statistics and clinical practice will emerge over the next few decades, rather than large-scale, more disruptive edition changes.

The National Institute of Mental Health Research Domain Criteria

An alternative framework to guide psychopathology research

Charles A. Sanislow, Sarah E. Morris, Jennifer Pacheco, and Bruce N. Cuthbert

Introduction

The National Institute of Mental Health (NIMH) launched the Research Domain Criteria (RDoC) in 2009, in response to the 2008 NIMH Strategic Plan, call for new ways of classifying mental illnesses that are based on dimensions of observable behavioural and neurobiological measures. The RDoC initiative was motivated by the need to address the scientific concern that the field had equated psychiatric illness with syndromes based on clinically observed diagnostic criteria, which were not well connected with neural and psychological mechanisms. The RDoC was also motivated because progress in treatment development had been slowed by a disproportionately narrow focus on disorders as defined by mainstream diagnostic criteria. Specifically, psychiatric research strategies have been limited by explanations of disorders that have been organized around clinical presentation.

At the outset, we wish to be clear that DSM-5 and ICD-11 (and their predecessors) have been vital for informing the treatment of human distress and dysfunction, and continue to serve an important clinical role. Despite limitations (detailed in the forthcoming), these diagnostic manuals have been critical for the development of innovative theories of mental disorders (for example, anxiety, depression, bipolar disorder, schizophrenia), which, in turn, have facilitated empirical advances to develop a number of effective treatments. That said, a counterpoint consensus that progress could be accelerated has existed for some time, such that gains in understanding and treating mental illness are modest, relative to the more recent advances in integrative neuroscience. This view holds that research aimed at clarifying mechanisms of psychiatric illness (for example, disrupted neural circuits and mental processes) of clinically described syndromes has reached the asymptote of progress. As a result, research into new and potentially more effective treatments has waned. We argue that a change in the conceptualizations of mental

disorders is needed to improve diagnostic validity, to open new avenues of research, and to expedite progress in the development of new and more effective treatments.

Background and rationale for the RDoC

How did psychiatry research reach the paradoxical state of being constrained by a diagnostic system of its own creation? The answer is a story about reliability and validity. In the late 1960s and early 1970s, Washington University became the centre of psychiatric research in the United States, so much so that influential academic leaders of the time became known in some circles as ‘The St Louis Group’. For that era, this was a radical collection of psychiatrists. Researchers leading this charge eschewed aetiological theories (mainly psychoanalytic) on the promissory note (mistaken, as it turns out) that if reliable diagnoses were developed, then laboratory studies to elucidate the biological and genetic underpinnings would follow. The motivation was to bring respect to the field by establishing psychiatry as science, in part because one consequence of the psychoanalytic zeitgeist that had prevailed up until that time was that clinicians frequently disagreed about a patient’s diagnosis (that is, reliability was poor). Some psychiatrists were concerned that physicians in other specialties espoused the view that psychiatry was not ‘real medicine’. The St Louis Group wanted to change this impression and led the charge for psychiatry researchers to focus squarely on improving reliability, with the expectation that the discovery of biological substrates would eventually follow.

Drawing from the heritage of Emil Kraepelin’s work (as well as incorporating efforts by Kurt Schneider), clinically observable diagnostic criteria for psychiatric research were developed—earning the researchers the label ‘neo-Kraepelinians’ [1]. The new diagnostic criteria were first colloquially referred to as the ‘Feighner Criteria’ [2],

and later became the Research Diagnostic Criteria, or 'RDC' (not to be confused with RDoC). This was a major advance for psychiatry. The new criteria were largely descriptive, freeing researchers from the constraint of psychoanalytic theory. Importantly, psychiatric researchers could now be confident that they were studying the same symptom sets in patients. Working from these clinical syndromes, it was assumed that valid diagnoses could be established. In this vein, Robins and Guze (1970) [3] proclaimed five criteria for the validity of psychiatric diagnoses: (1) clinical description; (2) laboratory tests; (3) delimitation from other disorders; (4) follow-up studies and course; and (5) family studies. These criteria became the bedrock principles guiding the development of psychiatric nosology for the next five decades [4].

The field was at a crossroads on the clinical side too. The development of a radically changed DSM was on the horizon, and the psychiatrist Robert Spitzer was appointed to revise the manual. Among clinicians, there was resistance for overly rapid change, but the RDC were ready-made to be transposed to clinical diagnoses for the 'new' DSM diagnostic manual. As the research criteria were translated to the clinical realm, much of the resulting formulations were based on 'expert consensus', and this led to some notable changes. In the process, however, some duration criteria were relaxed for clinical translation in ways that, while stringent for research purposes, would be less inclusive for clinical purposes; for instance, in the case of major depressive disorder, depressed mood was tightened from 1 month to 2 weeks [5].

DSM-III [6] was both embraced and disparaged by the field. Clinicians could finally agree on a diagnosis with confidence. This was an improvement for developing coherent treatment plans. When used in research, the uniformity of patient groups was all but guaranteed. However, it gave false assurance that psychiatrists were treating 'real' diseases, giving the impression that these new diagnoses were 'natural kinds', and this led to a problem of reification and overconfidence that corresponding mental and neural mechanisms could be unearthed for each disorder [7]. It also unleashed political fury, consequent to the incorporation of symptom criteria that were criticized for being chosen on the arbitrary basis of clinical consensus and for being value-laden with stereotypical cultural beliefs.

Just over a decade after DSM-III was introduced, Jerome Wakefield (1992) [8] addressed these issues by articulating a definition of mental disorder that he termed 'harmful dysfunction'. His definition held two central tenets for a mental illness—firstly, that an 'internal mechanism' was not functioning, and secondly, that the dysfunction caused harm either to the individual, in the form of subjective distress, or to society by the inability for the afflicted person to fulfil his or her roles according to accepted cultural expectations. In psychology, Wakefield's model became the textbook definition of mental disorder; in psychiatry, the influence of the 'harmful' part of his definition was embraced and its influence persists throughout DSM-5, which relies, in many instances, on functional deficits to determine the clinical threshold. It is the second component of Wakefield's definition—the dysfunction of an 'internal mechanism'—that has yet to be elaborated for DSM-based diagnoses (post-1980 through the present), and it is now widely acknowledged that DSM sacrificed validity for reliability.

Manifest problems of the descriptive approach

The standardized criteria provided by the prevailing DSM diagnostic systems (DSM-III [6] going forward through the current fifth

edition) and the more recent iterations of the WHO's ICD (through the current eleventh version) have made possible the reliable diagnosis of patients for both clinical and research purposes. This has been essential to an important developmental phase of psychiatric science. The diagnostic manuals also improved the conception of mental disorders, as aspects of many disorders were refined, mainly on the basis of Robins and Guze (1970) [3] criteria of course and outcome, and some by delineation from other disorders. However, validation has come up short, particularly for biologically related systems. Moreover, with accumulated knowledge emerging from research using the tools of modern behavioural neuroscience, it became increasingly clear that the nature of psychopathology mechanisms did not align with the descriptively derived categorical diagnoses [9].

The problems evident from poor validity include polythetic criteria sets, high rates of diagnostic co-occurrence ('comorbidity'), heterogeneity within diagnoses, overspecification, arbitrary or subjective cut points, and a binary classification that excludes a dimensional gradience of symptoms. Phenotypes codified in DSM-III (and subsequently aligned in the ICDs) have yet to be validated with laboratory studies. Mental disorder syndromes based on descriptive diagnosis, it seems, have been lost in translational research. The early commentaries that the fundamental tenets of clinical syndromes for DSM-III, carried forward through DSM-5, were flawed for research purposes had been realized (for example, [10]).

By definition, DSM symptoms are imperfect indicators of the diagnosis to which they refer. No single symptom is required for a diagnosis; rather, collectively, a subgroup of symptoms represents the essence of a construct. This is termed 'polythetic' and means there are sundry ways to 'get' a DSM diagnosis. For instance, there are 256 combinations of symptoms for borderline personality disorder (BPD) [11]; two people can meet criteria for major depressive disorder (MDD) and not share a single symptom in common (if weight loss and weight gain are considered as separate symptoms) (APA, DSM-5). DSM also implies that many symptoms are equally important when actually they may be differentially related to functioning and the threshold number of symptoms required for a diagnosis is not empirically determined [12]. At the same time, clinicians demonstrate a proclivity to overweigh certain symptoms that steer them to a diagnosis, for instance, self-harm behaviour for BPD [13, 14, 15].

The exclusion of 'comorbid' diagnoses can artificially restrict the range of pathological mechanisms in psychiatric research [16]. Moreover, it has been argued that the term 'co-occurrence' is preferred over 'comorbidity' by many, precisely because associated neural and mental mechanisms have not been elaborated and it is unclear if two 'comorbid' psychiatric diagnoses have interrelated psychopathology or are merely different sets of descriptors for the same psychopathological processes (see [17]). Individuals who are diagnosed with more than one disorder are often excluded from research, so that confounding by co-occurring disorders is avoided. This approach may increase the specificity of claims resulting from significant between-groups differences, but the result is a predominant focus on reified patient groups and 'super-normal' comparison groups, neither of which are representative of the general patient and non-patient populations.

Another problem with research focusing on clinically described syndromes is the imposition of categories. By focusing research

efforts primarily on comparing individuals who meet diagnostic criteria with those who do not experience psychiatric symptoms, potentially meaningful variance in symptoms and neurobehavioural processes may be excluded. Arguments in favour of diagnostic categories include the idea that these extended phenotypes do not reflect a true continuum in symptoms due to varying degrees of disruption of a common symptom-related mechanism, but rather may be the result of distinct processes that distinguish latent clusters of individuals and result in variable symptom presentations which may relate to the likelihood that an individual will seek treatment [18, 19]. However, dimensionality in neurobehavioural processes is consistent with other disease-relevant biological processes. More generally, in internal medicine, hypertension provides an example. Blood pressure levels fall along a gradient, but a threshold—informed by research and subject to change in response to new information—defines the presence of disease and dictates the type of treatment.

With the DSM approach, many individuals experience psychiatric symptoms such as anxiety, depression, or disruptions in thinking that are not sufficient in number, duration, or severity to meet diagnostic criteria. Some of these cases are handled with the ‘Unspecified’ (formerly ‘Not otherwise specified’) categories. When the DSM is used for research purposes, however, these incomplete diagnoses are typically excluded from study design, eliminating a potentially significant range of psychopathology. Epidemiological studies find that sub-syndromal psychiatric symptoms are not unusual in the general population. Thus, using the DSM for research potentially excludes a large segment of the population from a study. When DSM disorders are considered dimensionally, it has been shown for some disorders that those who are sub-diagnostic-threshold suffer similar degrees of functional impairment and distress as those who meet the full criteria for the disorder (for example, [20]). Indeed, there is a solid base of evidence and growing consensus for dimensional approaches to diagnosis [21]. When dimensional approaches are applied to DSM symptom sets, considerable improvement in reliability and validity has been demonstrated [22]. However, to connect clinical symptoms to neurobiological mechanisms, more than a simple dimensionalization DSM category is needed (for example, [23]; see also [24]).

A new approach

These problems illustrate how dividing the lines between psychological health and mental illness can be clinically subjective and suggest that there may be useful discontinuities or thresholds with implications for treatment decisions or the illness course. However, narrowing the definition of a positive diagnosis for clinical purposes can create problems when applied to research design by focusing only on the extremes of a hypothetical health–illness spectrum, excluding the full variation of symptom expression and associated mechanisms. The reasoning implicit in the current diagnostic frameworks is consistent with an infectious disease model in which an individual is either infected with the disease-causing agent or is not, prompting a dichotomous diagnostic decision for each disorder—are diagnostic criteria met or not? This approach provides an acceptably reliable method for sorting research participants into patient and non-patient groups for the purposes of looking for group differences but may have the unintended consequence

of distorting our understanding of the true nature of the landscape of mental disorders. In an ironic twist, other areas of medicine are confronting similar issues and trying to align their diagnostic systems with a new understanding of systems biology. For instance, the National Academies of Sciences issued in 2011 a call for all disease taxonomies to be revised to align more closely with the new understanding of molecular biological processes [25].

In sum, psychiatric diagnosis achieved good reliability, essential for clinical practice and research, but this came at the expense of validity. Definitions of disorders have evolved over centuries and rely heavily on patient self-report of internal experiences. The diagnoses identify common clinical presentations of syndromes, but the foundations for these frameworks precede modern behavioural neuroscience and do not incorporate an understanding of the ways in which the brain develops and functions. Although neuroscience has yielded important insights about mental disorders, these methods are failing to bring about the revolution in understanding and treatment that was anticipated when they were developed [26].

Finally, a persistent myth that has stymied novel solutions to these problems should not go unmentioned: Over the past several decades, the hope was held that mental disorders would be better understood once better tools were developed. That hope is gradually fading. The brain’s complexity is daunting, consisting of millions of neurons and other types of cells, with connections and patterns of activity continually changing according to developmental trajectories and in response to experiences and exposures. Technology for visualizing and quantifying the structure and function of the brain has yielded an ever expanding corpus of published studies, and the tools of genetics, molecular biology, and neuroimaging continue to improve; yet no method has emerged that has detected a specific neuropathological process that accounts for a psychiatric disorder and would determine the classification of individuals into diagnostic groups.

The futility of mapping syndromal phenotypes (that is, DSM-based diagnoses) onto dysfunctional internal mechanisms has also been recognized by those developing pharmaceutical agents [27]. Over the past decade, research driven by pharmaceutical companies waned, in large part due to problems that symptom-based phenotypes were not the right targets for drug development (see [28]). Thus, both scientific concerns about psychiatry’s approach to diagnosis, along with practical matters obviating treatment development, were motivations for the development of the RDoC. Indeed, others articulated this problem and argued for approaches that would embrace intermediate phenotypes [29, 30].

Despite widespread recognition of these problems, funding for the bulk of psychopathology research in the United States has curiously remained harnessed to the DSM categories. The DSM classifications had become the *de facto* standards for psychiatric research, such that the entire scientific cycle, from grant applications, review and funding decisions, to publication, was dominated by DSM-based disorders, and little space was left for psychopathology research conducted outside this framework. Some investigators have reported to their programme officers a reluctance to submit non-DSM-based research for funding applications because of concerns such research would not fare well in review for scientific merit, even for proposals in response to specific requests for funding. Other investigators have complained of arbitrary constraints for how to handle co-occurring diagnoses in the culture of grant review committees, as well as

favoritisms for certain DSM disorders [31]. The RDoC was introduced to provide an alternative path for researchers to study psychopathology mechanisms, in part so that these impositions could be circumvented.

Van Praag and colleagues (1990) [32] alerted the field to the risks of ‘nosological tunnel vision’, noting that ‘exclusive adherence to nosology has not served biological psychiatry well [but] has been a factor stunting its growth’ ([32], p. 507); a decade later, van Praag diagnosed psychiatry with ‘nosologomania’ [33]. Psychiatry departments have generally been organized according to DSM disorders, and this might also be seen as an impediment to progress, encouraging both research and training in ‘silos’ and cordoning off knowledge that ideally would be integrated. As recognition of these impediments has become clearer, the field is responding. The journal *Schizophrenia Bulletin* recently added the subtitle ‘*The Journal of Psychoses and Related Disorders*’ to reflect the changing nature of the field. The NIMH is presently addressing the inherent limitations of extramural research largely programmatically organized around disorders by encouraging a focus on trans-diagnostic diagnoses, cross-cutting features, and the RDoC.

Development of the RDoC framework

In March 2009, the then NIMH director Thomas Insel formed an Internal Working Group to address the 2008 NIMH Strategic Objective to develop new ways to classify mental illnesses based on dimensions of observable behavioural and neurobiological measures (see [34] for a brief summary of the process, including the original working group members). The initial development of the RDoC was influenced by non-DSM-based models of psychopathology research, including the earlier mentioned intermediate phenotype approach [29, 30], as well as pre-DSM-III [6] experimental psychopathology approaches, including work from experimental psychopathology (for example, [35, 36]) and research in developmental psychology (for example, [37]). Facing a *tabula rasa*, and drawing from these approaches, five domains were initially proposed as a starting point: ‘Negative valence systems’, ‘Positive valence systems’, ‘Cognitive systems’, ‘Social processes’, and ‘Regulatory and arousal systems’. Within each of these five domains were grouped a number of potential constructs (and subconstructs), each with evidence for a valid psychological construct, including evidence for a neural circuit associated with a psychological function relevant to psychopathology.

To integrate basic neural and psychological mechanisms with observable behaviour relevant to palpable psychopathology, the Internal Working Group proposed ‘units of analyses’. These included *genes, molecules, neural circuits, physiology, behaviour, and self-report* (the latter including patient verbal reports). The framework took shape as a matrix, with the original five domains grouping relevant constructs in the rows of the matrix, and ‘units of analysis’ forming the columns. An additional column—*paradigms*—was added to the matrix to include tasks and assessments to measure the constructs.

The next step in the development of the RDoC matrix was the collaborative effort of leading scientists across multiple workshops to review the evidence and articulate and define each of the domains. Each of the workshops was focused on evaluating evidence for potential constructs and elaborating specific definitions for each

construct, including differentiating them from related constructs. One workshop was convened for each domain, except for cognitive systems, for which there were two because the first RDoC workshop piloted the Cognitive Construct ‘Working Memory’. Proceedings from the workshops can be found on the RDoC website (<https://www.nimh.nih.gov/research-priorities/rdoc/development-of-the-rdoc-framework.shtml>). Prior to each workshop, surveys were sent to NIMH awardees and psychiatry and psychology department chairs across the United States. Survey feedback was presented at the start of each workshop. Workshop participants (invited by the NIMH, based on expertise in the relevant research domain, as evidenced by published work and funding history) were organized into breakout groups to consider and refine the constructs or to discard them and propose new constructs. The groups examined what was known about the units of analysis for each construct and considered what questions remained unanswered, as well as potential avenues of research that might answer these questions. These considerations were then reported out to each full domain group where construct definitions were minted. The end result included an annotated listing of the elements that would populate the RDoC matrix with respect to the genes, molecules, cells, circuits, physiology, and self-reports comprising each defined construct, as well as the nomination of promising and reliable behavioural tasks (paradigms) that could be used to assess function within a construct. The listings from all six independent meetings, when combined, comprised the first version of the RDoC matrix (see <https://www.nimh.nih.gov/research-priorities/rdoc/rdoc-snapshot-version-1-saved-3-7-2016.shtml>).

Structure of the RDoC matrix

The RDoC matrix provides a research framework to specify fundamental processes of mental illness in biological and behavioural units of analyses. The rows of the matrix represent specific dimensions of function (domains and constructs), and columns represent different kinds of observations for study (units of analysis). The constructs embody specified functional dimensions of behaviour and are characterized in the aggregate by the genes, molecules, circuits, etc. that correspond to certain behaviours. Constructs are, in turn, grouped into higher-level domains of functioning, reflecting contemporary knowledge about major systems of cognition, motivation, and social behaviour. In its present form, there are six domains in the RDoC matrix: ‘Negative valence systems’, ‘Positive valence systems’, ‘Cognitive systems’, ‘Systems for social processes’, and ‘Arousal/regulatory systems’, and ‘Sensorimotor systems’, the latter domain incorporated in 2018 (Table 8.1). The matrix columns specify units of analysis used to study the constructs and include genes, molecules, cells, circuits, physiology (for example, heart rate or event-related potentials), behaviour, and self-reports. In the cells of the matrix are specific elements that serve as exemplars which are empirically associated with the construct and the corresponding unit of analysis.

The RDoC domains were selected to be purposefully broad, to link directly to psychopathological mechanisms, and for their potential for theoretical integration. The framework is directed towards constructs most relevant to mental disorders and is not intended to span the entire scope of functional behaviour [38–41]. The domains are ‘superordinate’, and each one includes

Table 8.1 RDoC domains, domain definitions, and corresponding constructs and subconstructs

Domains	Definition	Constructs and subconstructs
Negative valence systems	Activation of the brain's defensive motivational system to promote behaviours that protect the organism from perceived danger. Normal fear involves a pattern of adaptive responses to conditioned or unconditioned threat stimuli (exteroceptive or interoceptive). Fear can involve internal representations and cognitive processing and can be modulated by a variety of factors	Acute threat ('fear') Potential threat ('anxiety') Sustained threat Loss Frustrative non-reward
Positive valence systems	Systems primarily responsible for responses to positive motivational situations or contexts such as reward seeking, consummatory behaviour, and reward/habit learning	Reward responsiveness Reward anticipation; Initial response to reward; Reward satiation Reward learning Probabilistic and reinforcement learning; Reward prediction error; Habit – PVS Reward valuation Reward (probability); Delay; Effort
Cognitive systems	Systems are responsible for various cognitive processes	Attention Perception Visual perception; Auditory perception; Olfactory/somatosensory/multimodal perception Declarative memory Language Cognitive control Goal selection; updating, representation, maintenance Response selection; inhibition/suppression Performance monitoring
Social processes	Systems that mediate responses to interpersonal settings of various types, including perception and interpretation of others' actions	Affiliation and attachment Social communication Reception of facial communication; Production of facial communication; Reception of non-facial communication; Production of non-facial communication Working memory Active maintenance; Flexible updating; Limited capacity; Interference control
Arousal and regulatory systems	Systems responsible for generating activation of neural systems as appropriate for various contexts, and providing appropriate homeostatic regulation of such systems as energy balance and sleep	Arousal Circadian rhythms Sleep–wakefulness
Sensorimotor systems	Sensorimotor systems are primarily responsible for the control and execution of motor behaviours and their refinement during learning and development	Motor actions Action, planning and selection; Sensorimotor dynamics; Initiation; Execution; Inhibition and termination Agency and ownership Habit – sensorimotor Innate motor patterns

multiple, more specific constructs and subconstructs (indented in the third column of Table 8.1). In devising and defining the constructs that would comprise each domain, workshop members were asked to consider three criteria when evaluating the merits of a construct: (1) sufficient evidence for the validity of the construct as a functional unit of behaviour or cognitive process; (2) sufficient evidence for a neural circuit or system that

played a primary role in implementing the construct's function; and (3) sufficient relevance for understanding some aspects of psychopathology [38].

The current set of constructs is focused on, and constrained by, circuit definitions to avoid overspecification and proliferation of constructs. The intent is not to arbitrarily exclude constructs, but rather to foster thinking about how constructs are related

across observations of different systems (that is, units of analysis). Acknowledged are the complexities of the brain and behaviour, such that circuits and constructs will necessarily overlap and interrelate, such that, to some degree, arbitrary separations are unavoidable. The spelling out of interrelations among constructs and across units of analysis will help to refine or otherwise clarify the constructs in a bootstrapping fashion. In fact, the framework is meant to foster, not discourage, research that explicates mechanisms within and across the constructs as listed. As such, RDoC research design is likely to foster interdisciplinary research collaborations.

The RDoC matrix is best viewed as a work in progress, and not as *fait accompli*. The matrix is not a finite determination of the field of psychopathology, and by no means is—or was it ever—meant to be a comprehensive framework of psychopathology to be cast in stone. In other words, constructs (and subconstructs), as well as the tasks that are listed in the matrix, are best viewed as exemplars. From its inception, we have indicated that the matrix is expected to undergo revision and updates with accumulating data, and the understanding of psychopathological systems and symptoms is recognized. Because the RDoC was initiated by the NIMH, the National Advisory Mental Health Council (NAMHC) oversees revisions. The NAMHC has convened a committee—the ‘Changes to the Matrix Council’ (CMAT) Workgroup—to evaluate alterations, updates, and additions to the matrix. Recent revisions include the addition of the earlier mentioned ‘Sensorimotor systems’ domain. There have also been revisions motivated by the accumulation of new scientific evidence, as well as for purposes of clarity, for instance an update to the ‘Positive valence systems’ domain. The CMAT Workgroup is provided with resources to consult with experts in the field and to convene meetings as appropriate. All revisions are detailed and available on the RDoC website (see <https://www.nimh.nih.gov/about/advisory-boards-and-groups/namhc/reports/rdoc-changes-to-the-matrix-cmat-workgroup-update-addition-of-the-sensorimotor-domain.shtml> and https://www.nimh.nih.gov/about/advisory-boards-and-groups/namhc/reports/cmat-pvs-report-508_157003.pdf, respectively, for these changes).

Some have questioned whether the number of constructs is too sparse. In framing the RDoC, the goal was to include relatively high-level constructs to avoid overspecification of functions that could become unwieldy and thereby necessitate unnecessarily frequent revisions to the list or otherwise constrain investigators as research progresses. As one obvious example, a single ‘Perception’ construct is listed that includes visual, auditory, and other sensory modalities. Defined in this way, the constructs are more easily subject to refinement as new research emerges. Potential constructs not specified in the matrix can be studied with the RDoC framework. As new constructs are considered, the three criteria outlined should be used to evaluate their merits in order to achieve the goals of the RDoC initiative [38].

Units of analysis

The columns of the matrix represent the units of analysis typically employed in psychopathology research. The term ‘units’ was deliberately chosen over the term ‘levels’ of analyses, so as not to privilege any one type of observation or to imply a reductionist ideology (see [42] for a detailed discussion of these issues). As the RDoC

intends to promote integration of knowledge across multiple disciplines, the framework emphasizes the integration of knowledge about genes, cells, and circuits, with knowledge about cognition, emotion, and behaviour. The ‘Circuit’ unit of analysis refers to measurements of particular neural circuits, as studied by neuroimaging techniques or other measures, such as event-related potentials with established source localization, that have been validated by animal models or functional neuroimaging. The ‘Physiology’ unit of analysis refers to measures, such as heart rate and cortisol levels, that are well-established indices of certain constructs but that are not direct measures of neural circuits. The ‘Behaviour’ unit of analysis can refer variously to behavioural tasks (for example, a working memory task) or to systematic behavioural observations (for example, a toddler behavioural assessment). The ‘Self-report’ unit of analysis refers to interview-based scales, self-report questionnaires, or other instruments that may encompass normal-range and/or abnormal aspects of the dimension of interest.

When initially constructed, the units of analyses for the ‘genes’ column included candidate genes relevant to psychopathology. The idea was that connecting certain gene products to physiology would help to clarify specific aberrations in psychopathology. However, some researchers have raised questions about statistical power issues and the replicability of candidate gene studies (see [43]; see also [44]), and ‘... the current state of the field emphasizes the need for robust evidence of association, generally resulting from adequately powered genome wide association studies, as opposed to candidate gene approaches’ [45]. Interestingly, during the original RDoC workshops, questions about how to distinguish genes from molecules (that is, gene products) were raised on multiple occasions. As evidence and various approaches to genetic studies are further evaluated, this column of the matrix will be updated accordingly.

Paradigms (tasks)

The matrix includes a separate column to specify well-validated, reliable tasks and measures, or ‘paradigms’, used in studying each construct. These paradigms may be relevant for more than one unit of analysis, and rather than list them in separate columns, they are included under the ‘Paradigms’ heading. A National Advisory Mental Health Council (NAMHC) workgroup was assembled and charged with developing recommendations for paradigms for each construct, according to several critical considerations. Their work considered the development of exemplar tasks and led to revisions in the matrix (the full report can be found at: https://www.nimh.nih.gov/about/advisory-boards-and-groups/namhc/reports/rdoc_council_workgroup_report_153440.pdf).

Development and environment

Since its inception, the RDoC has held that developmental processes and environmental influences are inseparable from the consideration of psychopathology [46]. However, a logistical problem is created if one assumes the two-dimensional RDoC matrix to be a complete model, rather than an organizational framework, in which case the absence of explicitly representing development and environment in the matrix would indeed be problematic. For research

purposes, empirical aspects of the matrix may be incorporated into the developmental theory. In this way, the RDoC additionally provides a platform to organize the connections of research findings, or the development of a nomological network, conducted from various theoretical paradigms. Investigators are demonstrating the utility of the RDoC for developmental psychopathology research, as evidenced by the substantial proportion (approximately half, to date) of NIMH-funded RDoC grants that focus on the role of developmental processes and/or environmental factors in psychopathology.

Understanding developmental trajectories across various phases of the lifespan represents a critical consideration that is implicit for the RDoC and might be thought of as a third dimension in the overall framework. To fully explore the contributions of development to RDoC constructs, investigators must bear in mind the complexities of development. Not all capacities develop in a linear manner, and understanding the interaction between constructs as they appear, mature, and differentiate is important. Characterizing these developmental trajectories will help inform how development occurs, which systems come online before or after others, and how they interact differentially across development. It will likewise be important for investigators to explore the continuities (and discontinuities) that exist across development itself, with some behaviours being normal at certain developmental stages, but a sign of mental illness at others. Relatedly, the concept of sensitive periods, when the effects of particular experiences have a strong influence on brain and behaviour, is key to understanding how the timing of events can impact the risk for atypical development [46, 47].

The types of constructs typically found in the literature on human neurodevelopment are similar to several RDoC domains, and many areas of the child psychopathology literature (for example, reward sensitivity, cognitive and emotional dysregulation, behavioural inhibition) serve as a more compatible model for a dimensionally based approach, compared to the highly specified categories of adult psychopathology. The goal is to place these constructs in the context of theories of development (for example, [48]). A more comprehensive understanding of the trajectories that lead to disorders, particularly in the context of quantified measures that can validly identify pre-symptomatic dysfunction, will aid early prevention efforts. In addition, the RDoC's focus on integrative methodologies may lead to earlier detection of psychopathology. By not relying on self-report as the 'gold standard', deviations in developmental processes may be detectable before they are observable as overt clinical symptoms.

The importance of environmental influences on psychiatric illnesses is incontrovertible, and RDoC-based research promotes a systematic focus on development and the environment—as well as with their mutual interactions—and their individual and interacting relationships to specific circuits and functions [38]. One way to approach the environment is to equate it with the variable of time, typically represented in science as 'the fourth dimension'. Just as empirical and theoretical interrelations are expected to be specified across units of analyses and constructs, environmental factors, including those reciprocating with developmental changes, can be theoretically spelt out—and empirically tested—with changes in the elements across time.

Older ideas about environmental influences have given way to advances in neuroscience that articulate how stress and deprivation can have a negative impact, including epigenetic factors. Abnormalities in stress responses can result from maladaptive maturation of the

nervous system, including its interaction with the wide variety of external influences beginning at conception. The social and physical environment comprises sources of both risk and protection for many different disorders occurring at all points along the lifespan, and methods for studying phenomena such as gene expression, neural plasticity, and various types of learning are rapidly advancing. As with developmental aspects, environmental influences may thus be considered as another critical element of the RDoC matrix. Particular environmental stressors, such as early child abuse, may increase risk for a wide variety of disorders. Environmental effects are most ideally studied bidirectionally; for example, an individual's behaviour affects his/her social environment (for example, family or friends), which, in turn, affects the nature of others' behaviour towards the individual. Research organized around the relevant circuit-based dimensions that are affected, independent of a particular disorder, may thereby accelerate knowledge regarding environmental influences across multiple units of analysis.

RDoC research design

What does RDoC research look like? Early in our formulations of how one might conduct RDoC research, we emphasized the idea of choosing a 'sampling frame' or a study group of participants that varied widely enough across a spectrum of symptoms or clinical problems that no relevant mechanisms would be excluded. For instance, a researcher interested in studying fear mechanisms might take 'all comers' at an anxiety disorders treatment clinic (regardless of DSM-5 diagnosis) and then use results from a task or paradigm to determine different study groups or dimensions, for instance, the degree to which a fear response could be extinguished through an extinction paradigm. Even though the dimensions being studied would not involve DSM-5 diagnoses per se, those diagnoses could be adjunctively tracked and used to draw trans-diagnostic connections. The latter would assist in future versions of clinical diagnostic manuals.

A sometimes mistaken notion drawn by investigators is that the RDoC necessitates the complete exclusion of DSM diagnoses. This is not the case. For example, investigators might select participants on the basis of a single DSM diagnosis to clarify component dimensions of that diagnosis, for instance, affective dysregulation among patients diagnosed with BPD. For the RDoC, the caveats of this approach would be that inclusion criteria should not be overly restrictive. For example, in this case, high rates of diagnostic co-occurrence would be expected and co-occurring diagnoses should not be used as a basis of exclusion, lest important variation in systems relevant to the regulation of affect be eliminated. Also, understanding of affective dysregulation would be expected to generalize—and might be studied in follow-up—to those suffering similar problems, but not necessarily diagnosable with BPD.

Research that examines features that cross-cut traditional diagnostic categories or trans-diagnostic research are consistent with the RDoC approach. Several groups of researchers have reported findings using trans-diagnostic approaches that have identified trans-diagnostic features for psychotic disorders (for example, Sabharwal *et al.*, 2017 [49]), obsessive-compulsive disorders (for example, [50]), and attention-deficit/hyperactivity disorder (for example, [52]), and depression (for example, [52]). Similarly, for depression, Liston and

colleagues have identified four biotypes of depression using computational approaches [53]. Researchers have been making advances in precision medicine by clarifying such cross-cutting dimensions to serve as treatment targets (for example, [54]). With an RDoC approach, these dimensions provide a new beginning and can serve as a starting point for defining participant groups or dimensions to serve as independent variables for study, in lieu of traditional diagnostic categories or dimensions (see [55]). Tamminga and colleagues identified biotypes from a collective sample across bipolar disorder, schizoaffective disorder, and schizophrenia and found that the biotypes were more predictive of functional impairment [56]. Their approach exemplifies the RDoC approach.

Change is afoot

Collectively, the field of psychiatry, particularly the area of diagnosis, is in a state of unrest that historically characterizes the conditions under which a paradigm change is afoot [57]. Motivations for NIMH efforts with the RDoC are evident in other quarters. The authors of DSM-5 had strived for the ambitious goal of a paradigm change [58]. For a number of reasons, some logistical and some based on the inherent structure, as discussed in earlier parts of this chapter, this goal was not achieved. However, the cross-cutting symptom checklists for DSM-5 are currently being developed, with evidence of good reliability [59], including dimensional characteristics of severity, number, and duration of symptoms (for example, [60, 61]). The alternative model of personality disorders provides another example where the DSM-approach is progressing [62].

Decades of work on structural approaches to psychopathology have now been codified in the Hierarchical Taxonomy of Psychopathology (HiTOP) [63]. As is the case with the RDoC, the HiTOP approach reorganizes clinical symptoms found throughout the DSM agnostic to the original diagnostic categories; however, links to cross-validate these constructs with internal mechanisms (biological or psychological) are limited [64]. Early efforts on this front are promising, especially the psychoneurometric approach developed by Patrick and colleagues [65, 66]. Observations from computational neuroscience working from the ‘bottom up’ may be particularly informative to help spell out a theoretical understanding of these connections [67, 68]. Finally, an international effort has been undertaken with the Neuroscience-based Nomenclature (NbN) [69] (see also Chapter 9). The NbN offers a template for clinicians to prescribe, based on common symptom sets of familiar mental disorders, but by aggregating symptoms on the basis of how they connect to neurobiological systems.

Going forward with the RDoC

The RDoC was developed out of the recognition by NIMH leadership that something radically different was needed to effect change in research, so that advances in integrative neuroscience could inform the understanding of biological and psychological processes involved with human suffering and dysfunction. From its inception, the NIMH has emphasized that the RDoC depends on input from the field and on strong empirical support for both its structure and research executed with the RDoC framework. The degree to which

the RDoC will be embraced by the field—or perhaps, more importantly, the ways that the field will take hold of the RDoC and use it to move research forward—will ultimately be determined by scientific peer review of funding applications and journal publications. To this end, the NIMH/RDoC have relied on the NAMHC to evaluate the future development of the RDoC. New generations of clinical scientists will also determine the future of the RDoC, and early indications suggest that the RDoC offers a viable means to teach translational neuroscience [70].

A second way in which the RDoC approach relates to the field concerns data sharing. The NIMH Data Archive (NDA) (see <https://data-archive.nimh.nih.gov/>) houses and shares with qualified researchers harmonized, item-level data of all types and concerning all levels of biological and behavioural organization. The NDA is made up of several repositories, including the RDoC Database (RDoCdb) (see <https://data-archive.nimh.nih.gov/rdocdb>). The RDoCdb provides an infrastructure for sharing subject-level data and serves as a resource for hypothesis testing and exploration. The NIMH encourages the use of these resources to achieve rapid scientific progress. Sharing data, associated tools, and methodologies, rather than just their summaries or interpretations, accelerates research progress by allowing re-analysis of data, as well as re-aggregation, integration, and rigorous comparison with other data, tools, and methods. Data from more than 16,000 research participants have already been received.

To facilitate data sharing and the combination of large data sets, in order to fully understand the mechanisms underlying the psychopathology, it is important to develop a set of paradigms and measures that are generally accepted by the field and can ensure that constructs are being measured using systematic and reliable means. As mentioned earlier, the NAMHC workgroup that was formed to look critically at the ‘Paradigms’ column of the RDoC matrix offered recommendations for currently existing tasks that adequately measure each construct. An incentive was to have a set of common data elements to be used widely to allow for future aggregation of RDoC data. The resulting report includes an abundance of information from domain area experts, including the items they considered when discussing each task, the overall organization of each domain, and recommendations of tasks that are useable, that need more work, and that should not be used for each construct.

In contrast to clinical diagnostic manuals, as a research framework, the RDoC has the luxury to be more nimble, building on recent findings to test new hypotheses. In contrast, changes in clinical diagnostic manuals have immediate implications for patients in terms of treatment prescriptions or reimbursement, as well as disability services or accommodations. Even with the aspiration to update changes in the present DSM-5 more expeditiously, processes described so far (for example, [71]) still rely on consensus vetting procedures and will need to address the implications of change for patient groups. The RDoC, in contrast, can advance new research ideas that, once fully formed, may be utilized to inform clinical diagnostic manuals. One limitation of RDoC research that will need to be addressed for treatment research will be the way that RDoC constructs will be handled by regulatory bodies.

As the RDoC matrix became established and understood by the field, changes to the matrix have become possible. Recently, some ‘cosmetic’ changes to the matrix have been made, taking advantage of web-based tools to link constructs and elements of the matrix for

a more fluid and intuitive design, allowing for ease of future growth and expansion, along with providing a space to elaborate on certain elements and constructs as data emerged. The CMAT and other appointed workgroups overseen by the NAMHC will continue to be tasked with evaluating matrix updates and revisions, including the evaluation of new domains and constructs. The hope is that the RDoC matrix will reflect the needs and growth of the field, with transparent input from the scientists who use it most. With the 10-year anniversary of the RDoC, the RDoC Unit and working groups have their ears open to the field and their eyes on new and innovative ways to help the RDoC grow and adapt, as psychopathology researchers work to build systematic ties to advances in neuroscience.

Application of research evidence in clinical practice

Andrea Cipriani, Stefan Leucht, and John R. Geddes

Introduction

More than 20 years ago, evidence-based medicine was defined as ‘the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients, and the integration of clinical expertise and patient values’ [1]. Three components are essential: (1) the current best research evidence, which is found in methodologically sound and clinically relevant research reports; (2) clinical expertise, which relates to a clinician’s cumulative experience, education, and clinical skills; (3) patients, who bring their own personal preferences, unique concerns, and values to the clinical encounter. The full integration of these three components improves clinical outcomes and quality of life. Evidence-based medicine aimed at closing the gap between research and practice by incorporating the advances in clinical epidemiology and medical knowledge into clinical activities [2]. The reason why evidence-based medicine was developed and adopted worldwide is for clinicians to keep abreast of the latest therapeutic advances, cope with rapidly changing policies, and face increasing public expectations and demands [3]. The best course of action is to use an evidence-based approach, because it optimizes clinical decisions (making practice more standardized and more efficient) and also justifies them [4]. This applies to all fields in medicine, including psychiatry.

The idea that clinical practice should be based on good evidence is not new [5, 6]. Over the years, evidence-based medicine has been criticized because its ‘quality mark’ has been misappropriated by vested interests and the volume of evidence, especially clinical guidelines, has become unmanageable [7]. However, by providing clinicians with a set of skills which allow them to base clinical decisions on the best available and most up-to-date evidence, evidence-based medicine is not only a useful tool for clinical practice, but also an efficient method of self-directed, career-long learning [8].

Evidence-based medicine has been listed among the most important 15 medical advances since 1840 [9] (Kamath 2016), and nowadays mental health professionals are encouraged to use an evidence-based approach in their daily activities [10]. However, it is known that one of the major challenges for clinicians is to move from the theory of evidence-based medicine to the practice of it.

A study, now over 30 years old, estimated that, on average, five clinical questions are raised at each bedside encounter with a patient [11]. In 1998, it was estimated that only 4% of health care decisions were based on sound evidence, 45% on strong consensus among physicians, and 51% in neither [4]. Evidence-based practice requires new skills of the clinician, including efficient literature searching and the application of formal rules of evidence in evaluating the clinical literature. The implementation of evidence-based practice involves four steps [12]:

- To frame a clear question, based on a clinical problem (which arises from the care of one patient).
- To search for the relevant best available evidence in the literature (selecting the appropriate resource).
- To critically appraise the validity (closeness to the truth) and applicability (usefulness in clinical practice) of the retrieved evidence.
- To apply the findings to clinical decision-making and routine practice (integrating the evidence with clinical expertise and patient’s preferences and values).

These steps are referred in some textbooks as the 5 As: Assess (the patient), Ask (the question), Acquire and Appraise (the evidence), and Apply (talk with the patient), with the fifth step being the all-important evaluation of the clinician’s own performance in consultation with the patient (the so-called self-evaluation).

In this chapter, we will explore how research evidence should be used to inform real-world practice, taking into account the perspective of both the practising clinician and the clinical researcher.

What is evidence and why does it matter?

Decision-making processes are enhanced through the use of valid and reliable evidence. Evidence is the information we gather on which to base, or support, our decisions. It is therefore important to be able to determine which evidence is ‘the best evidence’, that is, the most valid and reliable. This term is used quite frequently in medical journals and international meetings, and it basically refers

to the methodological quality of the study design that produces the information we are looking for, in relation to the clinical question. Studies from the scientific literature can be broadly categorized either as *experimental* (when the investigators assign the exposures) or *observational* (when investigators observe usual clinical practice) [13]. Experimental studies become randomized trials only when the exposures are assigned by a random technique and the allocation of the upcoming assignment is concealed. Experimental and observational studies are placed into a hierarchy which may vary, depending on the specific clinical question to address, but only the study designs at the top are considered ‘the best evidence’. For example, in the case of assessing the efficacy of interventions, randomized controlled trials are at the top of the ranking [14]. Randomization approximates the controlled experiment of basic science, and it is the only known way to avoid selection and confounding biases in clinical research. Bias (that is, systematic error) can confound the outcome of a study, such that the study may overestimate or underestimate what the true treatment effect is. Within a sample population, a properly conducted randomization is able to reduce the risk of selection bias by not only controlling for *known*, but also (and possibly more importantly) controlling for *unknown* prognostic variables. This bias-controlling measure helps attain a more accurate estimation of the truth.

Randomized controlled trials have drawbacks too. For instance, a methodologically sound randomized controlled trial can have good *internal validity* (that is, the study measures what it sets out to measure), but it might not have ‘good enough’ *external validity* (that is, the extent to which results from the individual study can be generalized to the broader community of patients outside the trial). Internal validity relates to whether the study answers its research question *correctly*, that is, in a manner which is free from bias (and researchers and clinicians should learn how to appraise the validity of such studies). By contrast, external validity is closely connected with the applicability of a study’s findings, and its assessment depends on the purpose for which the study is to be used. Trials are usually conducted by industry on single patented compounds and are designed to meet the requirements of the regulatory agencies. In order not to delay the introduction of drugs onto the market, the majority of such trials are short term, highly controlled, highly monitored, and typically designed to separate between a new drug and placebo as efficiently as possible. This approach to clinical trial design has been described as *explanatory*, in which the aim is to determine if the treatment *can* work [15]. Patients in these trials are characteristically highly selected, and outcomes are essentially sensitive proxies of clinically relevant outcomes. Even for pharmaceutical companies, the risk of mounting a very large expensive clinical trial on a promising compound has to be offset against the risk that such a trial will demonstrate that the investigational compound is either of limited or no efficacy or causes serious adverse effects. Pharmaceutical companies are therefore under pressure to do everything they can to design the trial to show their product in the optimal light and to ensure that any positive results have maximum impact, leading to as rapid uptake of the new drug as possible following market authorization. Because the design of these trials is based on a negotiation between regulators and the industry, these trials often have substantial limitations for answering clinical questions in the real world, and hence limited clinical external validity. The results of the available evidence often need to

be extrapolated—to an unknown degree—when they are applied to the target clinical question.

Finally, randomized controlled trials are usually very expensive, take many years to be conducted (from conception to publication), and cannot be used in some instances (for example, in special populations such as pregnant women who should not be exposed to potentially harmful substances, as this would be unethical).

It has been recognized that much larger trials are required, and trial procedures should be very simple and efficient, allowing widespread recruitment by practising clinicians [16]. If representative samples of patients are enrolled in the trial, the results will be of widespread applicability to future patients. Inclusion criteria are broad and as unrestrictive as possible. The key entry criterion is that both the patient and the investigator are substantially uncertain which of the trial treatments would be most appropriate. This ‘uncertainty principle’ is ethical because it effectively excludes patients for whom a specific treatment is known to be the most appropriate. All trial procedures are radically simplified. Keeping the trial procedures and data collection to an absolute minimum is essential to achieve widespread participation, and hence the required sample size for realizing the key objectives of the trial. Such trials are termed *pragmatic* [17] and, in contrast to the question of ‘*Can* the treatment work?’ answered by the explanatory trial?, they ask: ‘*Does* the intervention work?’ [18] Pragmatic trials should not be seen as a research design that should replace explanatory trials. There is a continuum between explanatory and pragmatic trials and, ideally, pragmatic trials should be conducted after the results of explanatory trials allowed a new medicine to enter the market. Important examples of pragmatic trials in psychopharmacology include the Bipolar Affective disorder: Lithium/ANTiconvulsant Evaluation [19], the European First Episode Schizophrenia Trial [20], the Clinical Antipsychotic Trials of Intervention Effectiveness [21], the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study [22], and Clozapine plus Haloperidol or Aripiprazole Trial [23].

How to collect the best available evidence

The number of randomized studies is growing, so too does the science of reviewing trials [24]. The history of synthesizing research is inextricably bound up in the history of evidence-based medicine, but it actually goes back centuries. The pioneer in the field was James Lind, a Scottish naval surgeon, who is credited not only with having produced one of the early records of a scientific trial, but also with having written one of the first systematic reviews of evidence. In 1747, Lind took 12 patients with scurvy, whose cases ‘were as similar as I could have them’ and divided them into six groups of two [25]. According to his planned intervention, Lind administered six different treatments to each pair of sufferers: (1) cider; (2) elixir vitriol; (3) vinegar; (4) seawater; (5) a combination of oranges and lemons; and (6) a mixture of garlic, mustard seed, and balsam of Peru. A week later, Lind’s findings were clear: ‘The result of all my experiments was that oranges and lemons were the most effectual remedies for this distemper at sea’ (<http://www.jameslindlibrary.org>). The results of this study were published a few years later, and interestingly, Lind wrote: ‘As it is no easy matter to root out prejudices ... it became requisite to exhibit a full and impartial view of what had hitherto been published on the scurvy ... by which the sources of these

mistakes may be detected. Indeed, before the subject could be set in a clear and proper light, it was necessary to remove a great deal of rubbish.' To gather the available research, get rid of the 'rubbish', and summarize the best of what remains are essentially the science of a properly conducted systematic review. It took a while to understand the value and the methodological implications of Lind's attitude; however, in the past century, there were eminent figures, like Archie Cochrane, a British epidemiologist, who persuasively advocated the scientific evaluation of commonly used medical therapies through objective sources of information [26]. Even though the importance of evidence synthesis in medicine was recognized since the 1970s, the widespread use of these systematic reviews and meta-analyses did not occur until 1990s, when it became clear that the judgements and opinions of experts were often biased [27].

There are two main approaches to reviewing literature: *narrative reviews* and *systematic reviews* [28].

Narrative reviews are the old, traditional approach. They are broad in scope and qualitative and do not include a method section (where the authors describe how they retrieved the relevant information); therefore, they are mainly based on the experience and subjectivity of the authors, who are often experts in the area. The absence of an objective method section, together with the lack of clear and replicable criteria, leads to a number of methodological flaws (for instance, the bias in selecting the scientific literature), which can materially affect the author's conclusions. The results from narrative reviews must be viewed with suspicion, as they are likely to be misleading (and one of the major problems is that the extent to which they are unreliable is almost impossible to judge).

By contrast, systematic reviews (or sometimes called 'overviews') are syntheses of primary research studies and are qualitative and focused around clinical questions. They describe and use specific, explicit, and therefore reproducible, methodological strategies to identify, assemble, and critically appraise all relevant issues on a specific topic [29]. Systematic reviews should be designed to answer only a narrow and specific question, because, if the question is too broad or too generic, it will be impossible for the researchers to collate and assess all the relevant information. The nature of the question determines the optimal primary study design, and hence the *a priori* inclusion and exclusion criteria.

If the question concerns efficacy and safety of an intervention (*Which treatment is better? Which dose is better tolerated?*), the most reliable study design would be a randomized controlled trial—randomization avoids any systematic tendency to produce an unequal distribution of prognostic factors between the experimental and control treatments, influencing the outcome [30]. However, randomized controlled trials are certainly not the most appropriate research design for all questions [31]. For example, for aetiological questions, it would be neither possible nor ethical to randomize subjects to many harmful exposures—systematic reviews would therefore need to include cohort and case-control studies. Likewise, a diagnostic question such as *'How well can a screening tool identify patients with a psychiatric disorder?'* would be best answered by a cross-sectional study of patients at risk of being ill [32]. Systematic reviews of these other study designs have their own methodological problems—guidelines exist for undertaking reviews (and meta-analyses) of diagnostic tests [33] and the observational epidemiological designs used in aetiological research [34]. The review protocol is where these criteria are reported and defined before the

review starts, and they should be followed by the researchers to select the relevant studies.

There is a further difference between narrative reviews and systematic reviews. New research data emerge continuously, and reviews are useful if they are up-to-date. This tends not to be the case with conventionally published reviews, but the systematic reviews of the Cochrane Library, for instance, are published electronically and periodically updated to take into account the emergence of new evidence (<http://www.cochranelibrary.com/>). There is evidence that systematic reviews improve the reliability and accuracy of conclusions; however, the results are rarely unequivocal and require careful assessment and interpretation [35]. Evidence-based practice is not cookbook medicine [36], also because clinicians need to integrate the results from systematic reviews with the clinical situation, their own expertise, and patients' preferences.

Despite their potential to avoid bias, a number of factors can adversely affect the conclusions of a systematic review. When conducting a primary study, it is important to ensure that the sample recruited is representative of the target population; otherwise, the results may be misleading (*selection bias*). The most significant form of bias in systematic reviews is analogous to selection bias in primary studies but applies to the selection of primary studies, rather than participants. There are various forms of selection bias, including *publication bias*, *language of publication bias*, and *biases introduced by an overreliance on electronic databases*.

Publication bias is the tendency of investigators, peer reviewers, and also journal editors to differentially submit or accept manuscripts for publication, based on the direction or strength of the study findings. The conclusions of systematic reviews can be significantly affected by publication bias. The potential pitfalls of publication bias are obvious—if only studies which demonstrate a treatment benefit are published, the conclusions may be misleading if the true effect is neutral or even harmful. As early as 1959 it was noted that 97.3% of articles published in four major journals had statistically significant results, although it is likely that many studies were conducted which produced non-significant results—but these were less likely to be published [37]. Various strategies have been proposed to counter publication bias. These include methods aimed at detecting its presence and preventing its occurrence. It is generally accepted that prevention is likely to be the most effective strategy, and therefore, prospective registries of all clinical studies were established. This means that nowadays a record of a trial exists, regardless of whether or not the study is published, and it reduces the risk of *negative* studies disappearing. Registries of ongoing research have been slow to establish—perhaps because it is not clear who should take a lead or fund them—although some of them are working efficiently (for example, <http://www.controlled-trials.com> or <http://www.clinicaltrials.gov>). While such registries are useful for newer or relatively new trials, they do not solve the problem of retrospectively identifying unpublished primary studies. A number of methods for estimating the likelihood of the presence of publication bias in a sample of studies have been developed. One commonly used way of investigating publication bias is the funnel plot [38]. In a funnel plot, the study-specific odds ratios are plotted against a measure of the study's precision—such as the inverse of the standard error or the number of cases in each study. There will be more variation in the results of small studies because of their greater susceptibility to random error, and hence, the results of the larger studies, with less

random error, should cluster more closely around the *true value*. If publication bias is not present, the graphical distribution of odds ratios should resemble an inverted funnel. If there is a gap in the region of the funnel where the results of small negative studies would be expected, then this would imply that the results of these studies are missing. This could be due to publication bias or mean that the search failed to find small negative studies.

Restricting a search to one language—for example, searching only for English language papers—can be hazardous. It has been shown that studies which find a treatment effect are more likely to be published in English language journals, while opposing studies may be published in non-English language journals. *Language of publication bias* has also been called the *Tower of Babel* bias [39].

With the increasing availability of convenient electronic bibliographic databases, there is a danger that reviewers may rely on them unduly. This can cause bias because electronic databases do not offer comprehensive or unbiased coverage of the relevant primary literature. For instance, on investigating the adequacy of Medline searches for randomized controlled trials in mental health care, it has been shown that the optimal Medline search had a sensitivity of only 52% [40]. Sensitivity can be improved by searching other databases, in addition to Medline, for example Embase, PsycLIT, PSYINDEX, CINAHL, and Lilacs. To avoid the limitations of relying on electronic databases—or any other resource—for the identification of primary studies, reviews seek to use optimally sensitive, over-inclusive searches to identify as many studies as possible with a combination of electronic searching, hand searching, reference checking, and personal communications. Unpublished data refer to studies that are not published at all, but they may also refer to information that are not included in study reports published in scientific journals. Each study has a unique ID number. Trial registration is requested for study approval by local ethics committees and as a precondition for publication in many journals, so a full report of the study protocol, and sometimes of study results, can be found using the Internet. Clinical trial registries and websites of regulatory agencies are one option, but the most informative sources of unpublished data are pharmaceutical industries' websites. Not all companies have study registries, and not all the companies that have study registries report results in an easy-to-use and comprehensive format. Having access to this information may be useful also when the published paper is available, because it can help retrieve some missing information or, in case of discrepancies or inaccuracies, clarify the exact figures (for instance, when changes in rating scales are reported only in figures or graphs).

As a research tool, a systematic review of the literature can be applied to any form of research question. Results of systematic reviews can reliably and efficiently provide the information needed for rational clinical decision-making. However, the main conclusion of a systematic review may often be that there is little or even no good-quality information in the literature. Even this conclusion may be useful in that it highlights areas in need of further primary research.

How to synthesize the best available evidence

The terms 'systematic review' and 'meta-analysis' are often used interchangeably, but actually they refer to different things. Systematic reviews are reviews of primary research studies, in which specific

methodological strategies that limit bias are used and clearly described in the protocol. By contrast, a meta-analysis is a statistical method to combine and summarize the results of several studies retrieved by a systematic review into one single estimate. This method of pooling research data from more than one study provides an estimate of effect size, which has greater power than any of the constituent studies. This has obvious advantages for clinical research and practice, because it minimizes *random error* and produces more precise, and potentially more generalizable, results. However, meta-analyses are not an essential part of a systematic review because sometimes it may be inappropriate to proceed to a statistical summary of the individual studies (for instance, when studies are not similar enough to be lumped together). Meta-analyses make the assumptions that clinically important differences between treated and untreated groups are not so large as to be intuitively obvious and that, although the treatment's effect varies in size among different patient populations, the effect's direction is consistently either beneficial or harmful [41]. A meta-analysis can estimate the degree of random error by presenting the quantitative results of individual studies and the 'pooled' weighted average result, with a confidence interval that provides a good indication of the precision of the estimate (it shows the extent to which the results are likely to differ from the 'true result' because of chance alone).

The technique of meta-analysis has been controversial, and this is perhaps because it is potentially so powerful, but it is also particularly susceptible to abuse [42]. A number of key issues should be borne in mind when assessing or carrying out a meta-analysis:

- A meta-analysis is a tool that can increase the sample size, and consequently the statistical power by pooling the results of individual trials (in psychiatry, many trials are small because of the difficulties in recruiting patients). Increasing the sample size also allows for more precision, that is, a pooled estimate with narrower confidence intervals [43]. Combining studies, however attractive, may not always be appropriate. The inappropriate pooling of disparate studies can make the final results meaningless. To avoid this, it is necessary to ensure that the individual studies are really looking at the same clinical or research question. Individual studies might vary with respect to study participants, intervention, duration of follow-up, and outcome measures. Such a decision will usually require a measure of judgement, and for this reason, a reviewer should always pre-specify the main criteria for including primary studies in the review protocol. Having decided that the primary studies are investigating a close enough question, an important role of the meta-analysis is to investigate variations between the results of individual studies (the so-called heterogeneity). When such variation exists, it is useful to estimate if more heterogeneity exists than can be reasonably explained by the play of chance alone [44]. If so, attempts should be made to identify the reasons for such heterogeneity, and it may then be decided that it is not reasonable to combine the studies, or that it is, but that the overall pooled estimate needs to take the variation into account.
- Individual studies vary in their methodological quality. Randomization, allocation concealment, blinding, and the type of analysis (for instance, whether or not the study participants are considered in the groups to which they were randomly allocated, that is intention-to-treat analysis) can all affect the direction of the results. In general, studies with poor methodology tend to

overestimate the effect of the intervention [45]. Rating scales and standardized tools have been developed to assess the quality (or risk of bias) of randomized trials. The quality scores can be incorporated into the meta-analysis, with a *quality weight* applied to the study-specific effect estimate. Although there are a large number of scales available, the current consensus is that their use is problematic because of uncertain validity, as it has been shown that using different scales leads to substantial differences in the pooled estimate [46]. The optimal approach at present is to assess the risk of bias of individual studies, focusing on the aspects of trial design that affect its internal validity. Nowadays, one of the most frequently used tools for assessing study quality is the Cochrane risk of bias tool. It is a domain-based evaluation, in which different domains are assessed individually, assigning a judgement of 'low', 'high', or 'unclear' risk of bias: sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, incomplete outcome data, selective outcome reporting, and other issues. More recently, a new systematic and explicit approach to making judgements about the quality of evidence and the strength of recommendations has been developed by a group of researchers—the Grading of Recommendations, Assessment, Development, and Evaluations (GRADE) Working Group (<http://www.gradeworkinggroup.org/>). When using GRADE, researchers rate evidence not study by study, but across studies for specific clinical outcomes. So the GRADE approach can specifically assess methodological flaws within the component studies, the consistency of results across different studies, the generalizability of the results to the wider patient base, and ultimately how effective the treatments have been shown to be.

- It is also possible to investigate and quantify the effect of poor-quality trials on the overall treatment outcome, by conducting pre-planned sensitivity analyses which exclude them from the pooled estimate. The main treatment effect of a trial gives an indication of the average response for an average patient meeting the inclusion criteria. Individual patients in real-life clinical practice deviate from the average to greater or lesser degrees. To tailor the results of a trial to an individual patient, it is tempting to perform a sub-analysis of the trial participants with a specific characteristic or a set of characteristics. Estimates of the treatment in subgroups of patients are more susceptible to random error—and therefore imprecision—than the estimate of the average effect for all patients' overall effect, because subgroups reduce the sample size and statistical power of the results. Furthermore, unless randomization was initially stratified according to the important subgroups, protection from confounding afforded by randomization may not be valid anymore and any observed subgroup difference in treatment effect may be due to type I error (that is, the incorrect rejection of a true null hypothesis, or a false positive). As a take-home message for clinicians, subgroup analyses should always be viewed cautiously.

By synthesizing evidence from studies with a similar design which address the same research question within the frame of a systematic review, standard meta-analyses can compare only two alternative treatments at a time [47]. For most clinical conditions where many treatment regimens already exist, standard meta-analysis approaches result into a plethora of pair-wise comparisons and do not inform on the comparative efficacy of all treatments simultaneously.

Moreover, if no trials exist which directly compare two interventions, it is not possible to estimate their relative efficacy, and thus, this specific information is missing from the overall picture. All this has led to the development of meta-analytical techniques that allow the incorporation of evidence from both direct and indirect comparisons in a network of trials and different interventions to estimate summary treatment effects as comprehensively and precisely as possible [48]. This meta-analytical technique is called *network meta-analysis*, also known as multiple treatments meta-analysis or *mixed-treatment comparison*. The combination of direct and indirect estimates into a single-effect size not only can provide information on missing comparisons, but also can increase the precision of treatment estimates of already existing direct comparisons, reducing confidence intervals and strengthening inferences concerning the relative efficacy of two treatments [49].

Another fruitful role of the network meta-analysis technique is to facilitate simultaneous inference regarding all treatments, in order to rank them according to any outcome of interest, for instance efficacy and acceptability [50]. Using network meta-analyses within the frame of a more complex statistical procedure, it is possible to calculate the probability of each treatment to be the most effective (first-best) regimen, the second-best, the third-best, and so on, and thus to rank treatments according to this hierarchical order. This is a very easy-to-understand and straightforward way to present network meta-analysis results, most of all for clinicians who want to know which the best treatment to be prescribed to patients is, on average [51].

Recently, network meta-analyses have become more widely employed and demanded, with the increased complexity of analyses that underpin clinical guidelines and health technology appraisals [52]. Expert statistical support, as well as subject expertise, is required for carrying out and interpreting network meta-analysis results. Several applications of the methodology have depicted the benefits of a joint analysis, but network meta-analysis approaches are far from being an established practice in the medical literature. Concerns have been expressed about the validity of network meta-analysis methods, as they rely on assumptions that are difficult to test [51]. Although network meta-analysis techniques preserve randomization, indirect evidence is not randomized evidence, as treatments have originally been compared *within*, but *not across*, studies. Therefore, indirect evidence may suffer the biases of observational studies (that is, confounding or selection bias). In this respect, direct evidence remains more robust, and in situations where both direct and indirect comparisons are available in a review, any use of network meta-analyses should be to supplement, rather than to replace, the direct comparisons. Several techniques exist, which can account for, but not eliminate, the impact of effect modifiers across studies involving different interventions [53]. However, recent empirical evidence suggests that direct and indirect evidence are in agreement in the majority of cases and that network meta-analyses can address biases that cannot be addressed in a standard meta-analysis such as sponsorship bias and optimism bias [54].

Meta-analyses can give an indication of the average response for an average patient meeting the inclusion criteria, but individual patients in real-life clinical practice deviate from the average to greater or lesser degrees. A potentially useful approach is to carry out meta-analyses of raw data from the included trials, the so-called 'individual patient data meta-analysis' [55]. In an individual patient data

analysis, it is possible to investigate important predictors (that is, baseline clinical and demographic characteristics) that might affect treatment response or prognosis, for example gender, age, ethnicity, family history, dose, severity of illness, age of onset, and number of previous episodes. The individual patient data methodology has been used in large-scale collaborative overviews, in which data from many randomized trials in a particular disease area were brought together [56]. Individual patient data meta-analyses usually require more time, resources, and expertise than other forms of review; however, the process brings with it a number of advantages [57]. The main difference between a standard meta-analysis and an individual patient data meta-analysis is that while the former is based on information that refers to each included study, the latter is based on information that refers to each subject included in the study. Individual patient data meta-analyses allow to describe the effects of competitive treatments over time [58]. In fact, information that refers to the outcome of each included subject is usually collected not only at endpoint, but also at various time intervals after random allocation.

Conclusions

As new evidence emerges, health care workers are constantly required to update their knowledge. In the scientific literature, a lot of information (sometimes too much and too often misleading) is continuously available and many websites or other sources keep updating, almost in real time, on the newest articles. In 1999, clinicians spoke of surviving an 'information flood', as trends demonstrated that the number of new journals doubled every 10–15 years [59]. In 2014, there were about 28,100 active scholarly peer-reviewed English language journals, collectively publishing 2.5 million articles a year, of which 30% were biomedical [60]. Even restricting reading to high-impact journals in a single field of interest, the number of articles is in the thousands. For this reason, health care workers chose to read so-called 'secondary journals', those which aim to highlight and summarize the recent evidence, methodological advances, and possible clinical implications of research [61]. Things may change in the near future, but at the moment, there are three secondary journals in the field of mental health with large readerships: *Current Opinion in Psychiatry*, *Harvard Review of Psychiatry*, and *Evidence-Based Mental Health*, established in 1988, 1993, and 1998, respectively. Even though there are differences between them, each adopts a systematic, comprehensive strategy to identify the best and most relevant new evidence for mental health workers and incorporates a rigorous peer review process for their articles [61].

A neuroscience-based nomenclature for psychotropic drugs

Guy M. Goodwin, Joseph Zohar, and David J. Kupfer

Introduction

A nomenclature can be defined as the devising or choosing of names for things. It sounds innocent enough, but in science, it is closely linked to the idea of classification or the creation of categories of like things. Such categories can also be the basis for a nomenclature. Since the words we use carry meanings, they influence how we think and communicate. If we need to make distinctions between objects, we need appropriate categories—not too many, not too few. Moreover, we need classifications which assist creative thought and do not retard it.

For many years, there has been dissatisfaction with the nomenclature widely employed to classify the medicines used in the treatment of psychiatric disorder. It has lurched between the obscure, the inconsistent, and the incomprehensible. To start with the obscure, a WHO symposium in Oslo in 1969 agreed a consensus that an international system of drug classification was needed, and the Drug Utilisation Research Group (DURG) was established. It created the WHO ATC (Anatomical Therapeutic Chemical) classification system, first published in 1976 and in use to this day, to present drug utilization data and so make national and international comparisons of drug utilization, evaluate long-term trends in drug use, assess the impact of external events on drug use, and provide denominator data in investigations of drug safety.

The ATC system sorts drugs initially into a target organ system (the nervous system, for psychotropics obviously) and then permits an ad hoc further subdivision broadly by therapeutic indication. [Fig. 10.1](#) illustrates the actual first-stage terminology for drugs targeting the nervous system: anaesthetics, analgesics, anti-epileptics, anti-parkinsonians, psycholeptics, psychoanaleptics, and 'other' (which includes drugs used to treat 'addictive disorders'). The very words 'psycholeptic' and 'psychoanaleptic' are strikingly unfamiliar to most prescribers, even though they fit logically with the therapeutic principle of the classification's structure.

Thus, as further illustrated in [Fig. 10.1](#), 'psychoanaleptics' include anti-dementia, antidepressant, psychostimulant, and psycholeptics and psychoanaleptics in combination. The term psychoanaleptic means 'to exert a stimulating effect on the mind'. It reflects an antique

way of thinking about drug action and now conjures up a property that is too vague to be useful. The further grouping is, in part, a classification by indication (anti-dementia, antidepressant) and, in part, by imprecise drug action (psychostimulation).

Classification by indication: the overlap in primary indications

Naming drugs by primary indication has an obvious superficial attraction. It means we can remember how to use them easily, the classes automatically give us alternatives, and we can communicate our intention to treat with patients and their families. So, while the terms psycholeptic and psychoanaleptic are unfamiliar, we use the next-level terms routinely. The psycholeptics carve into antipsychotics, anxiolytics, and hypnotics, with corresponding indications of psychosis, anxiety, and insomnia. Moving to the psychoanaleptics, antidepressants are effective in treating depression. This terminology currently covers most of what many non-specialist prescribers probably know about psychotropic drugs.

The immediate difficulty is that these primary indications are not unique to the drugs assigned to the relevant classes. In the case of antipsychotics, a number are effective in resistant depression, quite independently of any antipsychotic action. Moreover, lithium is classified as an antipsychotic but has no primary antipsychotic action. In the case of anxiolytics and hypnotics, many are benzodiazepine derivatives with both anxiolytic and hypnotic actions. Indeed, the most important differences are pharmacokinetic, with shorter-acting drugs being the most suitable to hypnotic actions, but such differences cannot be represented explicitly in the classification.

In the case of antidepressants, many of them are commonly prescribed as monotherapy for anxiety disorders. While a drug like paroxetine has multiple licensed indications for anxiety, other drugs with essentially identical mechanisms of action (selective serotonin reuptake inhibitors—the so-called SSRIs) do not necessarily have evidence to support actions on anxiety. However, they are used by extrapolation to treat anxiety disorders. In addition, SSRIs may be useful to treat a variety of pain states [1]. Nevertheless, SSRIs are all

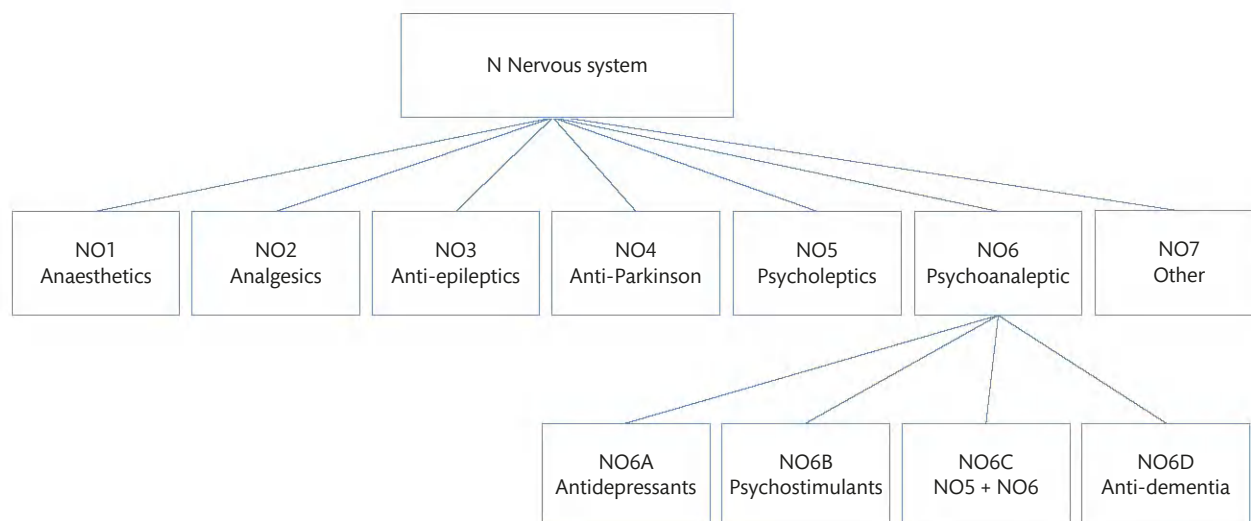

Fig. 10.1 First-stage terminology for drugs targeting the nervous system.

Source: data from ATC/DDD Index 2017, N NERVOUS SYSTEM, © WHO Collaborating Centre for Drug Statistics Methodology, Oslo, Norway. Available at https://www.whocc.no/atc_ddd_index/?code=N

classified as antidepressants. This inexactitude has a negative effect on public and patient perception of our clinical practice.

Thus, the strident argument has been made that increasing numbers of prescription of SSRIs imply that doctors are overdiagnosing ‘depression’ and overprescribing ‘antidepressants’ [2]. It has made for unnecessary controversy and has devalued the evidence that prescribing an SSRI can be both evidence-based and useful to patients [3]. Together with this negative public discourse, the current nomenclature clouds direct personal communication with patients. It must be confusing to find that your anxiety disorder is being treated with an antidepressant. The use of an antipsychotic to augment the treatment for your depression (added to an SSRI or a similar medication) means having to cope with the thought that you have developed psychosis. Psychosis implies both severity of illness and stigma. Finally, anti-epileptic drugs (valproate, carbamazepine, lamotrigine) are used to treat bipolar disorder, but the package inserts for common formulations of these drugs may only reflect their use in epilepsy. The present classification certainly has the potential to confuse patients. Sophisticated prescribers may be well able to tolerate these inconsistencies, but it fails their needs in even more important ways, as will be illustrated later.

Finally, the emphasis on indication has served the purposes of marketing by the makers of drugs perhaps too well. It lends itself to the addition of soothing adjectives. Therefore, we have words like ‘atypical’, ‘second generation’, and ‘novel’ entered in the marketing pitch for new business. It has been almost entirely designed to persuade, Madison Avenue style. Who would want an old smart phone if the next-generation phone were on offer? But the analogy suggested by ‘second-generation’ antipsychotic drugs is entirely specious. Even specialists appear to have been taken in by this terminology. To take an important example, the CULASS trial compared ‘first-’ with ‘second-generation’ drugs for psychosis. However many patients in the study received sulpiride as a ‘first-generation drug’ and amisulpride as a ‘second-generation drug’. These drugs are very similar molecules both chemically and pharmacologically, so to compare them is very unlikely to reveal an important difference.

Nevertheless, despite also being underpowered, the CULASS study is widely cited as evidence that new drugs for psychosis have no advantage over what went before [4, 5].

In summary, the ATC principle may be adequate for its given limited purposes in pharmacoepidemiology. It probably makes little difference how licensed drugs are actually grouped, since groups may be recombined to answer specific epidemiological questions. Indeed, the home website of the WHO Collaborating Centre for drug statistics methodology carries an important disclaimer: ‘the classification of a substance in the ATC/DDD system is not a recommendation for use, nor does it imply any judgements about efficacy or relative efficacy of drugs and groups of drugs’ (https://www.whocc.no/atc_ddd_methodology/purpose_of_the_atc_ddd_system/). However, as a classification that is used in everyday practice, it is both confused and confusing. Moreover, it poses a significant barrier to understanding drug action, and hence to rational prescribing. This is a problem psychiatrists need to solve, and the incentive to do so resides in our current practice. We need to change, and this chapter will explain why.

Classification and the therapeutic challenge

When chemical classification does not help

The guiding principle of the ATC recognizes ‘chemistry’ as a key classificatory level. This may sometimes mean pharmacology, but just as often, it is simply a classification on the basis of the organic chemistry of drugs. In the case of anti-epileptics, for example, pharmacology is not considered at all—it is just chemical structures of drugs. This means that the mechanisms of action of anti-epileptics may not be commonly known to prescribers at all. As an example, carbamazepine is an antagonist at the calcium channel [6]. It may be highly relevant that genome-wide association studies implicate variation in the encoding and expression of calcium channels in the aetiology of bipolar disorder and schizophrenia [7]. To describe

carbamazepine as an anti-epileptic makes it seem surprising that it is an effective anti-manic drug; to describe it as a calcium channel antagonist at least provokes the thought that its actions might extend beyond the epilepsy indication.

There are many other examples within the existing terminology of psycholeptics and psychoanaleptics that also refer to chemistry. This has the virtue of neutrality, but the vice for most of us of conveying no useful information whatsoever. The case of antipsychotics is particularly instructive. See https://www.whocc.no/atc_ddd_index/?code=N05A for an example of how antipsychotics may be sub-classified. **Fig. 10.2** shows how antipsychotics are sub-classified entirely on the basis of chemistry. As trainees, some of us may have attempted to remember the names, if not the chemical structures (for example, phenothiazines, butyrophenones, thioxanthenes). All were antagonists at the dopamine D2 receptor, and this monocular perspective on their mode of action was probably encouraged by the pointless nomenclature. This only changed with the commercial effort to produce drugs with a low propensity for producing extrapyramidal side effects (EPS) in the 1980s and 1990s. The so-called atypical drugs fall into three new categories (**Fig. 10.2**): NO5AE (indole derivatives), NO5AH (diazepines, oxazepines, thiazepines, and

oxepines—the ‘-pines’), and NO5AL (benzamides). However, what is important about indole derivatives and the ‘-pines’ is the addition of affinity for neurotransmitter receptors other than dopamine into their pharmacology. This pharmacology is complex [8]. In the case of the ‘-pines’ from NO5AH, the affinity for 5-HT2A receptors is much higher than for D2 receptors. It is widely believed that this is key to the reduced risk of EPS; moreover, reduced function at 5-HT2A receptors may be intrinsically ‘antipsychotic’. Indeed, pimavanserin is a completely novel antipsychotic (developed for the treatment of psychosis in Parkinson’s disease), with no dopamine receptor antagonism at all; its mechanism appears to be via an inverse agonist action at the 5-HT2A receptor. So in treating and combining drugs for psychosis, one needs to know that a drug like clozapine will have a small impact on D2 blockade and a large impact on 5-HT2A receptor function, while a drug like amisulpride will block D2/D3 receptors quite selectively (and effectively). If a patient fails to respond fully to clozapine, the addition of amisulpride as augmentation would be more logical than to add olanzapine (which simply mimics a range of the actions of clozapine) [9].

Finally, side effects are an important limitation of most antipsychotic medications. There is a high affinity for histamine

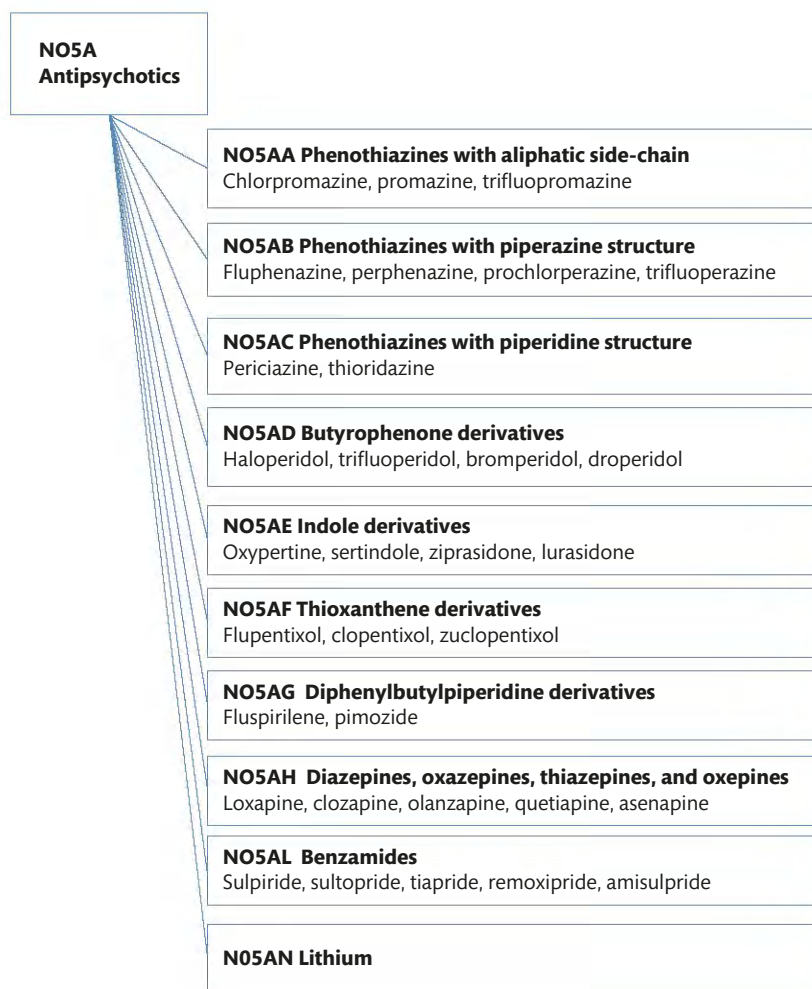

Fig. 10.2 Current antipsychotic nomenclature under the WHO system.

Source: data from ATC/DDD Index 2017, N05A ANTIPSYCHOTICS, © WHO Collaborating Centre for Drug Statistics Methodology, Oslo, Norway. Available at https://www.whocc.no/atc_ddd_index/?code=N05A

receptors, which may result in weight gain and metabolic disturbance with clozapine, olanzapine, and quetiapine (but not asenapine). For other drugs, there may be a higher affinity for muscarinic receptors, which might be expected to produce a dry mouth, accommodation difficulties, etc. In general, to classify by indication fails to draw the prescriber's attention to the properties of drugs which will be important for treating individual patients.

Why is pharmacology so important to psychiatry?

Obviously, most doctors take some pride in knowing how drugs work and how to use them. But pharmacological investigation of the mode of action has had a special place in psychiatry, because effective medicines were discovered before their pharmacology was understood. Investigation of the mode of action was, and arguably remains, a cutting-edge theme in neuroscience. Axelrod, Carlsson, von Euler, and Greengard won Nobel prizes for working out how the monoamine systems and the drugs acting on them function in the brain. Completely new fields of cognitive and computational neuroscience have opened up, because we know that dopamine neurons are involved in motor function and decision-making. This scientific development was recognized by the award of the Brain Prize in 2017 for multi-disciplinary analysis of brain mechanisms that link learning to reward (<http://www.thebrainprize.org>).

Psychopharmacology also provided, and still provides, one of the few starting points for mechanistic understanding of psychiatric disorder. By contrast, diagnosis (the indication) remains quite arbitrary and essentially provisional, based as it is on symptoms, rather than mechanisms of disease (see Chapters 7 and 8). So pharmacology provides a very appropriate space in which to name, describe, summarize, and classify psychotropic medicines. Obviously, some subclasses of drugs are already described in this way. We have selective monoamine oxidase inhibitors (MAOIs) and SSRIs. The WHO classification of antidepressants (that is, those drugs with evidence for efficacy as monotherapy in unipolar depression) is another case in point (see https://www.whocc.no/atc_ddd_index/?code=N06A). The classification of antidepressants (that is, those drugs with evidence for efficacy as monotherapy in unipolar depression) is shown in Fig. 10.3. Monoamine reuptake inhibitors (non-selective and selective for serotonin) and MAOIs (non-selective and type A-specific) comprise the first four reasonable categories. However, the fifth group NO6AX is 'other'. It includes currently 26 chemical entities and seven mechanisms of action (Fig. 10.3). It automatically includes all new drugs with novel mechanisms of action.

Unfortunately, we have even lacked a systematic approach to describing the pharmacological properties of those medicines we do classify by mode of action. The use of the term SSRI was promoted by companies marketing novel antidepressants in the 'Prozac' era. It is a fair summary of the key property of such drugs. However, the term SNRI does not stand for selective *noradrenaline* reuptake inhibitors,

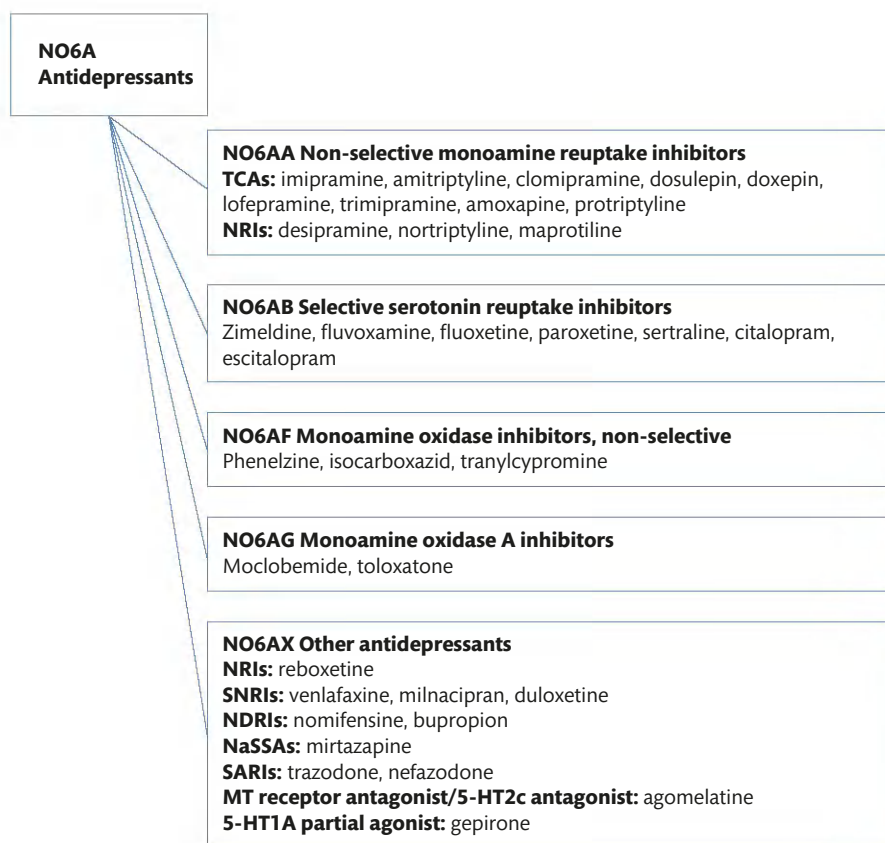

Fig. 10.3 Current antidepressant nomenclature under the WHO system.

Source: data from ATC/DDD Index 2017, N06A ANTIDEPRESSANTS, © WHO Collaborating Centre for Drug Statistics Methodology, Oslo, Norway. Available at https://www.whocc.no/atc_ddd_index/?code=N06A

as you might expect. Instead, ‘SNRI’ stands for serotonin/noradrenaline reuptake inhibitor (Fig. 10.2). Selective noradrenergic reuptake inhibitors are instead abbreviated NRIs. More consistently, noradrenaline/dopamine reuptake inhibitors are NDRI. In the case of serotonin antagonist and reuptake inhibitors, the preferred abbreviation is SARIs. Individual drugs like mirtazapine, agomelatine, and gepirone are single examples of particularly quite complex mechanisms of action.

Conclusions

So in summary, we have antipsychotics and anti-epileptics used to treat patients with bipolar disorder who are neither psychotic nor epileptic. We have SSRIs and SNRIs, although SNRIs are *not* selective noradrenaline reuptake inhibitors, but instead serotonin/noradrenaline reuptake inhibitors, and finally we have a growing majority of antidepressants classed simply as ‘other’. It is undeniably a mess. Does it matter? It has been tolerated for a long time, without serious efforts to change. Our desire to make changes now should be fuelled by embarrassment. However, there are more serious reasons to change too. With Lewis Carroll, we often do not know what we think until we speak. Defining our treatments by diagnoses of limited validity limits our capacity to speak. Our failure to use pharmacological criteria and define drug actions limits our capacity to think. An emphasis on mechanism should stimulate clinicians to think what they are doing when they prescribe for patients. It will be a continuing nudge to stay on top of the science that underpins our understanding. Moreover, a more nuanced system for describing medicines can grow flexibly—it can accommodate a mechanistic understanding at any number of levels, from molecules, to systems, to cognition. There is also the potential to harness the shift in emphasis from operational diagnosis to dimensional neurobiology, as currently enshrined in the RDoC project (see Chapter 8).

Neuroscience-based nomenclature

The NbN initiative represents the efforts of colleagues from the five major international neuropsychopharmacological scientific organizations to reform the nomenclature of drugs used by psychiatrists. The taskforce was formed in 2008 (Box 10.1).

All expenses related to the project were covered by the European College of Neuropsychopharmacology (ECNP). Throughout the entire process, there was no direct or indirect support from any pharmacological company or other organization.

It was agreed that the guiding criteria were to:

1. Be based on contemporary knowledge.
2. Assist clinicians to make informed choices while prescribing.
3. Provide a system that does not conflict with the use of medications.
4. Be future-proof and accommodate new types of compounds.
5. Decrease stigma attached to a classification by indication (and enhance adherence).

The methodology was expert consensus informed by prescriber feedback [10, 11].

The future of naming by indication

If our existing terminology is misleading and constrains creative thought, we should try to give up this approach completely. This recommendation of the taskforce has been broadly accepted by the editors of many major cognate journals (Box 10.2)

This means trying to use less often the words antipsychotics, antidepressants, anxiolytics, and hypnotics when what we could say is simply ‘drugs for psychosis’, ‘drugs for depression’, ‘drugs for anxiety’, and ‘drugs for insomnia’. Simply changing the stress to the indication, rather than the class of drug, is often an easy adjustment to make.

Where an author wants to use the words antipsychotics, antidepressants, anxiolytics, and hypnotics, then s/he should define exactly what is meant. If one is actually wanting to say dopamine antagonists/partial agonists, then that is preferable to ‘antipsychotics’. In the case of ‘antidepressants’ and ‘anxiolytics’, it is much more difficult to substitute a single word based on the mode of action. However, defining in advance exactly what drugs are subsumed within one’s meaning of ‘antidepressant’ is a good discipline. The British Association for Psychopharmacology guidelines for the treatment of bipolar disorder were written from this perspective and proved acceptable to the consensus group involved [12].

The NbN nomenclature

The NbN nomenclature classifies drug action by domain (the neurotransmitter target) and mechanism of drug action. As shown in [Table 10.1](#), domains range from dopamine or orexin (with quite a restricted anatomy based on small groups of neurons and their projections) to ‘ion channels’ or GABA (gamma aminobutyric acid) which implies a much more diffuse whole brain anatomy. We currently identify ten domains, but they are very likely to increase over time with the discovery of new drug targets. Some drugs (the SSRIs are an example) have been developed to be highly specific, so we already think of them as working in one domain exclusively. Many other drugs may act on more than one domain. Thus, drugs for psychosis will often be dopamine/serotonin drugs, as described previously. However, the reality is even more complicated, and we believe a dimensional approach is a better way to capture this adequately.

Along with a domain, drugs have different modes of action or functions. [Table 10.1](#) shows the current proposals. Characterization as agonist, antagonist, partial agonist, or partial allosteric modulator defines drug action at the level of the neurotransmitter receptor. Reuptake inhibitor or releaser addresses the functional consequences of drug action. Enzyme inhibitor or modulator, or ion channel blocker, identifies functional targets potentially outside the conceptual synapse. These categories are based on familiarity, rather than a strict understanding of molecular mechanism. It is an open question of whether they will stand the test of time; however, the NbN is equipped to accommodate new insights.

Most of the current pharmacopoeia can be mapped into this nomenclature. For drugs working in a single domain with a single action, like the SRIs, there is little change. Drugs for psychosis pose a different challenge. The ‘-pines’ illustrated previously can be described as dopamine/serotonin receptor inhibitors. Other examples (like aripiprazole and brexpiprazole) produce functional inhibition via partial agonist properties at dopamine receptors and have weaker antagonist properties at 5-HT_{2A} receptors. The NbN approach pushes the prescriber to employ more words to describe their treatments and hopefully think more accurately about what they do. However, this increased complexity is potentially problematic. It exemplifies that medicine is entering a new era, in which

it is being transformed by the explosion of knowledge and access to knowledge. We have deliberately invested in developing an app which will provide the prescribing information we think doctors and patients need. The founding version of the NbN was launched at the ECNP congress in Berlin in 2014 as a booklet and app. The app format allows medicines to be searched under the old categories and new ones. It will allow translation into many languages. It will soon be linked to another specialist database [International Union of Basic and Clinical Pharmacology (IUPHAR)]. It can expand or extend through linking, almost without limit. This would be part of a broader movement to make more informed choices and to practise a more precise pharmacological strategy.

Use of the NbN app

The NbN app can be searched and downloaded for use on Android (https://play.google.com/store/apps/details?id=il.co.inmanage.nbnomenclature&hl=en_GB) and iOS platforms (<https://itunes.apple.com/gb/app/nbn-neuroscience-based-nomenclature/id927272449?mt=8>). Use of the app is explained by a brief tutorial, but it is best appreciated by downloading it and using it. However, [Fig. 10.4](#) shows the opening screen/search page (left) and the result from typing ‘olanzapine’ (right). Further information (practical notes and neurobiology) can be obtained by scrolling down. The domains are dopamine and serotonin, and the mode of action is receptor antagonism.

The app also shows a brief summary of the approved indications, the spectrum of efficacy, and the adverse reactions commonly associated with olanzapine. The user can scroll down and see practical notes (which describe the availability of depot and the use in combination with fluoxetine for bipolar depression), former terminology (antipsychotic), and a link to a summary of the neurobiology. There are currently 130 drugs in the second edition of NbN (NbN-2) and 40 drugs in the child and adolescent version of NbN (NbN-ca).

The NbN as a multi-dimensional classificatory system

The searchable fields of the NbN app can also be thought of as a pragmatic multi-axial classificatory system. It recognizes DSM-5 as a system for providing (mostly) familiar diagnoses, which we will continue to use to communicate with ourselves and our patients and estimate societal morbidity. However, the multi-dimensional system of NbN has some parallels with the approach of the RDoC initiative (see Chapter 8). Both highlight heterogeneity, challenge disease-based existing systems, detect subtypes, and provide a better match between research findings and clinical decision-making ([Table 10.2](#)).

If the RDoC can create a reliable and valid alternative system for classifying disorders, the NbN may be able to align how it represents drug action. For example, the RDoC proposes the constructs, negative valence, and positive valence, within which different levels of analysis are possible. These RDoC domains have something in common with NbN domains (serotonin and dopamine, for example), and the different levels of analysis in the RDoC (for example, fear, anxiety, loss, frustrated non-reward) provide targets for defining different drug actions. The key property of the

NbN is that it is not bound by the limits of a two-dimensional table. Its creation as a digital device builds in a flexibility we have never enjoyed before. Moreover, being on a mobile platform makes it a widely accessible tool for use across the developed and developing world.

As it has developed, the point of the NbN has grown more obvious to more and more people. The major journals have accepted our critique of existing practice and have published editorials recommending change [13–24]. However, it is a work in progress. The hope is that the NbN encourages us to use different words, but crucially more words and concepts when describing our treatments. We may thereby be better informed when we take our initial ‘pharmacological step’ or later when we combine treatments after a first monotherapy fails. We can also improve how prescribers communicate among themselves and with their patients.

Neurodevelopment

Karl Zilles and Nicola Palomero-Gallagher

Neural induction

The central nervous system originates from the midline region of the embryo as a specialized area of the ectoderm—the *neuroectoderm* or *neural plate* (Fig. 11.1a). Fibroblast growth factor (FGF) signalling and bone morphogenetic protein (BMP), as well as *Wnt* (wingless gene) inhibition, are required as steps for neural induction [1]. As the neuroectodermal cells proliferate, the neural plate is transformed into an indentation—the *neural groove* (Fig. 11.1b). The lateral parts of this groove approach each other and join in the midline, forming the *neural tube* (Fig. 11.1c–f). This fusion of the groove to a tube by a folding process starts in the middle portion of the groove and proceeds in rostral and caudal directions like a zipper. The most rostral and caudal parts close only later, initially leaving rostral and caudal neuropores. A small transitional zone between the neural plate and the surrounding ectoderm provides the cells of the *neural crest* (Fig. 11.1a), which develop into post-ganglionic cells of the sympathetic and parasympathetic nervous system, sensory neurons of the spinal ganglia and ganglia of cranial nerves, Schwann cells, and chromaffin cells of the suprarenal glands (Fig. 11.1f).

Neural tube formation requires a controlled expression of cell adhesion molecules in the lateral folds of the neural groove. If the rostral neuropore fails to close, the development of the forebrain is impaired, leading to *anencephaly*. If the caudal neuropore fails to close, the most severe result is *rachischisis*, a malformation with a dorsally exposed neural groove. The mildest outcome is *spina bifida occulta*, which is a cleft of a vertebral arch covered by the epidermis.

As development continues, the neural tube and crest are found between the ectoderm and the notochord. The rostral part of the neural tube differentiates into the brain; the caudal part (behind the fifth somite) differentiates into the spinal cord.

Organogenesis of the central nervous system

The embryonic brain has three vesicular enlargements: the forebrain (telencephalon plus diencephalon), the midbrain (mesencephalon), and the hindbrain (rhombencephalon, including the cerebellum). At this early stage of brain development, a principal organization of the wall of the neural tube and its derivatives is still recognizable. There is a concentric organization around the central

canal, with the ventricular zone most interior, the intermediate zone surrounding the ventricular zone, and an outer cell-sparse marginal zone (Fig. 11.2e). The ventricular zone contains neuroblasts. Sections orthogonal to the longitudinal axis of the neural tube allow the stratification of its wall into four zones in a dorsal to ventral direction: roof plate, alar lamina, basal lamina, and floor plate (Fig. 11.2e). The alar and basal laminae are separated by a shallow sulcus in the ventricular surface, that is the *sulcus limitans* (double arrow in Fig. 11.2e). This sulcus demarcates a principal functional subdivision, since the alar lamina is the source for sensory neurons in the spinal cord and brainstem, whereas motor neurons originate in the basal lamina. Local expression of homeobox genes leads to the formation of the pallium and the ganglionic hill in the forebrain. Because the brain grows much faster than the rest of the embryo, it becomes deflected ventrally. A dorsally convex cephalic flexure marks the border between the hindbrain and the midbrain, and a cervical flexure marks the border between the spinal cord and the hindbrain (Fig. 11.2a–c). The ventrally convex pontine flexure is found at the central level of the hindbrain (Fig. 11.2b). During week 5, the forebrain differentiates further into the rostral telencephalon and the more caudal diencephalon. The telencephalon consists of two hemispheric vesicles connected by a thin lamina terminalis. A part of the lamina terminalis develops into the commissural plate—the *anlage* of the later corpus callosum (Fig. 11.2d). The ventral part of the lamina terminalis differentiates into the anterior commissure. The hemispheric vesicles show a spatially directed growth around the future insular lobe, which leads to a backward-directed elongation towards the occipital lobe and a backward- and ventrally directed growth, forming the temporal lobe (Fig. 11.2f). Further enlargement of the frontal, parietal, and temporal lobes, together with a slower growth rate of the insular lobe, leads to a gradual covering of the latter brain region, a process called *opercularization* (Fig. 11.2g, h). This process is associated with the appearance of the lateral fissure (Fig. 11.2h).

Extensive growth of the parieto-occipito-temporal association cortex leads to a bend in the temporal lobe around the lateral fissure, and the temporal pole is pushed rostrally. This direction of growth (Fig. 11.2f) also affects the structures situated dorsomedially, that is, the archicortex with the hippocampus, corpus striatum, and lateral ventricles. The corpus striatum is split by the ingrowing fibres of the internal capsule into the caudate nucleus and putamen. The head of

Fig. 11.1 Early developmental stages of the nervous system in schematic drawings of cross-sections through embryos.

the caudate is situated ventrolateral to the corpus callosum in the frontal lobe, and the tail of the caudate is located dorsal to the inferior horn of the lateral ventricle. The hippocampus forms its largest extension (the retrocommissural part) in the temporal lobe, bends around the posterior end (splenium) of the corpus callosum, and reaches a position on top of the corpus callosum (the supracommissural part). The precommissural part of the hippocampus ends in front of the genu of the corpus callosum. Finally, the first primary sulci appear, for example, the central sulcus (Fig. 11.2h).

The central cavity of the diencephalon (the third ventricle) is connected with the cavities of the hemispheric vesicles (the lateral ventricles) by the interventricular foramen (Fig. 11.2d). The diencephalon forms bilateral evaginations—the eye vesicles—which differentiate into the retina and the optic nerve.

The tectum with the superior and inferior colliculi evolves from midbrain enlargement. Gradients in the expression of *Gbx2* and *Otx2* determine the midbrain–hindbrain boundary [2]. This region is enriched in *Engrailed-1*, *Engrailed-2*, *Pax-2*, *Pax-5*, and *mbx* genes, which are important for the development of the tectum [3, 4].

Meanwhile, the hindbrain becomes subdivided into a rostral part (that is, the metencephalon) and a caudal part (that is, the myelencephalon). The cerebellum starts to develop from the rostral part of the metencephalon during week 6. At first, the enlarged central cavity of the neural tube (the future fourth ventricle) has a thin roof plate, bordered by two thickenings of the neural tube—the *rhombic lips*—which merge in the midline (Fig. 11.2d, f). These thickenings are the source of the later cerebellar hemispheres, while its midline develops into the cerebellar vermis.

The hindbrain is temporarily divided into eight rhombomeres [5], the borders of which are specified by combinations of transcription factors (for example, *Hox*, *Krox*, *Wnt* genes). It develops in close association with the visceral arches, which appear during week 4. It innervates these arches and the organs derived from them by a group of branchial nerves, which later become the trigeminal (V), facial (VII), glossopharyngeal (IX), vagal (X), and accessory (XI) cranial nerves. Other cranial nerves develop connections between the hindbrain and peripheral organs not derived from the visceral arches. They are the oculomotor (III), trochlear (IV), abducens (VI),

vestibulocochlear (VIII), and hypoglossal (XII) nerves. The olfactory (I) and optic (II) nerves arise separately as evaginations of the forebrain.

Histogenesis of the spinal cord

The neural tube initially consists of a single layer of neuroepithelial cells surrounding a central canal filled with cerebrospinal fluid

(Fig. 11.1c–f). The outer surface of the future spinal cord has an external limiting membrane, and the inner surface bordering the central canal has an inner limiting membrane. The entire wall of the early neural tube is called the ventricular zone [6].

The cells of the ventricular zone proliferate, and the surface of the spinal cord enlarges. The cord then thickens, as cells divide further to produce a multi-layered epithelium. The daughter cells have different potentialities; one type of cell (the neuroblast) retains the capability for mitosis, whereas another type (the proneuron) is

post-mitotic and represents an immature neuron. Proliferation of neurons is almost complete around birth.

Some neuroepithelial cells develop into precursors of glial cells, that is, glioblasts, which differentiate into astroglial, oligodendroglial, and microglial cells. The first glioblasts differentiate into radially extended cells, spanning the entire width of the wall of the spinal cord (the same occurs in the cerebral hemispheres and the cerebellar cortex, as described here). During later development, these radially extended cells are transformed into ependymal cells and astroglia.

Histogenesis of the spinal cord starts at the cervical level and progresses in a caudal direction. After week 3, the longitudinal sulcus limitans is recognizable on the inner surface of the neural tube (Fig. 11.2e). The alar lamina differentiates into a sensory zone—the dorsal horn of the adult spinal cord—and the basal lamina differentiates into a motor zone—the ventral horn. The sympathetic preganglionic neurons form in the lateral horn, which is present only at thoracic levels. The subdivision into alar and basal laminae is functionally important not only in the spinal cord, but also in the brainstem.

Proneurons leave the ventricular zone and migrate along radial glial cells into the intermediate zone where they become organized into cell groups. The motor neurons develop the axons of the ventral root, and the processes from spinal ganglionic cells grow into the spinal cord to form the dorsal roots. Synapses develop first in the motor zone, and later in the sensory zone, during weeks 10 to 13.

During the third month, the ventricular zone is reduced to a small rim surrounding the central canal and is finally transformed into the ependymal cell layer. The intermediate zone becomes organized into dorsal, ventral, and (at thoracic levels) lateral horns. The ascending and descending fibre tracts of the spinal cord are increased in size in the marginal zone. During weeks 14 and 15, oligodendrocytes begin to myelinate these fibre tracts. The corticospinal, or pyramidal, tract becomes visible for the first time during week 14 and reaches its target neurons, mainly motor neurons of the ventral horn, between weeks 17 and 29. Myelination of the pyramidal tract is completed between the first and second post-natal years. This late myelination explains the presence of the Babinski reflex in newborns and its disappearance during the first 2 years of life.

Histogenesis of the brainstem and cerebellum

At the level of the fourth ventricle, the various zones of the hindbrain are arranged in a lateral-to-medial sequence (somatosensory–viscerosensory–visceromotor–somatomotor). In the hindbrain, proneurons not only migrate radially, as in the spinal cord, but also tangentially and longitudinally. This complex migration course and the growth of fibre tracts lead to further changes of the lateral-to-medial and dorsal-to-ventral ‘displacements’ of cranial nerve nuclei (for example, the facial nucleus) in the adult.

At the level of the cerebellar anlage, the undifferentiated matrix cells form two major zones—a larger ventricular matrix zone and a smaller, most dorsally positioned upper rhombic lip zone. From the upper rhombic lip zone, a first wave of progenitor cells migrate between weeks 10 and 11, which sequentially express *Pax6*, *TBR2*, and *TBR1*, and form a transitory peripheral zone before migrating

down to a position where the adult cerebellar nuclei with their glutamatergic neurons are found (Fig. 11.3a, b). A second wave from the upper rhombic lip zone leads to the formation of an external granular layer (dotted arrow in Fig. 11.3a). Cells in this layer remain mitotically active long after birth. Thus, the external granular layer is a major source of cells for the adult cerebellum. From this layer, cells migrate to form the internal granular layer of the adult cerebellum, with its small and abundant granular cells and the somewhat larger and less abundant Golgi cells. Proneurons from the external granular layer also give rise to the basket and star cells of the adult molecular layer (Fig. 11.3a, b).

A second source of progenitor cells is located around the ventricle, that is, the ventricular matrix zone. The progenitor cells begin to migrate during weeks 12 and 13 along radially extended glial cells—Bergmann glia—into a region below the external granular layer (Fig. 11.3a) where they mature into GABA (gamma aminobutyric acid)-ergic Purkinje cells of the ganglionic layer of the adult cerebellar cortex (Fig. 11.3b). Therefore, the cerebellum originates out of two major migration streams, one starting in the ventricular matrix zone and the other one originating in the external granular layer. Migration of cerebellar proneurons is not completed until the first postnatal year. During weeks 16 and 26, synapses develop and afferent fibre systems begin to form. The external granular layer finally disappears during the first 2 years of

life, leaving the three-layered structure (molecular, ganglionic, and internal granular layers) of the adult cerebellar cortex.

Histogenesis of the cerebral cortex, basal ganglia, amygdala, and basal forebrain

Initially, the entire wall of the hemispheric vesicle consists of very densely packed mitotic cells. These cells undergo more than 28 mitotic rounds in the human brain [7]. In week 5, an inner cell-dense *periventricular zone* and an outer cell-poor *marginal zone* can be recognized. During week 6, the first post-mitotic proneurons leave the inner periventricular zone and form an *intermediate (mantle) zone* between the marginal and periventricular zones. By the end of week 6, the periventricular zone is further subdivided into a cell-dense *ventricular zone* and a less cell-dense *subventricular zone*.

During week 8, the *cortical plate* between the marginal and intermediate zones is formed by proneurons which have migrated along *radial glial cells* from the ventricular and subventricular zones through the intermediate zone (Fig. 11.4a) [6–10]. A single radial glial cell can span the entire distance between the ventricular and pial surfaces. As the proneurons ‘climb’ to the *cortical plate* along the processes of the radial glial cell, they produce a vertically oriented cortical cell column. This *radial migration* of immature neurons ultimately leads to the formation of cortical layers II to VI, and these proneurons differentiate into the various types of glutamatergic pyramidal neurons in the adult cerebral cortex. A prototype of the structural segregation of the cerebral cortex into numerous areas in the adult brain is already preformed during this migration [11]. A further feature of migration is the *inside-to-outside layering* of the immature, radially migrating

neurons. The earliest-born neurons are found in the deepest layers, and the latest in the most superficial layers of the cortical plate. Thus, adult layers V and VI of the cerebral cortex are generated before layer IV, and layer IV is generated before layers III and II (Fig. 11.4b). The inside-out layering process is controlled by the extracellular matrix glycoprotein *reelin*, expressed in the Cajal-Retzius cells of the marginal zone. When cortical proneurons are migrating radially, *reelin* stops the approaching cells as they approach the marginal zone. The next wave of migrating cells moves through the first already ‘immobilized’ wave and is brought to halt again near the marginal zone. This process continues until the production of proneurons is exhausted, and thus migration is terminated. Therefore, *reelin* is important for the control of the inside-to-outside layering of the cortex [7]. Loss of *reelin* leads to severe disturbances of the normal layering of the cerebral cortex. In addition to *reelin*, the microtubule regulator protein LIS1, the neuronal migration protein doublecortin DCX, and the tumour suppressor protein p73 are also crucial factors for the normal migration of proneurons.

At the same time, tangential migration of immature cells born in the ganglionic eminence and the preoptic area (PoA) in the subpallium takes place. The ganglionic eminence can be subdivided into a medial (MGE) and a lateral ganglionic eminence (LGE) at more rostral levels, which merge to the caudal ganglionic eminence (CGE) caudally. These immature cells migrate from the MGE, CGE, and PoA through the marginal and intermediate zones into the cortical plate (Fig. 11.5) and develop into the inhibitory interneurons of the adult cerebral cortex [7, 12]. The cells stemming from the dorsal part of the MGE represent 60% of the later cortical interneurons, that is, the parvalbumin-positive basket and chandelier cells, whereas the ventral part of the MGE generates the somatostatin-positive

Fig. 11.4 (see Colour Plate section) Histogenesis and radial migration in the cerebral cortex. (a) Development in the fetal hemispheric wall based on recent data [48, 54–56, 62, 63]. (b) Adult cortical layering in the human neopallium. I–VI, cortical layers; EP, ependymal layer; cp, cortical plate; isvz, inner subventricular zone; iz, intermediate zone with the first arriving nerve fibres establishing connection with immature neurons; mz, marginal zone; sp, subplate; osvz, outer subventricular zone; vz, ventricular zone; WM, white matter.

Fig. 11.5 (see Colour Plate section) Schematic drawing of the precursor regions of inhibitory neurons later found in the cerebral cortex, basal ganglia, amygdala, and basal forebrain [64]. Precursor regions: CGE, caudal ganglionic eminence; DG, diagonal area; LGE, lateral ganglionic eminence; MGE, medial ganglionic eminence; PoA, preoptic area. Transcription factors: Dbx1, developing brain homeobox protein 1; Dlx2, Distal-less protein 2; Nkx2.1, thyroid transcription factor 1; Nr2f2, ligand-activated transcription factor Nr2f2. interneurons, mainly Martinotti cells [13–16]. The CGE gives rise to about 30% of the later cortical interneurons, which include calretinin and vasoactive inhibitory polypeptide-expressing bipolar and double bouquet cells, as well as reelin-expressing neurogliaform and multipolar cells [17–19]. The cells originating in the PoA contribute to 10% of the cortical interneurons and are represented in all groups of GABAergic interneurons. They all are derived from progenitor cells expressing the developing brain homeobox protein 1 (Dbx1) [16, 20]. Additionally, oligodendrocyte precursor cells migrate from the PoA to the pallium and subpallial target regions [21]. Therefore, the cells of the cerebral cortex have, like those of the cerebellar cortex, two different sources. In the case of the cerebral cortex, the sources are the ventricular and subventricular zones for the glutamatergic pyramidal neurons, and the MGE and CGE, as well as the PoA, for the inhibitory interneurons.

Although interneurons are mainly born in the ganglionic eminence and have completed their tangential migration by the end of fetal development [7, 12], a small number of perinatally born neurons which express doublecortin DCX and markers of interneurons are found during the first 2–5 months of life in the subventricular zone of the lateral ventricles [22]. Some of these young neurons migrate tangentially along the ventricular wall, while others move radially through the developing white matter into the overlying cortex where they develop into GABAergic interneurons, which are thought to contribute to developmental plasticity [22].

The LGE is the precursor region of GABAergic projection neurons of the striatum and pallidum [23, 24], and the MGE of those of the striatum and pallidum [25, 26]. The CGE develops into the larger subpallial part of the amygdala, although the MGE, LGE, CGE, and PoA also contribute precursor cells to the amygdala [23, 27–29]. The progenitor cells from the diagonal area (Fig. 11.5) migrate into the subcortical regions and develop into the adult cholinergic neurons of the basal forebrain and striatum [25, 27].

Regional differences in the development of the cortical plate subdivide the hemisphere into segments. The lateral segment, with a well-developed cortical plate and *presubplate*, develops into the *neocortex*. The mediodorsal segment, with a wide marginal zone and a thin, folded cortical plate, develops into the *archicortex*, including the hippocampus. The mediobasal segment, with its inconspicuously developed cortical plate, is the precursor of the *palaecortex*. The basolateral segment, that is, the ganglionic eminence, generates cortical interneurons and develops into the corpus striatum, amygdala, and septum.

During weeks 10 and 12, the axons of serotonergic and noradrenergic neurons contribute to the first synapses in the marginal and presubplate zones where neurotrophin receptors are expressed. During the following 3 weeks, the subplate zone develops, as axons grow in from the basal forebrain and thalamus, dendrites enlarge, and synapses form. From weeks 16–24, the cortical *anlage* has a small marginal zone, a wide cell-dense cortical plate, and a very wide and less cell-dense *subplate*.

Transformation into the adult neocortical pattern starts between weeks 25 and 34, as migration and proliferation of proneurons diminish. Dendrites begin to differentiate, and synapses begin to develop in the deepest cortical layers, progressing to the most superficial layer. Before birth, six cortical layers can be recognized in all regions of the neocortex. In the region of the motor cortex, layer IV (inner granular layer) is invaded by pyramidal cells during the postnatal period, to such a degree that this layer becomes inconspicuous. Therefore, the motor cortex has been classified as five-layered, agranular neocortex [30], although the typical granular cells of layer IV could be demonstrated between the pyramidal cells [31, 32]. Shortly before birth, the subplate, the subventricular zone, and most of the ventricular zone disappear; neuronal proliferation ceases, and the intermediate zone is transformed into the white matter of the pallium. The rest of the ventricular zone contributes to the ependymal layer of the ventricular surface.

Dendritic and axonal differentiation continue after birth and into adult life, and their time courses differ across brain regions. Myelination of the cortical–vestibular system is finished shortly before birth; that of the somatosensory, visual, auditory, pyramidal, and extra-pyramidal fibre tracts is nearly complete by the end of the third postnatal year, and that of the associative fibre tracts in the cerebral hemispheres is continued until the second decade [33, 34]. Although synaptic density in neonatal brains is comparable to that found in adults, synaptogenesis continues after birth, reaches a maximum during the first postnatal year, and proceeds at a lower rate during childhood. The peak period of synapse formation in the primary visual cortex is reached between 3 and 4 months, whereas in the prefrontal cortex, it occurs at around 8 months of age [35, 36]. The key change in synapses after birth, however, is pruning, that is, the process of selective elimination of excess synapses, which is essential for the balance between

excitatory and inhibitory synapses and for the normal development of functional neural circuits. Developmental pruning is initiated during late fetal stages; it increases considerably shortly after birth and continues into puberty, when synaptic density stabilizes at adult levels. Pruning occurs earlier in sensorimotor areas than in association cortices.

Microglia play a role in the pruning process, and their activity is modulated by the initiating protein of the classical complement cascade (C1q) and the complement cascade components 3 and 4 (C3 and C4, respectively), as well as the microglial complement receptor 3 (CR3) [37–40]. Early loss of hippocampal synapses, as a result of an abnormally high C1q expression during development, was reported in a mouse model of Alzheimer's disease [40], and the low synapse density found in the brain of schizophrenics has been associated with excessive C4 activity during development [41–43], highlighting the importance of normal pruning process for correct neurodevelopment.

Cortical folding

After the appearance of the lateral fissure, the neocortical surface develops many additional sulci and gyri during the fetal period (Fig. 11.6). The central, collateral, cingulate, parieto-occipital, superior temporal, and calcarine sulci appear between weeks 16 and 21, followed by the pre- and post-central, frontal, temporal, and intraparietal sulci. Highly variable secondary and tertiary sulci develop between week 29 and birth, when all sulci have been formed [44, 45]. Although all gyri and sulci are present at birth, the depth of the sulci increases until two-thirds of the cortical surface is hidden in them in the adult stage [44]. Measurements of the intensity of cortical folding show that gyrification is greatest in the regions where association cortices are found, particularly in the posterior

prefrontal, parietal, lateral temporal, and occipito-temporal cortices and the cuneus and precuneus (Fig. 11.7b) [44, 46].

The reasons for the formation of gyri in many mammalian brains, including the human brain, are not completely understood. Since the vertical cell columns positioned side by side represent a basic organizational principle of the cerebral cortex, growth of the cortex inevitably leads to a considerable enlargement of the cortical surface. A large unfolded cortical surface would have two major disadvantages: (1) the volume of the skull would increase to such a degree during fetal development that a normal delivery would be impossible; and (2) the distance between cortical regions interconnected by intrahemispheric projection fibres would increase and, with it, the information transmission time. Cortical folding therefore allows a maximal cortical surface in a minimal volume, and an optimization of the speed of neural transmission between cortical areas. This has led to speculations about the relationship between the growing brain surface and the skull size at birth. A large brain surface must be folded in order to minimize the brain diameter and thus enable a minimal skull diameter at the time of birth. In fact, a comparison between the growth of brain weight and cortical folding during human lifespan shows that the increase in cortical folding clearly precedes that of brain weight before and after birth (Fig. 11.7a). This, however, does not explain the mechanisms of cortical folding. Presently, the two most widely discussed hypotheses are the *mechanical tension hypothesis* [47] and the *grey matter hypothesis* [48].

The biophysical basis of the *mechanical tension hypothesis* are the three-dimensional courses and the viscoelastic properties of fibre tracts [47, 49, 50]. The first fibre tracts between cortical and other brain regions are already visible during subplate development and maintained during migration. More tangentially organized cortico-cortical than radially organized cortico-subcortical connections are found in the human brain. Therefore, the tension hypothesis predicts

Fig. 11.6 Drawings of coronal sections through a fetal brain during the 30th week of gestation. (a) A newborn brain and (b) an adult brain, (c) showing the increase in cortical folding.

an outward folding caused by strong cortico-cortical and weak cortico-subcortical connections [47]. However, tension is not found across developing gyri [51]. Despite this finding, regional variations in tension can shape the folding pattern and its correlation with the spatial organization of the connectome [52, 53]. Using computational modelling, it was demonstrated that differential growth of cortical sites drives folding, consistent with the folding geometry and stress distribution [51]. In summary, the tension-based hypothesis explains a major factor of the mechanisms behind cortical folding.

The *grey matter hypothesis* is founded on the role of the subventricular zone as a precursor domain of a new type of radial glia cells, that is, the intermediate radial glia cells (IRGCs). The subventricular zone of the fetal hemisphere (Fig. 11.4a) consists of an inner (isvz) and an outer (osvz) subventricular zone in human brains [54, 55]. The osvz contains neural stem and intermediate progenitor cells, becomes the predominant proliferative zone in the developing human brain, and expands considerably between

gestational weeks 11–16 in humans [56], just before the beginning of cortical folding. Additionally, a self-amplifying progenitor cell has recently been found in the osvz. This IRGC generates a radially oriented scaffold, in addition to that formed by the classical bipolar radial glia cells (Fig. 11.4b). This way, the osvz can modify the trajectory of migrating proneurons. An experimentally induced reduction of proliferation in the osvz causes a reduced cortical surface area and reduced folding [55]. Thus, proliferation of IRGCs could play an important role in the folding process of the fetal cortex [48, 55, 57] (for a recent review, see [58]).

The subplate zone (SP) reaches its largest extension in the region of the late-maturing and folding association cortices. During fetal development, transient cortico-cortical and callosal connections are found in the SP zone, before they enter the cortical plate [59]. The long, enduring growth of the SP zone and the entire brain (Fig. 11.7a), the regional heterochronicity of cortical folding [45], and particularly the early connections in the SP zone may contribute

to mechanical tensions, resulting in the late-appearing, numerous gyri in multimodal association regions. The differential growth of cortical layers may also contribute to cortical folding [60]. Since the growth of the supragranular layers exceeds that of the infragranular layers, folding could be a result of this differential growth process, but the regionally different proportions between supra- and infragranular layers have not been comprehensively studied and precisely related to regions of high or low cortical folding. Finally, previous reports do not support a simple relationship between gyrification and the total number of cortical neurons or the cortical volume. Instead, a recent study demonstrates a universal scaling between cortical folding as a function of the product of the cortical surface area and the square root of cortical thickness in a large sample of mammalian gyrencephalic, as well as lissencephalic, brains [61].

Neuroimaging technologies

Mark Woolrich, Mark Jenkinson, and Clare Mackay

Introduction

Brain imaging provides a window into the living brain and is an increasingly essential tool for experimental medicine in psychiatry. The inaccessibility of central nervous system tissues to biopsy and the need to study the ‘system’, and not just the cell, make advanced brain imaging central to uncovering the pathophysiology, discovering and evaluating new targets, developing and testing the efficacy of drugs, and developing biomarkers for diagnosis, patient stratification, and therapeutic monitoring. Here, we introduce the three technical domains by which we can assay brain structure and function: magnetic resonance imaging (MRI), molecular imaging (positron emission tomography (PET), and single-photon emission computed tomography (SPECT)); electrophysiology [electroencephalography (EEG)]; and magnetoencephalography (MEG). Each of the imaging modalities has its own strengths and limitations, and the modalities should be regarded as complementary, rather than competing. Typically, the signal that is detected is an average of tens of thousands of cells. Nevertheless, imaging techniques are sensitive to everything, from molecular concentrations up to whole system dynamics, making the essential link between the cell and the system. [Table 12.1](#) gives an overview of the sensitivity of each imaging modality to aspects of neurophysiology.

Magnetic resonance imaging

One of the most widely used and flexible tools for neuroimaging studies is MRI. This imaging method is non-invasive, causes no tissue damage, and can provide high-quality images of brain anatomy, with excellent soft tissue contrast (structural MRI), or for measuring properties of axonal architecture in the white matter (diffusion MRI), or for detecting neuronal activity (functional MRI). Spatial resolution for MRI is in the order of a millimetre, and MRI scanners are readily available in both clinical and research settings.

Principles of MRI

MRI is based on magnetic interactions with specific nuclei, using the principle of nuclear magnetic resonance (NMR). Although NMR relies on properties of the nuclei within the atoms, it interacts in a way that does not harm tissue.

Two types of magnetic fields are important in MRI: (1) strong static B_0 field; and (2) radiofrequency (RF) fields. The B_0 field is created by the large, superconducting coil that defines the strength of the scanner; for instance, a 3T scanner has a B_0 field of 3 tesla (T). Both 1.5T and 3T scanners are common in clinical environments, while 3T and 7T scanners are more common for research. Higher-field scanners are advantageous, as they can reduce noise and improve spatial resolution.

RF fields are used to manipulate the magnetization of molecules in the brain. The magnetization can then be detected and measured by the MRI scanner to produce images. For most neuroimaging MRI applications, the RF is tuned to manipulate hydrogen nuclei in water molecules because of their high abundance in all biological tissues. Structural, functional, and diffusion MRI work by manipulating the magnetization in different ways to make it sensitive to particular microscopic properties of water and its environment.

Overview of acquisition and analysis

MRI acquisitions can be optimized for studies by varying options, for example, the type (modality) of image (for example, functional, diffusion, etc.) and various parameters (for example, echo time). However, some noise and artefacts are common in MRI, caused by scanner imperfections or the physics/physiology of subjects such as head motion. Most MRI artefacts are rare, but some are common (for example, head motion, bias field), and analysis strategies are needed to reduce their effects.

Almost all neuroimaging research studies involve groups of subjects, to infer results about the wider population, accounting for between-subject variation. Statistical analysis is usually conducted separately on each voxel (three-dimensional pixel), with corrections needed for the multiple statistical tests this requires, and results are generated in the form of statistical maps that are displayed as coloured overlays on brain images. These analyses require that all subjects are spatially aligned (registered) together, for anatomical consistency.

Structural MRI

The most common MRI modality is structural imaging, which is routinely used in both clinical practice and research studies. It provides images of brain anatomy, with excellent soft tissue contrast,

Table 12.1 The sensitivity of various imaging modalities in aspects of neurophysiology

Scale	Imaging modality	Examples
Neurotransmitters	PET, MRS	Radiotracers can probe dopamine and serotonin systems, including labels for synthesis capacity, receptors, and transporters. The glutamate system also has PET ligands. Both GABA and glutamate can be indirectly assayed with high-field MRS
Protein aggregates	PET	In ageing and dementia, tracers for amyloid plaques are now commercially available and novel tracers are in development for tau and alpha-synuclein
Action potentials	MEG/EEG	Synaptic potentials in the brain give rise to measurable changes in electrical and magnetic fields that are measurable outside the surface of the head
Metabolism	PET, MRI	PET radiotracers provide relatively direct measurement of blood flow, blood volume, and oxygen/glucose metabolism. MRI techniques, such as arterial spin labelling, can produce similar measures non-invasively
Individual brain structures	MRI	Structural MRI typically has a resolution of 1 mm ³ and good tissue contrast for examining individual brain structures
Tissue integrity	MRI	MRI provides contrast mechanisms to explore tissue integrity, including relaxometry and susceptibility mapping
White matter connectivity	MRI	Diffusion-weighted or diffusion tensor imaging provides indirect estimates of white matter pathways
Regional brain function	MRI, PET, M/EEG	PET has largely been replaced by fMRI for studying brain function. fMRI provides good spatial detail, but at low temporal resolution (seconds). This is complemented well by the high temporal resolution (milliseconds) of M/EEG
Brain networks	MRI, M/EEG	Brain connectomics is a new and growing field, enabling the use of neuroimaging data to model brain network dynamics

typical spatial resolution of 1 mm, and typical acquisition times of 3–15 minutes. In clinical practice, radiologists examine these images for signs of pathology for disease diagnosis. In neuroimaging research, images are either analysed directly to extract quantitative measures from them (for example, hippocampal volume) or used as part of other analysis pipelines (for example, for alignment in functional studies).

Measurement principles

Most structural images are based on three basic properties: proton density (PD), and T₁ and T₂ relaxation times. Each of these influences the signal that is received from the hydrogen nuclei in water molecules. Proton density is effectively the density of water in tissues, and the received signal is proportional to this, although this alone creates weak tissue contrast for grey and white matter.

The relaxation times T₁ and T₂ are related to different processes that affect magnetization within water molecules. Many factors affect T₁ and T₂ relaxation times such as molecular tumbling, chemical environment, geometry of nearby cells/structures, etc. Hence

relaxation times are a complicated function of tissue properties but depend on tissue composition (for example, proportion of neuronal bodies vs axons). These differences in relaxation time provide superior tissue contrast for grey and white matter.

Acquisitions

Many types of structural MRI acquisition exist, with PD, T₁-weighted, T₂-weighted, and fluid-attenuated inversion recovery (FLAIR) being the most common (Fig. 12.1). This variety is possible because of the detailed timings of fields applied by the scanner, specified by an MRI pulse sequence. These settings enable the influence of the T₁ and T₂ relaxation processes on the intensity to be separately adjusted.

For example, for a PD image, the sequence is set such that T₁ and T₂ relaxation times have minimal effect and the primary contrast (intensity difference between tissues) is driven by the PD. For a T₁-weighted image (which is the most commonly acquired structural MRI scan), the sequence is set to enhance the effect of T₁ relaxation, while minimizing the effect of T₂ relaxation, although

Fig. 12.1 Examples of the variety of structural images that can be acquired with MRI. From left: T₁-weighted, T₂-weighted, fluid-attenuated inversion recovery (FLAIR), FLAIR again, susceptibility-weighted gradient echo (SWI). Different types are sensitive to different tissue characteristics, particularly pathological lesions and tissues, and so it is common to get a range of structural images for each subject.

PD weighting remains. Another commonly acquired structural image is FLAIR, which attenuates signal from the cerebrospinal fluid (CSF), to reduce CSF contamination and highlight pathological lesions.

Limitations and artefacts

Noise is common across all MRI modalities, and this constrains the accuracy of quantitative results and limits statistical power. Consequently, research studies typically require groups of 20 subjects or more.

Another common limitation is the partial volume effect (PVE) due to the finite spatial resolution in MRI—typically between 0.5 and 1mm for structural images. At this scale, a voxel often contains several tissues (for example, in the cortical folds, voxels often contain grey matter and some CSF or white matter). The voxel intensity is then a mixture of tissue intensities, weighted according to the proportion of the voxel volume they occupy. This results in the borders of structures appearing blurry, limiting the precision of boundary localization and volume calculations.

Magnetic resonance intensity values are arbitrarily scaled, and not quantitative. Thus, image analysis techniques are necessary to estimate quantitative information, for example, the volume of grey matter.

It is essential to check for artefacts in MRI studies and keep in mind existing artefacts when interpreting results. One common artefact is bias field, caused by inhomogeneities in the RF fields, and results in large areas of the image being artificially brighter or darker than they should be. This artefact, unless extremely strong, is compensated for very well by analysis methods.

Analysis

Several different types of analysis are done with structural MRI, some specific for studying anatomical changes and some useful for other experiments such as diffusion MRI, functional MRI, or other modalities like PET, MEG, and EEG.

Registration is a fundamental analysis tool and involves aligning one image with another (for example, two images of the same subject or different subjects). Although modern registration methods work well generally, they cannot overcome some fundamental biological ambiguities such as aligning disparate folding patterns (for example, single vs double gyri, as is common in the cingulate).

Segmentation is another fundamental analysis tool, which involves determining the location of anatomical tissues or structures in the image. The two main types of segmentation are tissue-type segmentation and structural segmentation. Tissue-type segmentation aims to determine where the main ‘tissues’ (grey matter, white matter, and CSF) are in the image. The result of tissue-type segmentation is typically an image (or a map) where each voxel is assigned a tissue label.

Structural segmentation can identify specific anatomical structures (for example, hippocampus) or the grey matter cortex. Cortical segmentation, or modelling, usually outputs a surface, rather than a voxel-based, image, as this more accurately captures cortical folding and provides clearer ways of displaying the anatomy (Fig. 12.2). Notably, surface-based analysis of functional data is a powerful and growing alternative to voxel-based methods.

Anatomical analysis usually measures differences in structural shape or volume. Cortical thickness is one quantitative measure, and analysing thickness differences is done between groups or with

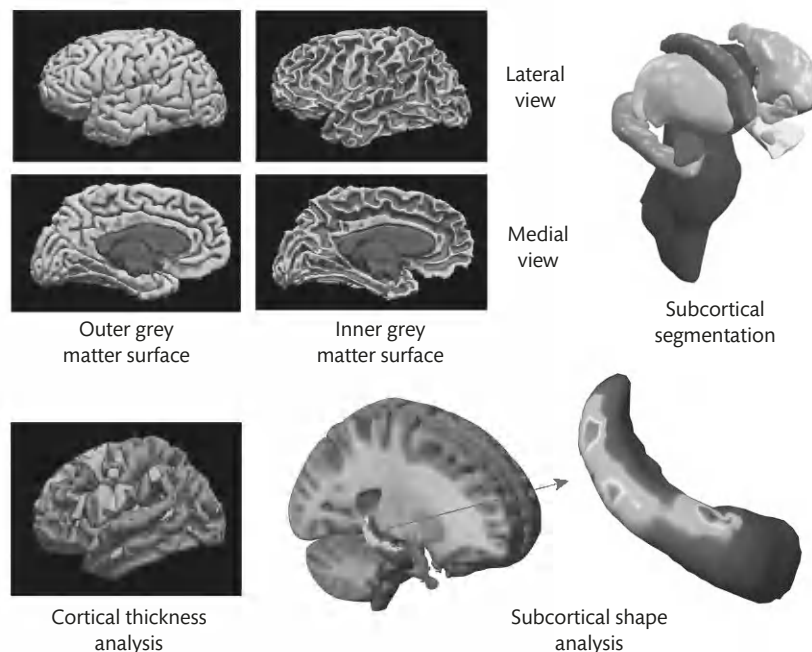

Fig. 12.2 (see Colour Plate section) Examples of structural segmentation and analysis. Top left shows cortical segmentation (left hemisphere) where the inner and outer surfaces of the cortical grey matter are modelled, and from this, the cortical thickness can be calculated and analysed to show areas of differing thickness between groups (bottom left). Top right shows a set of subcortical structures (for example, caudate, hippocampus, brainstem, etc.), and bottom right shows an example of a shape analysis (hippocampus) displaying localized areas of difference in the shape between a patient and control group.

respect to a covariate of interest (for example, disability score). Such analyses use statistical methods to produce a map of significant results—normally displayed as a colour overlay (Fig. 12.2).

Deep grey matter structure segmentations are typically summarized by volume measures or shape characteristics. In shape analysis, each localized region of the boundary is examined to find changes in position that relate to group differences or covariates of interest. This results in a map of significant results at the boundary of the structure (Fig. 12.2).

Whole brain voxel-wise analysis can be used to find anatomical differences at any location, for example, voxel-based morphometry (VBM) [1]. This combines tissue-type segmentation and registration to quantify the amount of 'local' grey matter volume for voxel-wise analysis (Fig. 12.3).

Diffusion MRI

White matter appears fairly uniform in structural MR images, whereas diffusion MRI provides richer information about micro-structure and anatomical connectivity.

Measurement principles

Axonal fibre bundles restrict how water molecules can diffuse, and this forms the basis of diffusion MRI. Both intracellular and extracellular water in a fibre bundle is less likely to encounter barriers when moving along the direction of the axons, as opposed to moving in other directions. Thus, maximum diffusion occurs along the direction of the axons.

To obtain a measurable signal, it is necessary for a large number of water molecules to behave in the same way, as a voxel is much bigger than an axon diameter. Therefore, only sizeable fibre bundles produce detectable signals. The amount of diffusion, in all directions, is also affected by axon diameter, packing density, and myelination, and diffusion MRI is a sensitive marker of changes in these micro-structural properties.

Acquisition

Diffusion MRI uses special *diffusion-encoding gradients* (magnetic fields that change in strength along a particular direction) in order

to measure the diffusion of water molecules. These gradients lead to a reduction in the signal from water that is diffusing in this encoding direction, and the amount of intensity reduction depends on the amount of diffusion.

A single diffusion magnetic resonance image only provides information about diffusion in one direction. Therefore, many images, with many different encoding directions, are required to build up a full picture of the diffusion. Acquiring many images in a short time requires fast imaging sequences such as *echo planar imaging* (EPI). Using EPI acquisitions and other accelerations, such as parallel imaging methods [for example, sensitivity encoding (SENSE) or generalized autocalibrating partial parallel acquisition (GRAPPA)] and/or simultaneous multi-slice methods, enables whole brain images to be acquired in a few seconds or less. In neuroimaging research, the number of encoding directions acquired can be up to 200, with acquisition times of around 5–15 minutes. Having a large number of encoding directions is required for tracing anatomical connections; however, this is not often used in clinical practice where a small number of directions (for example, 3–5) is often used for very short acquisitions.

Limitations and artefacts

Fast imaging sequences and diffusion encoding come with some drawbacks: lower spatial resolution (around 2–3 mm) and increased artefacts. Diffusion MRI artefacts include eddy current distortions and B_0 inhomogeneity distortions and motion, on top of artefacts that also occur in structural MRI. Many artefacts induce geometric distortions that require specialized pre-processing correction tools.

Analysis

Pre-processing steps are applied to correct for geometric distortions, though correcting for B_0 inhomogeneities requires separate scans (field maps or blip-up–blip-down pairs) to be acquired. After pre-processing, models of the diffusion process are fit to the intensities, to extract information about the physical diffusion of water molecules. One common model is the tensor model (as in *diffusion tensor imaging* or *DTI*), which assumes that the diffusion in different

Fig. 12.3 (see Colour Plate section) Example of standard analysis techniques in patients with schizophrenia (a–c) and carriers of the VAL and MET alleles of the *COMT* gene (d). (a) VBM analysis with areas of significant grey matter reduction in schizophrenia relative to controls shown in red–yellow. (b) fMRI using a letter fluency task showing significant areas of reduced activity in schizophrenia, relative to controls. (c) Diffusion MRI-based TBSS (tract-based spatial statistics) analysis of the same patients with schizophrenia, relative to controls, showing reduced fractional anisotropy in the corpus callosum and forceps major. (d) Resting fMRI analysis of healthy VAL and MET allele homozygotes of the *COMT* gene, showing greater functional connectivity in VAL carriers, relative to METs.

Reproduced under the Creative Commons Attribution License CC BY 3.0.

directions can be modelled using a spatial Gaussian probability, often visualized by an ellipsoid. Each voxel is fit separately, resulting in a set of tensor parameters per voxel, that is, a separate map/image of each parameter is obtained. However, this model is not very accurate for voxels containing two or more fibre bundles running in different directions (for example, crossing fibres).

From the tensor parameters, several key values are calculated such as mean diffusivity (MD) (average diffusion in all directions) and fractional anisotropy (FA), a measure of how diffusion varies with direction. The MD can be broken down into axial diffusivity (AD) and radial diffusivity (RD), which quantify the diffusion along the direction of the fibre bundle (AD) and perpendicular to it (RD). All of these quantities are surrogates of biological properties such as axon size, density, and myelination, but independent of direction. Changes in these quantities can help support or refute hypotheses relating to underlying biological changes, but they need to be interpreted carefully.

Analysing changes in DTI measures requires spatial alignment, but structural images are featureless within white matter, and therefore, registrations are based on diffusion information (for example, using original diffusion or FA images). A widely used method for such analyses is tract-based spatial statistics (TBSS), which aligns the centre of major white matter tracts, providing results only in tract centres (the skeleton) where alignment is the most reliable (Fig. 12.3) [2].

Tractography is an alternative analysis tool that traces out the pathways of the major axonal fibre bundles. Pre-processing is the same, but other models are sometimes used that can provide more precise estimates of the direction of the fibre bundle(s) and explicitly account for multiple fibres within a voxel. Information about the direction of fibre bundles is then used to trace out pathways; starting at a seed point and then moving, in small steps, along the locally estimated direction of fibre bundles, allowing entire pathways to be mapped out (Fig. 12.4).

Two main varieties of tractography algorithm exist: deterministic and probabilistic. Deterministic tractography uses a single estimate of direction (for each fibre) at each step. By using multiple seed points, a set of individual pathways, or streamlines, can be constructed, which are often displayed as an entire fibre tract. In probabilistic tractography, a probability distribution of directions is estimated at each voxel (for each fibre), in order to take into account noise and uncertainty.

Tractography outputs can be used to estimate anatomical connectivity matrices (the connectivity between a set of grey matter areas) or to map out the spatial location of tracts (used in presurgical planning) or as a way of parcellating other structures. The latter case—connectivity-based segmentation—is able to parcellate areas of the brain on the basis of where they are most ‘strongly’ connected, for example, segmenting thalamic nuclei based on connections to the cortex.

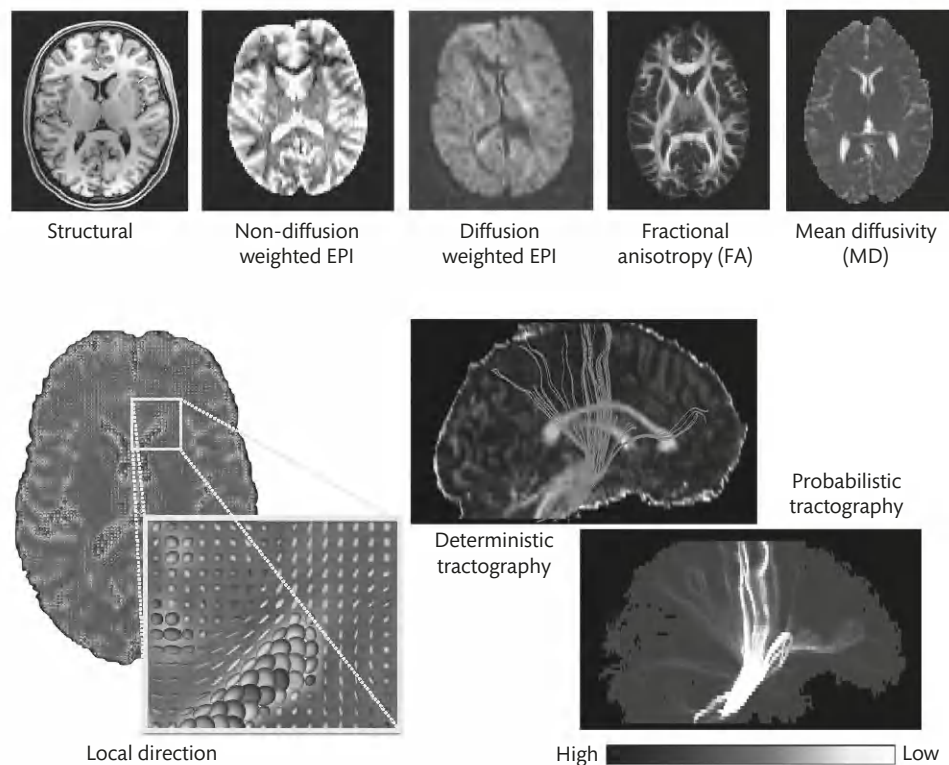

Fig. 12.4 (see Colour Plate section) Examples of diffusion MRI and analysis results. Top row shows a structural image (left) for comparison, along with a non-diffusion-weighted image and a single diffusion-weighted image. Many of these EPI-based images need to be acquired in a diffusion MRI study. The two images on the right of the top row show DTI-based measures calculated from the diffusion-weighted acquisitions, which are often used as surrogate measures of white matter microstructure. The bottom row shows an example of estimated white matter tract directions on the left (colour coding based on direction: red = left–right, green = anterior–posterior, blue = inferior–superior), and the tractography results based on these (right) using either deterministic or probabilistic methods for tracing major fibre pathways.

Functional MRI

Functional MRI (or fMRI) is sensitive to neuronal activity and has two main modes of use: task and resting state. In task fMRI, the participant performs a task in the scanner (for example, sensory, motor, cognitive), in order to determine the location and strength of brain activity related to the task. In resting state fMRI, no task is performed and the objective is to measure intrinsic characteristics of spontaneous brain activity such as functional connectivity between brain regions.

Measurement principles

fMRI measures neuronal activity indirectly via the BOLD (blood–oxygen level-dependent) effect, based on how activity changes the local concentration of deoxygenated haemoglobin. This is measurable because deoxygenated haemoglobin disturbs the magnetic field around it, reducing the signal from nearby water molecules. Notably, the haemodynamics lag considerably behind the electrical activity of neurons, with the signal peaking approximately 6 seconds after the electrical activity and taking approximately 20–30 seconds to return to the initial baseline level (Fig. 12.5).

Acquisitions

Measuring neuronal activity indirectly through the slow haemodynamics means that acquiring an image every few seconds is sufficient. This is typically achieved using gradient-echo EPI magnetic resonance images, tuned to detect signal changes caused by local magnetic field disturbances (which changes T_2^* relaxation). A typical fMRI acquisition will have a spatial resolution of 2–3 mm and a temporal resolution [also repetition time (TR), the time taken to acquire one image] of 1–3 seconds.

Limitations and artefacts

The signal in fMRI is a surrogate haemodynamic measure of neuronal activity, and precise timings in neuronal activity cannot be measured, making causality measurements extremely difficult. Furthermore, changes in fMRI signal between experimental or clinical conditions can be confounded by changes in the vasculature.

The artefacts in fMRI and diffusion are similar because they both use EPI. However, fMRI uses gradient-echo EPI (spin-echo used in diffusion), which causes signal loss in the inferior frontal and temporal areas, due to the proximity of air-filled sinuses and air cells.

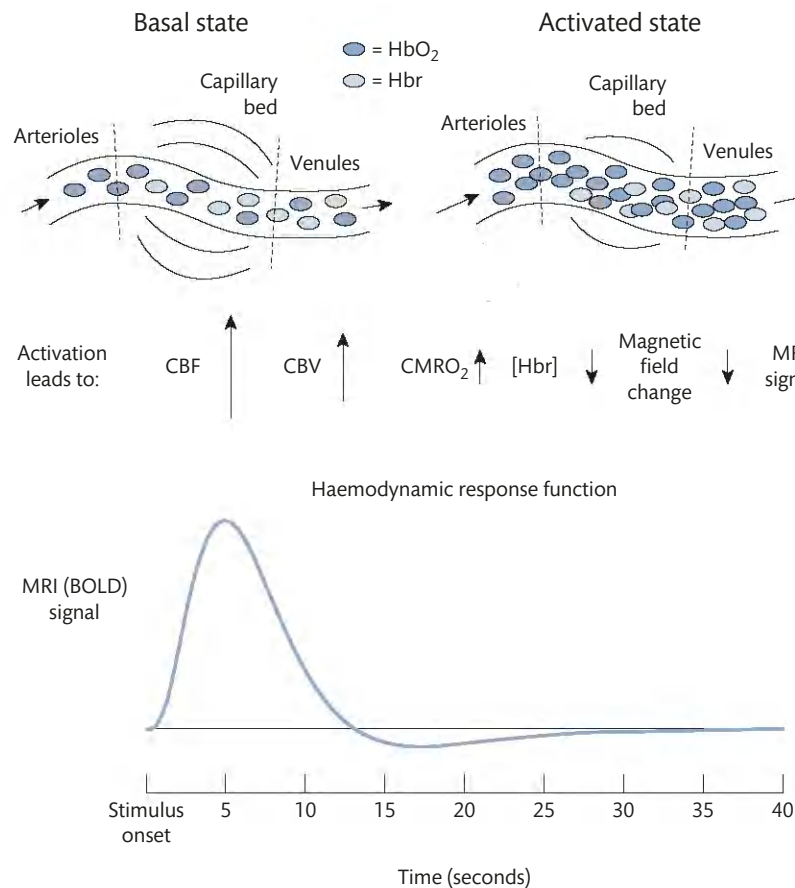

Fig. 12.5 Illustration of the BOLD (blood oxygenation level-dependent) signal used in fMRI. The top panel shows blood in a capillary within neuronal tissue that is in the basal (left) or activated state (right). Activity of the neurons increases both the cerebral blood flow (CBF) and the cerebral blood volume (CBV) in the tissue more than the oxygen extraction ($CMRO_2$), resulting in a net decrease in the concentration of deoxygenated haemoglobin (Hbr). Decreased Hbr leads to a greater MRI signal, as it disturbs the local magnetic fields less. The bottom panel demonstrates the typical dynamics of this signal (the haemodynamic response function or HRF) in response to a very short stimulus at time zero.

Adapted from Jenkinson M, Chappell M, *Introduction to Neuroimaging Analysis*, Copyright (2017), with permission from Oxford University Press.

Head motion effects are also a major confound in fMRI, requiring the use of specialized analysis strategies.

Analysis

Pipelines for fMRI analysis start with pre-processing steps for reducing artefacts or improving the signal-to-noise ratio (SNR). Many pipeline versions exist but share common elements, for example B_0 distortion correction, motion correction, slice-timing correction, spatial smoothing, and temporal filtering. Corrections for B_0 distortion and motion are broadly the same as for diffusion and still require an additional field map acquisition.

Slice-timing correction is needed in fMRI, since the images are acquired a slice at a time (or several slices at a time for multiband acquisitions), and timing of the analysis and acquisition must match. Spatial smoothing aims to improve the SNR but reduces the effective spatial resolution, and is sometimes avoided in high-quality data to maintain resolution. Temporal filtering removes signals that do not match the characteristics of neuronal signals such as very slow drifts caused by physical or physiological artefacts.

For task fMRI, a model is constructed that incorporates stimulus timings and the known haemodynamic properties to create a predicted response. These predicted responses to tasks are used in a multiple regression that is carried out separately in each voxel. The result is a spatial map showing brain areas that are significantly active (after correction for multiple statistical tests over many voxels) in response to particular tasks. The same framework can also be used to investigate how activation strength compares across differences in stimuli/tasks, groups, covariates, or experimental manipulations.

For resting state fMRI, the two common forms of analysis are: network matrix analysis and independent component analysis (ICA). In network matrix analysis, *functional connectivity*, defined as any measure of statistical dependency, is computed between all pairs of time series (brain activity over time) extracted from all brain regions of interest to build up a network matrix or graph. In fMRI, the most commonly used metric of functional connectivity is correlation. These matrices can then be analysed in various ways, including using graph theory. The analysis of network matrices is of great interest and an active neuroimaging research area.

In ICA, the data set is decomposed into a set of components (similar to principal component analysis), and each one contains a spatial map and time series (Fig. 12.6). Components may relate to neuronal signals, physiological noise, or artefacts. Each neuronally related component represents a set of brain regions that share, at least partially, a common time series. Importantly, certain components are reliably reproduced with recognizable spatial maps, often referred to (misleadingly) as ‘networks’ with specific names (for example, default mode network, dorsal attention network, etc.), and correspond well with the networks produced using a network matrix analysis approach.

Network analyses can also be used to ask how networks change with task. In general, analysis and interpretation of networks are a relatively new field, and much remains to be understood about functional connectivity. Nonetheless, many applications already exist, including the use of network features as disease biomarkers.

Other MRI modalities

The three main MRI research modalities have been described in detail, but the versatility of MRI goes beyond these. For example,

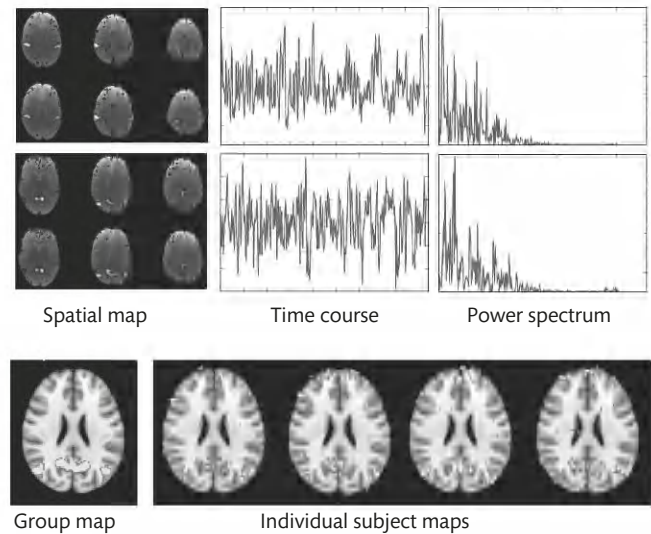

Fig. 12.6 (see Colour Plate section) Illustration of resting state networks. Top panel shows ICA components corresponding to two networks (motor and default mode in the first and second rows, respectively). These have spatial maps (left) that show the brain areas involved in each network (red-yellow), and time courses (middle) of fMRI signal fluctuations that are common across all parts of that network. The power spectra of the time courses (right) show low frequency fluctuations, characteristic of slow neuronally induced haemodynamic changes. Bottom panel shows an example of the spatial map of a resting state network (default mode network) estimated from a group of subjects (left) and from individual subjects (right). Features from these intrinsic networks can be analysed for differences across clinical populations or experimental conditions.

magnetization transfer (MT) can be used to detect white matter lesions; susceptibility-weighted imaging (SWI) is used to detect microbleeds or iron deposition; and arterial spin labelling (ASL) magnetically tags blood as an intrinsic contrast agent, providing quantitative measures of perfusion and cerebral blood flow and volume.

An MRI scanner can also be used to acquire information about molecular concentrations. Magnetic resonance spectroscopy (MRS) acquires signals from nuclei in molecules other than water, but their lower concentrations require reduced spatial resolution (several *centimetres*) to obtain sufficient signal, normally from one preselected region. Only signals from certain molecules can be separated by MRS [for example, GABA, *N*-acetyl aspartate (NAA)], which is a limitation, although higher-field scanners (for example, 7T) have greater specificity.

Molecular imaging

The vast majority of MRI-based research is based on contrasts that can be gleaned from manipulating the proton. The number of molecules that can be probed by emission tomography is far greater, limited only by the creativity of radiochemists and the substantial resources required to develop new tracers.

How does it work?

PET and SPECT both work on the same principle. A radiotracer is synthesized by adding a radioactive isotope to a molecule of interest. The tracer is injected into a participant who is then placed inside a PET or SPECT camera, and an image is formed that represents the rate of emission of positrons (PET) or gamma rays (SPECT) from a region of interest in the body. The number of PET isotopes is far greater than for SPECT, but SPECT technology is cheaper and more readily available (Fig. 12.7).

Radioisotopes

The radioisotopes most commonly used for SPECT are iodine-123 and technetium. For PET, the commonly used isotopes are oxygen-15 (^{15}O), carbon-11 (^{11}C), and fluorine-18 (^{18}F), which are manufactured in a particle accelerator (cyclotron). To develop a tracer, the radioisotope must be inserted into the molecule of interest in a way that does not impact the biology of the molecule and in small enough quantities that it does not become pharmacologically active in its own right. In biological compounds, it is relatively easy to insert (or exchange) an oxygen or carbon atom. However, the isotopes for ^{15}O and ^{11}C have very short half-lives (2 minutes and 20 minutes, respectively), meaning that for ^{11}C , the cyclotron must be proximal to the scanner, and for ^{15}O , the isotope must be piped directly from the cyclotron to radiochemistry and into the participant who is already lying in the scanner, with no delay. With its longer half-life, ^{18}F (half-life of 110 minutes) might be considered as the most convenient PET isotope, but the radiochemistry can be complex.

Image acquisition and analysis

Compared with the complex physics involved in MRI acquisition, PET and SPECT image acquisition are relatively straightforward. PET and SPECT 'scanners' are gamma cameras, with detectors arranged in a ring around the object of interest. PET radioisotopes all have unstable nuclei that will emit protons that rapidly collide

with an electron, causing an annihilation that generates two gamma rays (photons) with a separation angle of 180° . Two photons will be detected, and a 'line of response' used to localize the source of the annihilation (Fig. 12.7). Data are assimilated from tens of thousands of events, and an image of the relative distribution of the radiotracer in the sample is built up.

Analysis of SPECT images in clinical settings is either qualitative (radiologist's report) or semi-quantitative whereby a signal intensity is obtained from the region of interest and compared with a reference region where the signal is assumed to be unaffected by the experimental manipulation. PET data are amenable to more sophisticated analysis techniques. The unit of analysis is the 'binding potential', which is typically turned into a regional standard uptake value (SUVr) and can be mapped as either a static quantity obtained at a fixed time post-injection or a dynamic quantity with multiple image acquisitions showing both wash-in and washout of the tracer (Fig. 12.8).

PET can be fully quantitative if acquired with an arterial line *in situ*. The arterial input function, combined with metabolite measurement, can be used to produce a full arterial model. However, PET data do not contain any anatomical information, requiring the PET signal to be registered to, or acquired with, a structural scan. Modern PET cameras are usually combined with computed tomography (CT) scanners (PET/CT), and recently it has become possible to combine PET with MRI (PET-MR). PET-MR has advantages relating to the superior tissue contrast of magnetic resonance relative to CT, but there are also methodological hurdles to overcome. In particular, the signal from the annihilation event is attenuated by passing through the skull, and this can be relatively easily mapped using CT (which is, in essence, a 3-dimensional X-ray). MRI is insensitive to bone, so attenuation correction requires a more complex solution.

Radiotracers

The main innovations in PET come from the development of robust radiotracers by creating a ligand from a radioisotope and a

Fig. 12.7 How PET imaging works (similar for SPECT). The radioisotope is manufactured in a cyclotron and rapidly combined with the molecule of interest to create the tracer, which is injected into the patient. The patient is then positioned inside the PET scanner (gamma camera), which accumulates the data required to create the image.

Fig. 12.8 Signals obtained from semi-quantitative PET. Relative standard uptake units (SUVr) can be acquired from static data acquired at the optimal time post-injection (usually 40–90 minutes, depending on the tracer). Dynamic imaging requires long acquisition times but provides quantification of the pharmacokinetics of the tracer.

molecule of interest. The most commonly used PET radiotracer is fluorodeoxyglucose (FDG), a glucose analogue, labelled with ^{18}F , which is readily taken up by metabolically active cells. The resulting FDG-PET images represent regional glucose consumption (and thus metabolic activity), which is widely used in oncology because tumours are typically highly metabolically active. Both FDG and H_2^{15}O have been used as indirect measures of cerebral blood flow changes induced by neuronal activity in cognitive tasks. However, with fMRI being non-invasive, cheaper, and logistically simpler to implement, task-related PET has largely been consigned to history. FDG continues to be a useful tracer for assessment of metabolism, with particular application in dementia and neurodegeneration.

Neurotransmitter/receptor tracers

Tracers have also been developed for investigating neurotransmitter systems. Two good examples relevant to psychiatric research are the dopamine system in schizophrenia and the serotonin system in mood disorders. For dopamine, the best established PET tracers (for example, ^{11}C -raclopride and ^{18}F -fallypride) bind to D2 receptors and are sensitive to changes in the concentration of dopamine through competitive interaction. These tracers are important both for mechanistic studies (for example, reduced D2 receptors in schizophrenia [3]) and to investigate the pharmacokinetic effects of antipsychotic drugs (for example, receptor occupancy studies [4]). Tracers for the serotonin system include ^{11}C -MDL-1009 for 5-HT_{2A} receptors and ^{11}C -DASB for the 5-HT transporter and are helping to elucidate mechanisms of response to antidepressants [5].

Protein aggregate tracers

Pathological aggregated proteins are hallmarks of several neurodegenerative diseases, including Alzheimer's disease and dementia with Lewy bodies (DLB). By developing tracers sensitive to these aggregated proteins, it becomes possible to perform *in vivo* histology and vastly improve stratification for clinical trials [6].

Fig. 12.9 (see Colour Plate section) Examples of protein aggregate tracers for Alzheimer's disease.

Reproduced courtesy of Roger Gunn and Azadeh Firouzian.

Beta-amyloid plaques and tau tangles are the hallmarks of Alzheimer's disease (see Plate 6). PET with amyloid ligands is part of the leading edge in Alzheimer's disease research [7] and is fast becoming the 'standard' in clinical trials for disease modification. Hot on the heels of amyloid PET are the tau tracers, several of which are now in development [8]. Much international effort is also being spent on developing tracers for alpha-synuclein (the aggregated protein in Lewy bodies) and TDP-43 (hallmark of both fronto-temporal dementia and motor neuron disease) [6] (Fig. 12.9).

Non-invasive electrophysiology: EEG and MEG

MEG and EEG provide direct measures of neuronal activity, by recording the magnetic or electric fields that propagate outside of the head at millisecond-temporal resolution. As with fMRI, there are two main modes of use—task-based and resting state, both providing a non-invasive window on the brain, at the kind of fast subsecond timescales associated with typical cognition.

How it works

The different technologies used in MEG and EEG, and their relationship with the underlying electrophysiology, result in contrasting benefits between the two approaches (summarized in Table 12.1).

EEG

In EEG, the electric currents emanating from brain activity are measured by electrodes in contact with the scalp surface, with arrays of up to 256 electrodes typically housed within a fabric cap (Fig. 12.4). However, the currents measured at the scalp are limited by the distortive effects of the intervening structures in the head, which severely hamper efforts to localize the signal sources precisely. This forms one of the chief motivations for using the alternative technique of MEG, since magnetic fields pass through the dura, the skull, and the scalp relatively unaltered.

MEG

The magnetic fields produced by the brain are tiny, with field strengths of approximately 10 fT. The highly sensitive superconducting quantum interference device (SQUID) allows for detection of these tiny fields. Sensor arrays provide whole head coverage via a helmet containing up

Fig. 12.10 Left: subject wearing a 64-channel (electrode) EEG cap. Right: subject doing a visual stimulation study in an MEG scanner housing 306 sensors.

to 306 sensors, enveloped in cooling liquid helium. The subject's head is positioned underneath the helmet (Fig. 12.10).

What are we measuring?

In both MEG and EEG, the measured fields come from neuronal activity at the 'inputs' of neurons—the membrane potentials (also known as the post-synaptic, or local, field potentials), rather than at the 'outputs'—the action potentials. Furthermore, the activity produced by a single neuron is far too small to be detectable; instead signals must sum up over tens of thousands of neurons. This requires a population of neurons to be both temporally synchronous and spatially aligned, with their dendrites pointing in the same directions, such that their individual membrane potentials add up, rather than cancel out. Fortunately, within the cortex, populations of pyramidal neurons tend to fire synchronously and are arranged with their dendrites tending to extend in the same direction, perpendicular to the cortical surface.

Acquiring data

For EEG to work successfully, care needs to be taken to ensure good conductance between the electrodes and the scalp. This is often achieved by either soaking electrodes in a conducting fluid prior to fitting the cap (a 'wet' cap) or using conducting gels placed on each electrode.

MEG does not require contact between the sensors and the scalp; instead the subject's head is placed as close as comfort allows to the inner surface of the helmet of the scanner. The magnetic field generated by the brain is several orders of magnitude weaker than that of ambient electromagnetic noise, requiring scanners to be placed in magnetically shielded rooms (MSRs).

With both EEG and MEG, it is important that the location of the sensors with respect to subject's head is known, as this aids with mapping activity in the brain (source reconstruction) or with comparing results across subjects. In EEG, the locations of the electrodes are measured, for example by using a stylus pen, the position of which can be triangulated in space, with respect to some anatomical landmarks (for example, the ears and nose). In MEG, the scanner detects small magnetic coils placed at known locations on the subject's head. These can also be used to correct for head motion.

Data analysis

Both MEG and EEG analyses involve large amounts of data that often need substantial computing power to extract interpretable information from them.

Artefact cleaning

MEG and EEG recordings typically contain electromagnetic artefacts due to movement of the head or eyes (including saccades and blinking) and skeletal and cardiac muscle electromagnetic activity. To help with identifying artefacts, a combination of surface electro-oculography (EOG), infrared eye tracking, and electrocardiography (ECG) is often used. These recordings can be used in conjunction with techniques like ICA to identify and remove artefactual components in sensor recordings.

Source reconstruction

Recorded EEG and MEG data at each sensor location represent different weighted summations of the underlying brain activity. In many cases, this sensor-space description of neuronal activity may be sufficient to answer a particular neuroscientific question. Indeed, a large number of studies operate exclusively at this level (see Plate 7a).

Mapping the sources of neuronal activity in the brain (source reconstruction) is often desirable though and requires modelling the relationship between activity and measurable fields in the sensors. This model uses information about the location and geometry of different head structures (for example, scalp, skull, brain tissue) through which the fields pass and is inverted to estimate brain activity. However, the inversion is ill-posed, requiring additional constraints such as assuming the brain activity is sparse or smooth. The resulting spatial maps of brain activity typically have lower spatial resolution than fMRI, in the order of several millimetres (Fig. 12.11).

Experimental analysis

As with fMRI, M/EEG data analysis comes in two main flavours: task-based and resting state. In task-based M/EEG, the experiments typically consist of many repeats of trials. Data are extracted from each trial and time-locked to a common experimental event of interest

Fig. 12.11 (see Colour Plate section) (a) Sensor space MEG data presented as a two-dimensional (2D) topographic sensor map of contrasted oscillatory power (between 8 and 12 Hz) in a visual attention task. Power is lower in the contralateral (attending) hemisphere. (b) The same MEG data shown reconstructed into the source (brain) space and presented on a three-dimensional cortical map. (c) Time–frequency plot of oscillatory power in MEG sensors above the visual cortex following presentation of a visual stimulus. Changes in power can be resolved at sub-second resolution, with increases (synchronization) occurring in some frequencies and reductions (desynchronization) occurring in others. Vertical lines denote stimulus onset/offset.

(for example, the presentation of a visual stimulus; see Plate 1c), and then an average response to the event can be computed over trials. The average response of raw signals is referred to as an event-related field (ERF) in MEG, or an event-related potential (ERP) in EEG.

An alternative to working with raw signals, and a particular strength of M/EEG, is to work with oscillatory brain activity using time-varying frequency representations of the data. This describes task-locked responses in terms of the amount of oscillatory power or phase locking that is present in different frequency bands (see Plate 1c). It is thought that oscillatory power indicates the level of synchrony in the underlying neuronal populations [9].

Resting state M/EEG network matrix analysis, or ICA, often proceeds in a similar manner to fMRI [10, 11]. However, more sophisticated estimates of functional connectivity are needed to account for M/EEG being direct measures of neuronal activity. These are often based on frequency representations (for example, by looking at correlation in oscillatory power) or the phase locking of oscillatory cycles (for example, coherence) between brain areas. As with fMRI, functional connectivity analysis can also be carried out in task data.

Example applications

MEG and EEG are fundamental tools in both basic and clinical neuroscience research. They can be used to complement the spatial information available from fMRI, with exquisite temporal information.

Basic neuroscience research with M/EEG has often corresponded to the same kind of exploratory brain mapping often carried out with fMRI, albeit extended to also include exploration of the time and frequency domains. Arguably, the most constructive use of M/EEG, and arguably functional neuroimaging in general, comes from more hypothesis-driven work. For example, one approach is to collapse over the spatial dimension and make full use of the temporal information, by asking when in time particular task-related variables can be decoded from the M/EEG data (for example, [12]).

Clinically, EEG and MEG have found important roles in sleep disorders and epilepsy. In sleep research, EEG is used routinely in

sleep laboratories to diagnose sleep disorders [13]. In epilepsy, EEG and MEG are used for epileptic source localization, in particular for the planning of subsequent surgery. MEG is particularly promising in this regard, owing to the increased spatial information it has to offer, and shows close correlation to invasive studies of cortical activity [14].

How imaging is used in psychiatry research

Neuroimaging is now a mainstay of neuroscience research and experimental medicine for mental health diseases and disorders. Examples of its use in specific areas are to be found elsewhere in this book and will include the following.

Pathophysiology

The pathophysiology of most psychiatric diseases and disorders remains to be fully elucidated, and imaging plays an important role in discovering mechanisms and potential targets. For example, schizophrenia is characterized structurally by increased ventricular volume and subtle grey matter reductions (for example, [15]), and fMRI reveals reduced brain activity in frontal areas (for example, [16]), although the latter is now regarded to be an oversimplification (for example, [17]). Structural MRI abnormalities, albeit more subtle, have also been found in mood disorders (for example, [18]). fMRI has also been employed to produce signatures of brain activity associated with specific clinical phenomena such as auditory hallucinations [19] and PTSD-like flashbacks (for example, [20]).

Drug action and drug development

Functional imaging, in particular PET and fMRI, has an important role to play in investigations of therapeutic drug action and target engagement. D2 receptor PET has long been used in receptor occupancy studies to estimate the optimal dose of antipsychotics, so that they hit the sweet spot between maximum antipsychotic effect with minimal motor side effects (for example, [4]). In addition to molecular imaging studies, the mechanism of action of antidepressant drugs has been investigated using fMRI, demonstrating that the

neural effects of serotonin reuptake inhibitors are detectable after a single dose, despite the therapeutic effect taking 2–4 weeks (for example, [21]). In future, molecular imaging is expected to be an ideal companion technology, alongside cellular/molecular neuroscience, in the development of potential drug targets. In particular, radioligands can be co-developed alongside drug targets to act as *in vivo* validation tools and companion biomarkers. This work, in model organisms and in humans, has the potential to accelerate drug development and to enhance the portfolio of evidence required for partnering on a given compound or target.

Imaging biomarkers

A common goal of many neuroimaging studies in the context of psychiatric research is to develop novel biomarkers that will be useful for diagnosis, prognosis, stratification of participants for clinical trials, and surrogate endpoints for trials. Neuroimaging biomarkers, including amyloid PET and structural MRI, are now standard in trials for Alzheimer's disease drugs, and hippocampal volumetry is on the verge of being used as standard in memory clinics to aid with both earlier diagnosis and differential diagnosis for patients with cognitive decline. Neuroimaging is further from being ready for standard clinical use in other psychiatric diseases and disorders, but inclusion in trials of novel therapeutics for, for example, mood disorders is ever more common.

The future of neuroimaging

Each of the imaging modalities described in this chapter are active areas of research, and new ways of acquiring and analysing data are so frequent that a 'state-of-the-art' description would be rapidly out-of-date. For PET, the main areas of innovation are in developing new radiotracers, as well as adapting to new combined PET-MR acquisitions. For MEG, the analysis methodology is rapidly improving and becoming more standardized. The future might involve the use of atomic sensors [for example, optically pumped magnetometers (OPMs)], which could allow the sensors to be placed much nearer to the surface of the head, giving an estimated 5-fold increase in sensitivity. For MRI acquisition, the innovations include acquiring data more quickly, with greater spatial resolution and with an ever greater number of contrast mechanisms that improve sensitivity to specific pathologies. Some of the most exciting innovations come from combining data across modalities (within and beyond neuroimaging) and from 'big data' applications, including scanning much larger populations than ever before (for example, [22]) and developing systems and analysis tools for sharing imaging data across cohorts and studies.

The connectome

Olaf Sporns

Introduction

The project of linking anatomical features of the brain to distinct psychological and cognitive processes has been a core objective of cognitive and systems neuroscience for well over a century. A central goal has been the creation of brain maps that chart the localization of function across brain areas and systems [1]. The emphasis on building a cognitive anatomy largely defined by ‘place’ (topography) is increasingly supplemented by the recognition that cognitive processes are distributed and involve overlapping sets of often remote anatomical regions [2–4]. This complementary view emphasizes the need to map ‘relations’ (topology) or connectivity across the brain. The idea that connectivity is essential to understand how brain architecture supports cognitive processing underpins the emerging science of brain networks, or connectomics [5–8]. As originally defined [5], the connectome is a comprehensive map of the structural connections linking different elements of the nervous system. These elements may correspond to individual (micro-scale) neurons or entire (macro-scale) brain areas. This structural map is fundamental for a mechanistic account of functional brain activity and connectivity, with structural connections shaping and constraining the response patterns of neurons and brain regions. The study of the structural and functional networks of the human brain comprises the emerging field of ‘human connectomics’.

This chapter offers an overview of the core concept of the connectome. After a brief outline of the concept’s historical roots and origins, the chapter proceeds to define and contrast the two major modes of structural and functional brain connectivity. This is followed by a survey of the principal findings to date on the network architecture of the connectome, its role in shaping brain dynamics and functional networks, and applications in studies of development and brain disorders.

Background and origin

Mapping the connections linking neurons and brain regions has been a central goal of neuroscience for many decades—indeed compelling arguments for the importance of connectivity in brain function extend back centuries [9, 10]. The fundamental role of neuroanatomy in neurobiological accounts of brain function and

dysfunction was recognized by many nineteenth-century neurologists and anatomists, among whom were Carl Wernicke and Theodor Meynert. Meynert was among the first to clearly articulate that anatomical connectivity establishes physical links among otherwise remote parts of the brain. Distinguishing tracts of ‘projection systems’ and ‘association systems’ as major constituents of the cerebral white matter, he wrote that ‘the wealth of such fibres, and their variation in length, connecting as they do near and remote parts of the cortex, will suffice, without formulating an anatomical hypothesis, to unite any one part of the cortex to any other’ (page 150, ref [11]). In Meynert’s theoretical framework, disorganized fibre architecture was an important factor contributing to brain and mental disorders.

Modern studies of brain connectivity at first proceeded in model organisms such as the macaque monkey [12, 13] and other mammalian species. Invasive, but highly sensitive, methods for tracing the trajectories and terminations of axonal pathways were deployed to chart projections between anatomically distinct and functionally specialized brain areas. Comprehensive repositories of individual reports on projection patterns were created for monkey [13, 14] and cat cortex [15] and were studied extensively in search of anatomical substrates that could account for, or predict, functional specialization [16]. The lack of connectivity data for humans triggered calls for developing new methods to map the connectivity of the human brain [17] and eventually led to a proposal for mapping human brain connectivity in its entirety—the human connectome [5]. Over the past decade, these calls have been answered through the creation of multi-site projects aimed at mapping human brain connectivity in large cohorts of human subjects [18], including subject samples across the lifespan and from clinical populations. The connectome has emerged as a core concept in modern systems and cognitive neuroscience, providing a conceptual framework for characterizing structure–function relationships in the healthy and dysfunctional brain.

Structural and functional networks

Most complex systems in the natural, social, and technological world are composed of large numbers of interacting elements whose collective dynamics gives rise to global system states and determines

the evolution of these states through time. To understand the structure or function of a complex system, it is often advantageous to decompose the system into a set of nodes and edges, which can then be studied with the mathematical toolset of graph theory. This is the main idea behind mapping and analysing brain networks, or connectomes. There are two main modes of brain networks, derived from observations on anatomy (structural connectivity) or physiology (functional connectivity). The networks derived from measuring structural and functional connectivity share a set of common attributes. Both comprise collections of nodes (elements such as neurons or areas) and edges (their interrelations or connections). The arrangement of these nodes and edges relative to one another defines the network's topology, which is formally described as a graph. Defining nodes and edges is absolutely fundamental for the creation of any brain network, and a necessary step for any subsequent quantitative analysis of the structure of the graph. At the level of whole-brain human connectome networks, nodes correspond to the basic elements of parcellation of the cortical and subcortical grey matter into a set of areas. Parcellation schemes can be derived, based on a number of anatomical or functional criteria such as cytoarchitectonics, myelination patterns, gene expression profiles, or patterns of anatomical or functional connectivity [19]. The edges linking the nodes record their anatomical or physiological relations and, depending on the nature of the specific measure and how it is recorded, may be binary (0/1) or weighted, symmetric or directed.

Structural connectivity defines networks that record the presence/absence, as well as the strength or density, of physical links between neurons, neuronal populations, or brain areas. The totality of structural connections constitutes the connectome, as originally defined [5]. Human connectome networks derived from non-invasive imaging methodology comprise interregional projections that traverse the brain's white matter and connect cortical and subcortical regions. Because of fundamental limitations, these imaging approaches cannot resolve the directionality of projections and instead deliver measures of undirected connectivity. While most current accounts of human connectomes express connection weights solely in terms of the density or number of streamlines, it should be noted that the relationship of such simple measures to the true anatomical magnitude of a pathway is unclear [20] and that other indices that express connectional microstructure should be taken into account. White matter architecture can show signs of neuroplasticity on timescales of days to weeks [21] and exhibits characteristic changes in the course of development and ageing.

Functional connectivity differs from structural connectivity in several important respects. Firstly, functional connectivity is generally derived from neuronal or haemodynamic time series data and expresses patterns of statistical dependence among these time series [22]. Neuronal time series can be recorded with a broad array of techniques, from invasive multi-electrode recordings to whole brain electrophysiology or fMRI. Analytic techniques for extracting statistical dependence include information theoretic measures (such as mutual information or transfer entropy), spectral coherence, phase locking, and simple Pearson cross-correlation. The latter is currently widely used in human studies carried out with fMRI that track fluctuations in haemodynamic signals, either in response to specific task conditions or in a task-free 'resting state'. Unlike structural connectivity, patterns of functional connectivity can exhibit significant reorganizations over short timescales, as interactions among neurons

and brain areas are continually modulated, reflecting changes in sensory inputs and tasks. Measurement of functional connectivity, especially with fMRI, is prone to numerous sources of physiological noise, including involuntary head motion which can introduce systematic biases into functional connectivity estimates.

Once nodes and edges have been defined and pairwise relations among all system elements have been summarized in a graph or network, a large range of analysis and modelling tools from graph theory can be deployed to characterize or compare network architectures [23–25] (Fig. 13.1). Broadly, these measures can be divided into several classes that capture aspects of segregation, integration, and influence. Measures of segregation capture the extent to which the network is clustered and can be subdivided into separate network communities or modules. Examples are the clustering coefficient, network motifs, and methods for detecting network modules. The latter are particularly important, as they deliver putative structural and/or functional building blocks that have been the focus of much interest and research in cognitive neuroscience [26]. Measures of integration express the degree to which the network is globally interactive. A fundamental concept is that of path length, generally defined as the minimal distance (in terms of topology, that is the number of steps in a network, which may be unrelated to metric separation) between network nodes. In structural networks, the shorter the path length, the more directly two nodes can communicate and exchange information. Across an entire network, this capacity for direct communication is expressed as the network's

Fig. 13.1 Elementary graph concepts and measures, illustrated on a schematic illustration of a simple network. (a) The network shown here consists of 12 nodes linked by undirected and unweighted (binary) edges. (b) A low-degree node (maintaining a single edge) and a high-degree node (maintaining five edges) are indicated. Nodes A and B are linked by a minimally short path comprising three edges or steps. (c) The network is shown with a partition into two modules. The node labelled 'connector hub' maintains edges with its own module, as well as across module boundaries. The node labelled 'provincial hub', while highly connected, only links to nodes in its own community.

global efficiency. Measures of influence are useful for detecting those network elements that occupy central positions in the topology and may therefore be particularly important for the functioning of the system. Important nodes are, somewhat informally, designated as network hubs. Some measures of influence rely on local features of a network element (such as the node degree, that is the total number of distinct connections that each node maintains), while others take into account the global web of communication paths across the network (such as betweenness, that is the fraction of optimally short communication paths to which each network element contributes). Another way to define influence and detect hubs is by evaluating the position of a node or edge relative to network modules. For example, highly connected nodes whose connections span multiple modules (and thus form bridges between them) are considered connector hubs that cross-link different communities. In contrast, highly connected nodes whose connections remain predominantly within one module are considered provincial hubs, with potentially important roles in linking members of a single community to each other.

The network architecture of the connectome

Connectome data can be assembled from a very broad range of techniques and from virtually any species with a nervous system. Important achievements to date have included the complete reconstruction of the synaptic network of the brain of *Caenorhabditis elegans* [27] as well as the creation of network maps of large portions of the central nervous system of the mouse [28] and rat [29].

Most studies of the structural connectome of the human brain have utilized non-invasive imaging methodology and computational reconstruction to infer the spatial arrangement and trajectories of white matter interregional projections [30, 31]. These trajectories are represented as ‘streamlines’ that comprise putative white matter tracts. The complete set of these tracts, in combination with parcellation of the grey matter, forms a network of nodes and edges that can be quantitatively analysed with measures and tools from graph theory (Fig. 13.2). While current diffusion imaging and tractography approaches have significant limitations and pitfalls [32], continual refinements are made to better capture complex fibre architecture [33] and develop more principled methods for model-based connectome inference [34]. Despite these ongoing developments, several core findings on human connectome topology have proven to be both robust and reproducible. These include unique ‘connectivity fingerprints’ of brain areas, a broad distribution of node degrees indicating the presence of network hubs, dense connectivity among hubs linking them into a connective core or ‘rich club’, and distinct network communities or modules.

Connectivity fingerprints refer to the patterns of inputs and outputs (indistinguishable with diffusion imaging) maintained by each network node [35]. It is thought that these fingerprints are important for defining the functional specialization of nodes, as they determine the neuronal information to which each node has access, as well as the downstream targets to which its output signals are distributed. In all connectome studies carried out so far, anatomically distinct areas have been found to maintain a characteristic and unique connectivity fingerprint. Connectivity fingerprints are more similar among brain regions that contribute to similar functional domains

Fig. 13.2 (see Colour Plate section) Different representations of the connectome. (a) A set of streamlines, derived from diffusion imaging and computational tractography. Red, green, and blue lines indicate putative white matter tracts running along the medial-lateral, anterior-posterior, and dorsal-ventral directions, respectively. (b) Nodes derived from a cortical parcellation are shown as red dots, connected by edges (blue lines) that correspond to the density of streamlines linking each pair of nodes. For clarity, the diagram shows the strongest edges only. (c) Nodes are arranged in the same anatomical positions as in panel (b), with blue-coloured nodes indicating high betweenness centrality, a measure of influence that is computed as the number of optimally short communication paths to which each node contributes. Node diameter is proportional to the number of subjects (0–5), for which a given node received high betweenness scores.

or cognitive processes; conversely, distinct fingerprints can be taken as indications of functional specialization [36]. Connectivity fingerprints can be used for the purpose of parcellation, defining the boundaries between distinct brain areas that maintain distinct patterns of connectivity [19].

Network hubs may be identified on the basis of node degree (that is, the number of connections per node) or other measures of influence. The distribution of node degrees in human connectome studies has invariably been reported as heavy-tailed, that is, strongly skewed towards nodes with low degree. Put differently, a larger number of nodes have relatively few distinct pathways, while a smaller number of nodes maintain a larger set of distinct projections. Broad degree distributions, assuming a log-normal shape, have also been described in tract tracing studies in non-human primates [37]. In the human brain, hub regions have been identified in parts of the orbitofrontal, lateral prefrontal, superior frontal, cingulate, and medial parietal cortex [38], with most of these regions previously classified as multimodal or transmodal, based on their diverse functional responses.

A number of human connectome studies have shown that highly connected hubs are also densely connected to each other, more so than expected by chance. This aspect of network topology, called a 'connective core' or a 'rich club' [39], suggests that hubs are preferentially connected to allow direct communication and sharing of information. Indeed, graph analysis demonstrates that a very large proportion of all short communication paths across the human connectome access some portion of the brain's rich club and that damage to rich club nodes or edges has the potential to disproportionately disrupt patterns of interregional information transfer [40]. An attractive hypothesis suggests that rich club organization offers a structural substrate for integrative processes that may underpin high-level conscious processing. In support of this notion, rich club connectivity has been found to interlink the set of widely distributed resting state networks that form the basic building blocks of functional connectivity [41]. Connections among rich club members may thus play important roles in the exchange of neuronal information across different sensory and task domains.

Human connectome networks exhibit high clustering, with dense structural connections that define local communities or modules. These modules comprise nodes that tend to share not only dense interconnections, but also common sets of inputs and outputs, as well as common physiological responses and co-activation patterns. The concept of modularity has been especially important in studies of human functional networks. A large body of work has examined the topography and specialization of modules corresponding to resting state or intrinsic functional networks [42, 43]. These modules can be derived with a variety of decomposition or clustering techniques. Network-based detection of modules often utilizes an approach known as 'modularity optimization' [26], which attempts to maximize a quality metric that is designed to optimally partition a network into blocks that are internally densely and externally weakly connected. Partitioning of human resting state functional connectivity has resulted in maps of components/modules that are both highly reproducible across different subject cohorts and imaging parameters [44, 45], as well as sensitive to individual variations, including developmental stages and clinical status [46]. Importantly, network modules derived from fMRI time series recorded in the resting state are highly similar to the spatial patterns of

co-activation networks derived from task-evoked activations across large numbers of imaging studies [47, 48]. Hence, it appears that the architecture of functional networks at rest recapitulates or rehearses spatial patterns of co-activation that are engaged as the brain is challenged in different task contexts.

From the connectome to brain dynamics

The stability and reproducibility of resting state functional networks strongly suggest that these networks have an anatomical origin. Three lines of experimental evidence suggest that this is indeed the case. Firstly, systematic comparison of patterns of structural and functional connectivity recorded in non-human primates [49, 50], as well as in the human brain [51, 52], has shown that they are statistically strongly related. For example, among anatomically directly connected node pairs, the strength of the anatomical projection is partly predictive of the strength of the corresponding functional connection [50, 51]. Secondly, studies of specific resting state functional networks have shown that their constituent components are interconnected by anatomical projections. For example, the anterior and posterior divisions of the default mode network are directly linked by white matter projections running along the cortical midline, and variations in these anatomical projections are correlated with variations in functional connectivity [53]. Thirdly, in rare instances, it has been possible to observe changes in functional networks immediately after experimentally induced disturbances of anatomical connections. For example, transection of interhemispheric cortical pathways in a human patient undergoing surgery for epilepsy resulted in functional disconnection of the two cortical hemispheres [54].

Important insights into the relationship between structural and functional connectivity have come from computational studies of connectome networks (Fig. 13.3). Simulations of neural mass models using a structural coupling matrix, based on the macro-scale connectome of the macaque cerebral cortex, generated functional connectivity that was significantly correlated with the structure of empirical functional networks [50, 55]. Similar results were obtained in simulations of the human connectome [51, 56], including the topography of resting state networks. Additionally, computational studies have demonstrated a number of important dynamic properties of functional connectivity, including temporal fluctuations in network topology [55, 57], as well as the important roles of conduction delays and noise in shaping resting brain functional connectivity [56, 58]. While some research agendas aim to create more realistic and complex neuronal simulations of functional brain dynamics, other studies have attempted to model functional connectivity on the basis of simple dynamic processes such as diffusion [59] and spreading [60]. One example of this approach utilized a measure of 'searchability', derived from studies of network navigability and search, to successfully predict the strength and pattern of functional connectivity in the human brain [61]. What virtually all computational studies have shown is that functional connectivity results (at least in large part) from a complex combination of many (direct and indirect) communication events and dynamic influences that travel across the structural connectome.

While most fMRI studies of functional connectivity in the resting state have examined the structure of functional networks that were estimated over relatively long recording sessions (lasting in the order of 5–10 minutes), recent work has focused on fluctuations

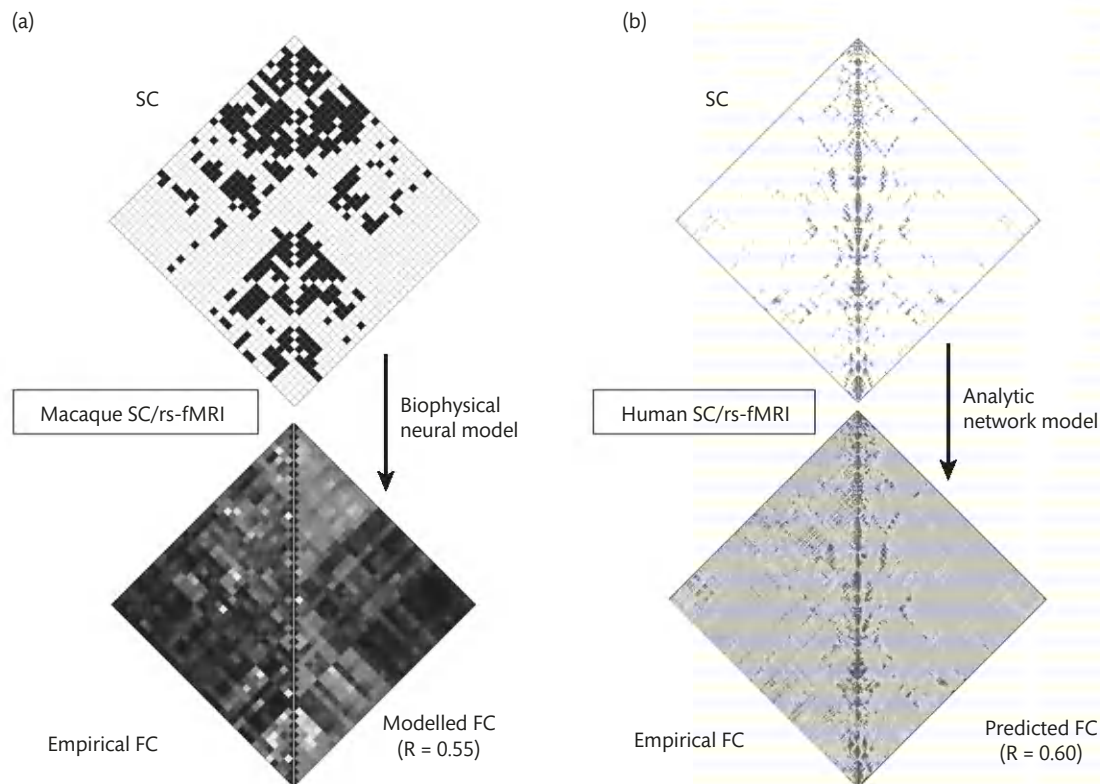

Fig. 13.3 (see Colour Plate section) Connectome-based computational models of functional connectivity. (a) The matrix at the top shows structural connectivity (SC) of directed projections among a set of macaque cortical areas. This connectome formed the coupling structure for a simulation of neural mass dynamics that generated synthetic fMRI time courses and a ‘modelled FC’ (functional connectivity) matrix (lower plot, right half). This computational analogue of macaque FC can be compared to empirical recordings of resting-state fMRI. The correlation between the empirical and modelled FC patterns is $R = 0.55$ [54]. (b) Human SC matrix (from [30]) and empirical FC (from [30]), as well as predicted FC (from [61]). The predicted FC was computed from an analytic model based on measures of communication in the structural graph SC. The correlation between the empirical and predicted FC patterns is $R = 0.60$ [61].

in functional connectivity that occur on shorter timescales (in the order of tens of seconds) [62]. These fluctuations can be detected by tracking individual functional connections over time [63] or by extracting and clustering network states [64]. Both approaches require the formulation of appropriate statistical null models to exclude spurious detection of fluctuations that are due to measurement artefact or noise. While much of the work in this area is still ongoing, a convergent set of findings suggests that resting brain dynamics seems to reflect ongoing transitions of functional networks between states of high segregation and high integration [65]. Statistically significant fluctuations coalesce into consistent network patterns with high modularity, characterized by a de-coupling of task-positive from task-negative (default mode) networks [66]. Much of the efforts to characterize dynamic changes in functional connectivity are motivated by the possibility that such changes may offer a novel biomarker for clinical disorders.

Another important emerging area is the study of functional connectivity in relation to task and cognitive function [43, 67]. Several studies have shown that functional networks are rapidly reconfigured as the brain engages in different tasks, including in continuous sensorimotor tasks [68] or in switching between continuous mental operation such as working memory, arithmetic, or navigation [69]. A comparison of resting state and task-evoked functional connectivity estimated across a battery of different tasks [70] has shown

the presence of an intrinsic functional connectivity state that persists across tasks and that is highly similar to functional connectivity emerging in the resting state. Task-evoked networks emerge on top of this intrinsic state and are associated with specific patterns of modulated functional connections. A different study showed that transitions between different cognitive tasks were accompanied by transitions between distinct functional connectivity states [71]. Using machine-learning approaches, these functional connectivity states could be used to infer cognitive operations in individual subjects.

Development and clinical disorders

Important applications of the connectome include the characterization of changes in connectome topology across developmental stages and in clinical populations. These studies pose a number of methodological and analytic challenges. While many study designs rely on comparison of group-averaged connectivity data sets, the heterogeneity of brain structure and function across individuals may be more appropriately captured by looking at longitudinal changes in individuals across development or by employing dimensional designs that can associate continuous variation in behavioural and/or cognitive phenotypes with network markers. In addition to

issues of study design, developmental or clinical subject cohorts can present issues related to differential head motion and the associated measurement artefacts.

Numerous studies have shown that structural and functional networks exhibit characteristic changes across the human lifespan. For example, an early study carried out on participants ranging between the ages of 2 and 18 years old showed that human connectome networks increase in density and become more efficient in terms of communication paths and progressively less modular (less highly segregated) with age [72]. These trends mirror similar tendencies in functional networks that were observed across a similar age range [73], with functional modules becoming less determined by spatial clustering and more coherent and integrated across remote regions of the brain. Looking across the human lifespan [74], several structural connectome metrics related to network density and efficiency exhibit inverted U-shaped time courses, with early increases followed by decreases later in life. Rich club organization was present across the entire lifespan, with the most pronounced expression in early adulthood [75]. In parallel with these evolving structural network features, resting state functional networks exhibit developmental trajectories of their own, for example, by becoming internally less strongly coupled, while developing stronger functional links between networks, especially among components of the somatomotor network, the dorsal attention network, and the saliency/ventral attention network [76]. Ongoing lifespan connectomics efforts are extending the range of these observations to neonates and the elderly population.

The fundamental rationale behind connectomics-based approaches to brain disorders is 2-fold. Firstly, most of these conditions cannot be traced to highly localized pathologies but are instead associated with disturbances of network organization across extended parts of the brain [77, 78]. Secondly, connectomics offers an intermediate

phenotype, based on structural and functional circuits and connectivity that is interspersed between the domains of genetics and molecular interactions at the lower end and human behaviour and social networks at the upper end of the scale [79] (Fig. 13.4). Structural brain networks not only allow information to become shared and integrated in the course of healthy brain function, but they also promote the spreading of disease processes. Examples are distributed functional changes resulting from brain damage due to an ischaemic attack [80], the progressive spread of degenerative conditions such as Alzheimer's disease along anatomical pathways [81], or the global effects such as generalized seizures that are triggered by focal epileptogenic activity [82]. Several classic clinical concepts, among them diaschisis and cognitive reserve, may be reconceptualized in the context of brain networks and the connectome. Diaschisis [83], which implies functional disruption that occurs at a distance, for example after a stroke, may reflect the brain's response to acute disturbances of connectome topology. For example, network approaches predict that the loss of a set of nodes and edges may be accompanied by altered functional connectivity among remote (including contralateral) brain regions and systems [84]. The extent of this reorganization would likely depend on the topological status of the damaged nodes, with damage to more central nodes (network hubs) causing more severe and widespread disruption. Cognitive reserve [85], or the capacity of the brain to counter impairment with compensatory strategies, may depend on the network's ability to provide alternative functional configurations or paths to counter the loss of nodes and edges. This ability would allow the brain to configure alternative sets of nodes and edges to carry out equivalent ('degenerate' [86, 87]) cognitive or behavioural processes.

A common theme in many clinical and translational applications of the connectome has been the role of important network elements in the origin and progression of brain disorders. Network hubs

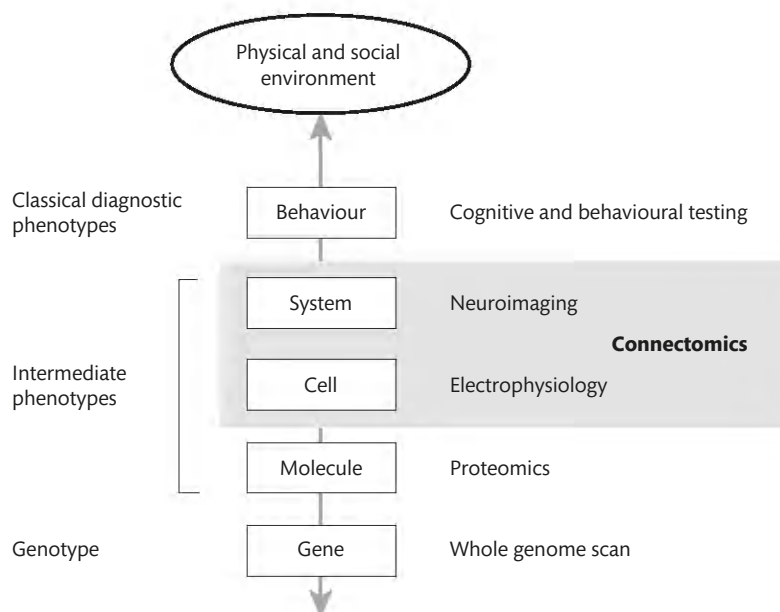

Fig. 13.4 Brain phenotypes are arranged in a hierarchy spanning several levels of organization, ranging from molecular processes to behaviour and social environment. Genetic and environmental factors contributing to brain disorders converge onto the connectome which occupies the position of an intermediate phenotype that bridges molecular and behavioural scales.

have caught significant attention, as they appear to play a causal role across a wide range of brain disorders. A meta-analysis of data from more than 20,000 subjects and 26 different disorders [88] has shown that many of these disorders were associated with hub-centric neuropathology, that is with lesions that predominantly involved topologically central elements of the human connectome. For example, hubs in the medial temporal lobe are among the first brain regions to exhibit pathological changes in Alzheimer's disease [89], while frontal and temporal cortical hubs are implicated in a number of studies of schizophrenia [90]. It appears that the existence of network hubs in the connectome offers unique functional advantages, while also creating points of vulnerability—the benefits of hubs in information integration turn into risk factors, as their disruption has disproportionate effects on the individual's cognitive and behavioural capacities.

Summary

The connectome refers to a comprehensive map of connections among elements of a neural system. In studies of the human brain, connectomics has so far largely focused on the macro-scale projections among distinct brain areas and their role in shaping functional connectivity during both rest and task-evoked activity. Computational models of the connectome have been instrumental in elucidating potential network mechanisms that create functional connectivity from communication events in structural networks. Numerous applications of the connectome in developmental and clinical studies have shown patterns of change in connectome topology across the lifespan, as well as the network basis of brain disorders. Future work will likely further illuminate the role of the connectome in the functioning of the healthy and diseased brain.

Neurotransmitters and signalling

Trevor Sharp

Introduction

The concept of signalling from one neuron to another began to form by the end of the nineteenth century when it was recognized from the histological work of Golgi and Ramon y Cajal that nerve cells were discrete entities and linked by specialized contacts, for which Sherrington coined the term 'synapse'. It took another half century for scientists to finally agree that information passes between neurons principally through the movement across synapses of chemicals, and not electrical current. Today changes in chemical transmission at brain synapses are accepted as being key to both successful drug treatment and the cause of many forms of psychiatric illness. This chapter focuses on fundamental aspects of chemical transmission and describes some recent advances relevant to psychiatry that may indicate the direction of future research.

Seminal work on the autonomic nervous system and glandular secretions around the turn of the twentieth century was conducted by pioneering physiologists like John Langley and his student Thomas Elliott. It culminated in studies in the 1920s by Otto Loewi and then Henry Dale who identified what is often cited as the first neurotransmitter—acetylcholine—the chemical that was released on stimulation of the vagus nerve to inhibit the heart. Subsequently, in 1946, Ulf von Euler reported the identification of the monoamine noradrenaline as the other key autonomic transmitter [1, 2]. Today evidence suggests that, in the brain (and peripheral nervous system), there are many tens, if not hundreds, of molecules that are involved in chemical transmission at synapses. These molecules include acetylcholine and monoamines [noradrenaline, dopamine, and 5-hydroxytryptamine (5-HT; serotonin)], certain amino acids (especially glutamate and GABA), and peptides, as well as specific purines, trophic factors, inflammatory mediators (chemokines and cytokines), lipid-like agents (endocannabinoids), and even gases [nitric oxide (NO)]. Examples of molecules that serve neurotransmitter functions in the brain are listed in Table 14.1. This list is not exhaustive, and more are likely to be discovered.

Basic principles of chemical transmission

Typically, a molecule is classified as a neurotransmitter if it is localized in neurons, released from nerve terminals (and often soma and

dendrites as well) on membrane depolarization, and exerts physiological and molecular effects through acting on postsynaptic receptors. However, the degree to which a particular molecule satisfies these criteria may vary. For example, the term 'neurotransmitter' was once commonly used to define those molecules that exert fast synaptic effects (glutamate, GABA), whereas molecules that exerted slower synaptic effects were often termed 'neuromodulators' (for example, monoamines and peptides). These distinctions are less useful today (and will not be used here) because it is recognized that many transmitter molecules are capable of exerting both fast and slow synaptic effects. For example, both glutamate and

Table 14.1 Examples of neurotransmitters in the brain

Chemical class	Example
Amines	Dopamine Noradrenaline 5-hydroxytryptamine (5-HT) Histamine Melatonin Acetylcholine
Amino acids	γ -aminobutyric acid (GABA) Glutamate Glycine
Neuropeptides	Substance P Leu- and met-enkephalin Galanin Orexin
Purines	Adenosine Adenosine triphosphate (ATP)
Neurotrophic factors [#]	Neurotrophins (for example, BDNF, NGF) Insulin-like growth factor (IGF) Vascular endothelial growth factor (VEGF)
Cytokines [*]	Interleukin-1 (IL-1) Tumour necrosis factor α (TNF α)
Chemokines [*]	CC chemokines [for example, interleukin-8 (IL-8)] CXC chemokines
Endocannabinoids [#]	Anandamide 2-arachidonyl-glycerol (2-AG)
Gases [*]	Nitric oxide (NO) Carbon monoxide (CO)

^{*} Putative class of neurotransmitters.

[#] Retrograde messengers.

GABA exert fast and slow synaptic effects, depending on which of their receptors they interact with. Moreover, in contrast to the classical view of neurotransmission in which information passes from the presynaptic to the postsynaptic neuron in an 'anterograde' direction, it is now recognized that certain molecules transfer information at a synapse in a 'retrograde' direction. In this case, the molecules are located in the postsynaptic neuron, and, when their synthesis is activated, the molecules diffuse back across the synapse to act presynaptically.

The general principles of chemical transmission at central synapses are similar for most neurotransmitter molecules. The differences in the detail will be illustrated by transmission mechanisms for

small neurotransmitters such as monoamines and amino acids, compared to larger neurotransmitters such as peptides (Fig. 14.1) [3].

Small neurotransmitters

Typically, small neurotransmitter molecules are synthesized at the nerve terminal by one or a few enzymatic steps, and then packaged in small membrane-bound vesicles via vesicular transporters (proton-coupled), prior to release into the synapse. The latter is triggered via a calcium-dependent mechanism on the arrival of a depolarizing action potential; this release process, referred to as

Fig. 14.1 Summary of the principal steps involved in chemical neurotransmission at CNS synapses. Neuropeptides are synthesized in the cell body and then packaged in large, dense core vesicles (LDCVs) that are transported into axons and dendrites (1). Small 'classic' neurotransmitters (for example, monoamines and amino acids) are synthesized at the nerve terminal and stored in synaptic vesicles, and released into the synaptic cleft. Evidence for the co-release of small transmitters is now clear (2). LDCVs contain proteolytic enzymes (convertases) that generate the active neuropeptide from the precursor. Neurotransmitter receptors are either of the G protein-coupled (metabotropic) or ligand-gated ion channel (ionotropic) type and are present on cell soma, dendrites, axons, and nerve endings (1, 4). The small neurotransmitters are released during low- and high-frequency firing, whereas neuropeptides are preferentially released under burst or high-frequency firing (2–4). Small transmitters have reuptake mechanisms (transporters) at both the plasma membrane and the vesicle membrane (5), which terminate neurotransmitter action and allow recycling (4). In contrast, neuropeptides are broken down by extracellular peptidases (6), and replacement occurs via axonal transport. Glial cells can express neurotransmitter receptors and transporters (7). Receptors are trafficked to and from the cell membrane by G protein-interacting proteins (8).

exocytosis, involves a complex machinery of 20–30 presynaptic proteins. After release, the neurotransmitter diffuses across the synapse to interact with specific receptors localized on the membrane of the postsynaptic neuron to trigger electrical and/or biochemical changes. Small neurotransmitters are also released from the soma and dendrites of neurons, one purpose being to interact with presynaptic receptors that signal negative feedback to the neuron; these receptors are often referred to as autoreceptors, and they are usually also located on the nerve terminals.

Typically, once released, the small neurotransmitters are selectively taken up by another type of transporter (sodium-coupled) located in the plasma membrane of the nerve terminal or neighbouring cells (neurons or glial cells). This transport helps terminate transmission at the postsynaptic receptor, maintains low extracellular levels of the transmitter, and allows its reuse by the neuron. Transport into the nerve terminal also presents the transmitter to catabolic enzymes, monoamine oxidase in the case of monoamine transmitters, to generate biologically inactive metabolites. Rather differently, acetylcholine is broken down in the synapse by the enzyme acetylcholinesterase, and then the metabolic product choline is transported back into the nerve terminal, allowing resynthesis to acetylcholine.

Neurotransmitter transporters

Advances in cloning technology have led to new discoveries regarding the structural and pharmacological identity of transporters located on the plasma membrane, as well as vesicular transporters located inside the nerve terminal [4]. The latter transporters concentrate transmitters in synaptic vesicles prior to release, and play a key role in determining the neurotransmitter phenotype of a neuron [5]. A summary of plasma membrane and vesicular transporters is given in Table 14.2.

Table 14.2 Examples of neurotransmitter transporters

Neurotransmitter	Transporter
<i>Plasma membrane transporters</i>	
Dopamine	DAT
Noradrenaline	NET
5-HT	SERT
GABA	
	GAT-1
	GAT-2
	GAT-3
Glutamate	BGT-1 (primarily in kidney)
	EAAT-1 (GLAST1)
	EAAT-2 (GLT-1)
	EAAT-3 (EAAC1)
	EAAT-4
Glycine	EAAT-5
	GLYT-1
	GLYT-2
Acetylcholine (choline)	CHT
<i>Vesicular transporters</i>	
Monoamines (dopamine, noradrenaline, 5-HT, histamine)	VMAT1
	VMAT2
GABA	VGAT
Glutamate	VGLUT1
	VGLUT2
	VGLUT3
Acetylcholine	VAchT

Plasma membrane transporters

The solute carrier (SLC) superfamily of transporters is the second largest family of membrane proteins in the human genome (approximately 52 families, around 400 individual members), after G protein-coupled receptors (GPCRs). These transporters selectively transport into and out of cells a large diversity of solutes, ranging from inorganic ions to amino acids and more complex molecules like haem.

The SLC6 family comprises four subfamilies that form high-affinity and selective transporters for GABA, glycine, and neutral amino acids, as well as the monoamines dopamine (DAT), noradrenaline (NET), and 5-HT (SERT). The latter three transporters have been identified and sequenced, and investigated in detail at the molecular level. Their distribution within the brain closely follows the pattern of innervation of their respective monoamine transmitter. These transporters play a key role in the homeostatic control of monoamine transmission, as is evident in the striking effects on monoamine function when these transporters are genetically knocked out [6]. These transporters are also the site of action of many important psychotropic drugs, including psychostimulants such as amphetamines and cocaine, tricyclic antidepressant drugs, and SSRIs [4]. The drug-binding site and the precise molecular mechanism of transporter inhibition have been revealed at a high level of structural resolution [7, 8].

When monoamines are in excess at the synapse and extra-synaptic areas, their clearance may also be facilitated by the low-affinity, non-selective organic cation transporters OCT1–3 and PMAT [9, 10]. In support of this idea, the regional brain distribution of OCT3 and PMAT overlaps largely with that for SERT, NET, and DAT.

Molecular cloning techniques have uncovered genes that generate four highly homologous, but pharmacologically distinct, transporters for the inhibitory neurotransmitter GABA: GAT-1, GAT-2, GAT-3, and BTG-1 [6]. GAT-1 and GAT-3 are the most abundant and preferentially expressed by neurons and glial cells, respectively, whereas GAT-2 and BTG-1 are expressed extra-synaptically by both cell types. Although their significance is yet to be fully understood, these transporters display overlapping, but different, expression patterns in the CNS, suggesting distinct functional roles. The anticonvulsant effect of tiagabine is likely mediated by blockade of GAT-1, and there is much scope for new GABA uptake inhibitors of as yet unclear utility.

Glycine, another inhibitory amino acid transmitter, also has specific transporters located preferentially on the plasma membranes of glial cells in the forebrain (GLYT1) and neurons of the hindbrain and spinal cord (GLYT2). Interestingly, glycine is a positive allosteric co-modulator of glutamate NMDA receptors. Therefore, disruption of GLYT1 glycine transport blockade may offer a means to facilitate the functioning of the NMDA receptor without incurring excitotoxic effects [4]. The antipsychotic potential of glycine transport inhibitors has been under investigation, because this action is associated with procognitive effects and the symptoms of schizophrenia appear linked to low NMDA receptor function [11]. GLYT2 is expressed by glycinergic neurons and thought to be important for the delivery of glycine into nerve terminals for loading into synaptic vesicles.

Four transporters for the excitatory amino acid neurotransmitter glutamate have been cloned: EAAT1 (excitatory amino

acid transporter 1; synonym GLAST), EAAT2 (GLT1), EAAT3 (EAAC1), EAAT4, and EAAT5 [5]. These transporters are located on both neurons (predominantly EAAT3/4/5) and glial cells (predominantly EAAT1/2) and serve to maintain low extracellular concentrations of glutamate, as well as provide a source of intracellular glutamate for metabolism. Pharmacological blockade of glutamate transport may lead to cognition enhancement and other potentially useful therapeutic effects but holds the risk of excitotoxicity, whereas pharmacologically enhanced EAAT expression appears to be neuroprotective [12]. EAAT inhibitors are currently in development, but few brain penetrant or selective agents have been identified thus far.

Vesicular transporters

Vesicular transporters facilitate the movement of neurotransmitters from the cytoplasm to be concentrated within synaptic vesicles. This transport is often driven by a proton gradient established by an adenosine triphosphate (ATP)-dependent proton pump that acidifies the secretory vesicles. There are two homologous vesicular monoamine transporters—VMAT2 is present in central and peripheral neurons and transports dopamine, noradrenaline, and 5-HT, as well as histamine, into vesicles, whereas VMAT1 is an integral protein in the membrane of secretory vesicles of peripheral neuroendocrine and endocrine cells. Reserpine is a blocker of VMAT and causes depletion of monoamines, and the drug's tranquillizer effects are directly linked to this action. Acetylcholine is loaded into synaptic vesicles by a distinct transporter, VAChT.

Three homologous vesicular transporters for glutamate VGLUT1, VGLUT2, and VGLUT3 have been identified and characterized. While all possess similar molecular properties, they have differential expression patterns, with VGLUT1 arising predominantly from cortical neurons, VGLUT2 from subcortical neurons, and VGLUT3 largely from midbrain neurons [5]. The vesicular GABA transporter is VGAT (also termed vesicular inhibitory amino acid transporter, VIAAT), and this transports GABA or glycine into synaptic vesicles. Loss of VGAT causes a drastic reduction in the release of not only GABA, but also glycine, indicating that glycinergic neurons do not express a separate vesicular transporter for glycine. The vesicular nucleotide transporter (VNUT) is a recent member of this transporter family and functions to load synaptic vesicles with ATP.

There is long-standing evidence that the release of one or more neuropeptides accompanies the release of classical small-molecule neurotransmitters (Fig. 14.1). Interestingly, recent studies based on the localization of vesicular transporters suggest that classical small-molecule neurotransmitters are also co-released. For instance, findings that VGLUT3 is localized in 5-HT-containing neurons and appears to be functional [13] raises the possibility that the release of glutamate contributes to the actions of 5-HT neurons that were previously attributed to 5-HT itself. This is not an isolated case. Neurons previously thought to release only glutamate, acetylcholine, dopamine, or histamine have been found to also release the major inhibitory neurotransmitter GABA [14]. Such evidence supports the emerging view that neuronal communication based on using more than one classical neurotransmitter is prevalent throughout the CNS.

Neuropeptides

Following the chemical identification of the neuropeptide substance P in 1971, evidence has accumulated that numerous peptides play neurotransmitter roles in the brain [3]. Some examples are shown in Table 14.3. The properties of peptidergic synapses are in many ways different from those of synapses that utilize small neurotransmitters. The neuropeptides comprise 3–100 amino acids and, together with other putative signalling peptides, such as growth factors and cytokines, are synthesized in the nucleus by deoxyribonucleic acid (DNA) transcription, followed by translation from messenger ribonucleic acid (mRNA) into precursor polypeptides (Fig. 14.1). These precursors typically undergo extensive post-translational processing that includes cleavage into smaller peptides by endopeptidases, as well as other enzymatic modifications. The precursor peptides usually contain an N-terminal signal sequence that directs the transport of newly synthesized protein to the lumen of the endoplasmic reticulum, and then the Golgi complex where it is packaged into vesicles (termed 'large, dense core vesicles' due to their appearance under the electron microscope) that are transported along the axon to the synapse. This obviates the need for neuropeptide vesicular transporters.

Proteolytic processing of a single precursor peptide often generates not one, but a family of biologically active peptides, although the proteolytic steps may be tissue-specific. The opioid peptides provide one of the best worked-out examples of this form of processing. Pro-opiomelanocortin (POMC) is a hypothalamic precursor opioid peptide whose structure contains sequences for adrenocorticotrophic hormone (ACTH), α -melanocyte-stimulating hormone (α -MSH), and β -endorphin. In the anterior lobe of the pituitary gland, POMC is processed to form ACTH, while in the intermediate lobe, POMC is processed to form α -MSH and β -endorphin. On the other

Table 14.3 Examples of families of neuropeptides

Opioid peptides	Leu-enkephalin Met-enkephalin Dynorphin β -endorphin Nociceptin
Tachykinins	Substance P Neurokinin A Neurokinin B
Hypothalamic-releasing factors	Thyrotrophin-releasing factor (TRH) Corticotrophin-releasing factor (CRF) Growth hormone-releasing hormone (GHRH) Somatostatin
Gut-brain peptides	Cholecystokinin (CCK) Galanin Insulin Neurotensin Neuropeptide Y (NPY) Vasointestinal polypeptide (VIP)
Other peptides	Bradykinin Calcitonin gene-related peptide Melanin-concentrating hormone (MCH) Melanocortin Orexin Oxytocin Vasopressin

hand, post-translational processing of the opioid precursor peptide proenkephalin gives rise to multiple copies of the pentapeptide met-enkephalin, as well as a copy of leu-enkephalin, while a third opioid precursor prodynorphin gives rise to dynorphin. In total, the three separate opioid peptide genes give rise to at least 18 endogenous peptides with opiate-like activity.

Many proteolytic enzymes involved in the processing of neuropeptides have been cloned and characterized, including prohormone convertases that produce striking phenotypic effects when genetically manipulated in mutant mouse models [15]. The therapeutic utility of pharmacological manipulation of neuropeptide synthesis and degradation in the brain has yet to be fully realized. However, the success of inhibitors of the prohormone convertase that synthesises angiotensin in the periphery [angiotensin-converting enzyme (ACE) inhibitors], for the treatment of hypertension, sets an important precedent.

In addition to enzymic processing, another mechanism to generate neuropeptide diversity is through alternative ribonucleic acid (RNA) splicing of a single gene. For example, in the case of tachykinins, alternative splicing of preprotachykinin gene A mRNA results in three splice variants which, after translation and post-translational processing, collectively generate the five biologically active peptides of the tachykinin family (including substance P).

To date, there is little evidence that neuropeptides are cleared from the synapse by transporters in the plasma membrane, indicating that they are not recycled after release. Rather, evidence suggests that their action is terminated by peptidases located on extracellular membranes. Thus, replenishment of neuropeptides during high levels of synaptic activity is dependent on the proteolytic enzymes that generate the active peptides in the neurons.

As noted, a feature of most, if not all, neuropeptides is their co-localization with classic neurotransmitters. Some of the best examples include GABA/dynorphin co-localization in movement control pathways (striatonigral neurons), cholecystikinin (CCK)/dopamine in reward pathways (mesoaccumbens neurons), and glutamate/substance P in pain pathways (dorsal root ganglion neurons). The functional significance of this co-localization is not fully clear, but evidence suggests that peptide release requires higher frequencies of neuronal discharge than classical transmitters, and once released, the neuropeptide either facilitates or opposes the function of the co-localized transmitter [3]. In a recent example, co-localization between 5-HT and galanin in midbrain raphe neurons was investigated to reveal an action of the peptide on 5-HT feedback mechanisms. This knowledge has been exploited to develop galanin ligands that are under development as novel antidepressant strategies [16].

Neurotrophic factors

Neurotrophic factors are brain peptides that were originally recognized for their role in supporting growth, differentiation, and survival of neurons but today these molecules are thought to possess many of the properties of neurotransmitters, including neuronal localization and release and an ability to modulate synaptic function. In addition, there is evidence that neurotrophic factors signal in a retrograde fashion (see later). Neurotrophic factors are currently named according to the action with which they were originally

characterized [brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF)], and they comprise many families [17].

Certain features distinguish neurotrophic factors from neuropeptides. In particular, neurotrophic factors are larger molecules; for example, BDNF has a molecular size of 14 kDa, whereas neuropeptides are typically much smaller peptides. Also, while neuropeptides signal via GPCRs, neurotrophic factors signal via direct activation of a class of transmembrane-spanning proteins called protein tyrosine kinases (Trk receptors), of which four types have been identified so far (TrkA, TrkB, TrkC, and p75). In some cases, the neurotrophic factor receptor and protein tyrosine kinase reside in the same protein, while in other cases, the receptor recruits an intracellular protein tyrosine kinase. Specific neurotrophic factors signal via specific protein kinases (for example, NGF–TrkA, BDNF–TrkB). Activation of the protein tyrosine kinase leads to the phosphorylation of proteins via their tyrosine residues and the triggering of signalling cascades that produce not only trophic effects, but also changes in synaptic transmission.

Much recent interest in neurotrophic factors derives from findings that they regulate synaptic transmission in the adult brain and that neurotrophic factor expression can be modulated through interactions with monoamine and amino acid neurotransmitters. For example, repeated administration with monoamine-targeted antidepressants increases BDNF expression in animal models and depressed patients, whereas decreases in BDNF have been linked to depression. These findings have informed a popular hypothesis that changes in neural plasticity at many levels (both BDNF-dependent and non-dependent) are important to the symptoms of depression, as well as the relief of these symptoms by antidepressant drug treatment [18, 19]. A more advanced version of this hypothesis combines with neuropsychological theories to suggest that increased neural plasticity at the molecular and cellular levels arms key neural circuits with the capacity to process emotional information and re-establish positive emotional associations that result in improved mood [20].

Chemokines and cytokines

Chemokines and cytokines comprise large families of homologous small proteins (6–10 kDa) and differ from neuropeptides and neurotrophic factors in that they are key signalling molecules of the immune system. However, these molecules and some of their receptors are also present in the brain in both glial cells and neurons, raising the possibility that they might also have neurotransmitter-like functions. Although the evidence is incomplete, data show that chemokine and cytokine molecules are synthesized in the brain and have several of the characteristics that define neurotransmitters, including interaction with receptors and modulation of release of other neurotransmitters or neuropeptides [21]. This suggests that chemokine and cytokine signalling may have a role in neuronal and glial cell signalling that is distinct from their role in inflammatory processes. On the other hand, it is quite clear that inflammatory and immunologic changes can trigger responses that play a role in CNS protection, but also a role in CNS injury.

This local presence of chemokine and cytokine signalling provides a route of communication between the immune system and the CNS, but there are many others, including several pathways through which peripheral inflammatory signals can be transmitted to the brain [22]. For example, cytokines may pass directly into the brain via leaky regions in the blood–brain barrier and also bind to

peripheral autonomic nerves such as the vagus nerve, resulting in modulation of afferent CNS inputs. A dysfunctional interaction between the immune system and the peripheral inflammatory response, in particular, is presently considered an important contributor to the pathophysiology of a number of psychiatric disorders, including major depression. Moreover, the irrefutable evidence of immunological and CNS interactions has challenged the previously held belief of CNS immune privilege, such that autoimmune mechanisms are emerging as a pathophysiology disease mechanism, as evidenced in recent discoveries of circulating NMDA receptor antibodies in some patients with schizophrenia. The development of drug tools and biologics (for example, antibodies) to target cytokine and chemokine mechanisms is an intense area of current neuroscience research.

Retrograde messengers

Whereas classical neurotransmitters and neuropeptides are generally considered to signal in an 'anterograde' direction (that is, presynaptic to postsynaptic), it is now recognized that certain brain molecules signal information at a synapse in a 'retrograde' direction. They are released from the postsynaptic neuron to act on the presynaptic neuron. Molecules falling into this category include certain neurotrophic factors, gaseous molecules, and lipid messengers.

Nitric oxide

One example of a retrograde messenger is the gaseous molecule NO that is produced in neurons from the amino acid *L*-arginine by a neuron-specific isoform of NO synthase (NOS). Some of the first evidence that NO might function as a chemical messenger in the brain came from findings that activation of glutamate NMDA receptors in the cerebellum caused the release of a diffusible messenger, which was subsequently identified as NO [23]. The current thinking is that increased activity at glutamatergic synapses triggers in postsynaptic neurons an NMDA-mediated, calcium-dependent activation of NOS. The resulting NO then diffuses back across the synapse to enhance presynaptic transmission. The latter occurs, at least in part, through NO acting on guanylate cyclase to increase the production of the second messenger cyclic guanosine monophosphate (cGMP). In postsynaptic neurons, NO also regulates certain protein kinase pathways and gene transcription factors, and changes cell signalling events by *S*-nitrosylation.

Since NOS is abundant and widely distributed in the CNS, NO signalling is likely to contribute to many brain functions. Indeed, on the basis of studies on the effects of NO donors and the pharmacological and genetic modulation of NOS, increased NO production is associated with a range of CNS functions, including improved cognition and an associated induction and maintenance of synaptic plasticity, and NO may be neuroprotective under some conditions [24]. However, because excess NO has neurotoxic potential, and because of the difficulty of delivering NO to the CNS without inducing side effects through the many actions of NO on peripheral tissues, the development of NO-based therapies for the treatment of CNS disorders has yet to reach fruition.

Endocannabinoids

Another example of retrograde signalling is by endocannabinoids [25]. These are a recently discovered family of naturally occurring lipids (including anandamide and 2-arachidonoylglycerol) that interact with cell surface receptors targeted by the psychotropic agent Δ^9 -tetrahydrocannabinol (THC). The latter is the principal biologically active constituent of the cannabis plant [26]. In essence, endocannabinoids appear to be to THC and cannabinoid receptors what opioid peptides are to morphine and opiate receptors.

The current thinking is that endocannabinoids are synthesized enzymatically on demand within the postsynaptic neuron and, once produced, diffuse across the synapse in a retrograde direction. Endocannabinoids then suppress neurotransmitter release through activation of a presynaptic CB₁ receptor, which is the main type of cannabinoid receptor in the brain (analogous in terms of structure and function to opiate receptors, but quite distinct pharmacologically).

The central actions of THC, including its psychotropic effects, nociception, increased appetite, and anti-emetic effects, are thought to be principally mediated by CB₁ receptors. Since CB₁ receptors have a powerful influence on synaptic transmission in the brain and have limited distribution in the periphery (although CB₂ receptors are abundant in the immune system), drugs targeting these receptors and/or the enzymes involved in endocannabinoid synthesis and metabolism have interesting therapeutic possibilities. Indeed, CB₁ receptor agonist preparations are currently prescribed as analgesic and anti-emetic agents.

Neurotransmitter receptors

Neurotransmitter receptors are located on the cell surface of both pre- and postsynaptic neurons and, as a general rule, can be divided into two main types; one activates an ion channel that is intrinsic to the receptor (ligand-gated ion channel—sometimes called an ionotropic receptor), and the other activates a guanosine triphosphate (GTP)-binding protein which acts as a transducer between the receptor and the effector system (GPCR—sometimes called a metabotropic receptor). As an exception to this general rule, certain trophic factors and cytokines directly activate protein tyrosine kinases, as noted above. In addition, steroid hormones signal in the brain by crossing the plasma membrane and activating receptors in the neuronal cytoplasm that translocate to the nucleus where they bind DNA and function as transcription factors.

Ligand-gated ion channels typically comprise a multimeric plasma membrane receptor complex (4–5 subunits, each with four transmembrane-spanning domains) that gate the influx of ions to evoke fast changes in synaptic signalling. For instance, nicotinic, 5-HT₃, GABA_A, and glycine receptors are pentameric in their subunit composition; these receptors are often termed 'Cys-loop' receptors due to a loop of amino acid residues formed by a disulfide bond in the extracellular domain. GPCRs comprise a superfamily of single proteins (seven transmembrane-spanning domains) that evoke slower changes in synaptic signalling through the generation of second messengers and interactions with intracellular signalling pathways.

A remarkable advance in molecular neuropharmacology in the last 20 years has been the discovery of huge diversity in neurotransmitter receptors. This complexity takes the form of not only several hundred of GPCRs [27], but also considerable heterogeneity in ligand-gated ion channels produced through the assembly of multiple receptor subunits [28, 29]. Receptors were once classified according to their pharmacological properties, but today receptor classification is based on a combination of pharmacological, functional, and structural properties. It is now evident that most, and probably all, neurotransmitters have more than one receptor type. As a consequence of their receptor diversity, individual neurotransmitters are conferred multiple downstream signalling properties. Typically, as soon as neurotransmitter receptors are identified, their distribution within the brain (and other organs and tissues) is established, and then a combination of pharmacological and genetic approaches are used to obtain an understanding of their function, which can then aid the development of novel drug therapies. Some examples are shown in Table 14.4, and more detailed information is available elsewhere [30].

Ligand-gated ion channels

The amino acids glutamate and GABA are, respectively, the principal excitatory and inhibitory transmitters in the brain and exert their fast synaptic effects via ligand-gated ion channels. Acetylcholine (nicotinic receptors) and ATP (P_{2X} receptors) transmitters also signal fast transmission via ligand-gated ion channels. The 5-HT₃ receptor is the only ligand-gated ion channel among the many monoamine receptors, and none exists for neuropeptides.

Ligand-gated ion channels for glutamate

Glutamate elicits fast excitatory effects by activating ligand-gated ion channels, and there are three types: α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, NMDA receptors, and less abundant kainate receptors. These receptors are named according to their preferred synthetic agonist, and gate cations (sodium, potassium, and calcium) with varying degrees of selectivity. Each receptor is assembled as a tetramer, which can comprise a combination of subunits, and this generates additional heterogeneity. For instance, AMPA receptors are formed from a combination of four subunits (GluA1–4), and NMDA receptors from two subunits (GluN1–2). There are a large number of naturally occurring variants of both AMPA and NMDA subunits generated through RNA editing and alternative splicing (Table 14.4).

The pharmacological and functional significance of this complexity is not yet fully clear, although evidence suggests that different receptor assemblies may confer distinct pharmacological and biophysical properties on the receptor [30]. For example, recent data suggest that changes in AMPA receptor subunit composition cause differences in calcium ion permeability and change synaptic efficacy [29].

In addition to a glutamate-binding site, both AMPA and NMDA receptors demonstrate allosteric modulatory sites, a feature common to many ligand-gated ion channels. Thus, in addition to glutamate, AMPA receptors are sensitive to ‘AMPAkines’, which comprise a chemically diverse group of exogenous agents that act at separate

chemically sensitive site on the receptor. The result is potentiated AMPA receptor ion channel function and associated procognitive effects *in vivo* [31]. Non-glutamate sites on the NMDA receptor include a site for magnesium ions that is the source of a voltage-dependent NMDA receptor block, which requires membrane depolarization to open. In addition, the NMDA receptor has a positive allosteric modulatory site for glycine and *D*-serine, and another for polyamines such as spermidine. While glutamate is released from presynaptic terminals in a phasic, activity-dependent fashion, endogenous glycine, *D*-serine, and polyamines (likely arising from non-neuronal sources) are thought to act as extracellular modulators that are present at more constant levels. These allosteric sites are under investigation as possible sources of NMDA receptor modulatory agents that do not suffer the excitotoxic effects of agonists acting directly at the glutamate site [32]. Such agents include inhibitors of glycine reuptake and *D*-serine metabolism.

Ligand-gated ion channels for GABA

GABA elicits fast inhibitory effects by activating the GABA_A receptor, which is a ligand-gated ion channel that is selectively permeable to chloride ions. GABA_A receptors are formed from five subunits, of which there are at least 19 types (α 1–6, β 1–3, γ 1–3, ρ 1–3, δ , ϵ , π , θ). Studies co-expressing different GABA_A receptor subunits in simple cells, such as frog oocytes, indicate the potential for several hundreds, if not thousands, of functional GABA_A receptor subunit combinations. However, findings on the distribution and abundance of GABA_A receptor subunits in brain tissue indicate the likely presence of α , β , and γ subunits in the vast majority of receptors, and that the number of naturally occurring types of GABA_A receptors is of the order of ten or fewer [33]. As with the glutamate ionotropic receptors, GABA_A receptors have a number of allosteric modulatory sites, and such sites are sensitive to a variety of pharmacological agents, including benzodiazepines, certain endogenous steroids, steroidal anaesthetic agents such as propofol, and alcohol (ethanol).

GABA_A receptors are influenced by the binding of benzodiazepines, such as diazepam, and ‘Z drugs’, like zolpidem, which produce their anxiolytic and sedative effects via the benzodiazepine-binding site. Given the high chemical specificity of the benzodiazepine-binding site, there has been an extensive search for an endogenous ligand. This has led to the discovery of the ‘endozepine’, a diazepam-binding inhibitor, which is a peptide with many of the properties that would be predicted of an endogenous ligand at the benzodiazepine-binding site. This includes secretion (possibly from glial cells) and modulation of the GABA_A receptor, although both positive and negative modulatory effects have been detected [34].

Genetic and pharmacological approaches have been used to identify the pharmacological significance of multiple GABA_A receptor subtypes, and specifically to determine the functional significance of six variants of the α subunit, which is critical to the binding of benzodiazepines [28]. In particular, studies with point-mutated mice have revealed that the sedative effect of diazepam is mediated by α 1-containing GABA_A receptors, whereas the anxiolytic action is mediated by α 2/ α 3-containing GABA_A receptors. Moreover, findings that ligands with selective actions at α 2- and/or α 3-containing GABA_A receptors display anxiolytic activity at doses lower than those that cause sedation [35]. This raises the possibility of interesting

future drug therapies, for example drug treatments for anxiety disorder that have the anxiolytic effect of benzodiazepines, such as diazepam, but lack their unwanted adverse effects [36]. Interestingly, $\alpha 5$ -containing GABA_A receptors may be an important site of action of alcohol. The GABA_A receptor subunit(s) targeted by steroids to produce CNS inhibitory effects of these agents are currently under investigation.

G protein-coupled receptors

Almost all neurotransmitters, including glutamate and GABA, signal effects via GPCRs, and most neurotransmitters signal via more than one type of GPCRs. For example, the monoamine 5-HT possesses 14 receptor subtypes (comprising seven receptor families 5-HT₁₋₇), 13 of which are GPCRs and one is a ligand-gated ion channel (5-HT₃). Each 5-HT GPCR has high affinity and selectivity for 5-HT, but individually the receptors are pharmacologically distinct, arise from different (but homologous) genes, and are formed from different protein sequences with different distributions and signalling effects [37]. Since several 5-HT GPCRs can co-localize at a single synapse, the signal received by a postsynaptic neuron may be quite complicated. This complexity for 5-HT can be seen in many other transmitters, including dopamine (D₁₋₅), glutamate (mGluR₁₋₈), noradrenaline ($\alpha_{1A,B,D}$, $\alpha_{2A,B,C}$, β_{1-3}), endocannabinoids (CB₁₋₂), and neuropeptides (Table 14.4).

Typically, GPCRs comprise a single membrane protein with seven transmembrane-spanning domains, an *N*-terminus facing the extracellular space, a *C*-terminus facing the cytoplasm, and several intracellular transmembrane domain linking loops. The *N*-terminus of some GPCRs (mGluR₁₋₈, GABA_B) contains the ligand-binding site, while for most GPCRs, the predicted ligand-binding site lies within the transmembrane domains. Both the *C*-terminus and the third transmembrane intracellular loops are phosphorylated by protein kinases, which can result in altered GPCR function, as well as trafficking to the plasma membrane. The third intracellular loop is the main site of G protein interaction.

G proteins

Each G protein is a heterotrimer comprising α , β , and γ subunits that dissociate on binding of the ligand to the GPCR. On dissociation, the α subunit binds GTP and, through intrinsic GTPase activity, directly regulates a number of specific downstream effector enzymes and ion channels. The β/γ subunits are also biologically active and regulate some of the same effector proteins.

There are four major types of G proteins—G_s, G_i, G_q, and G_o—that produce the following ‘canonical’ signalling effects, respectively: activation of adenylyl cyclase, inhibition of adenylyl cyclase, activation of phospholipase C (PLC), and interaction with calcium ion and potassium ion channels. Changes in the activity of adenylyl cyclase result in altered intracellular levels of the ‘second messenger’ cyclic adenosine monophosphate (cAMP). Similarly, PLC alters intracellular levels of inositol triphosphate (IP₃) and diacylglycerol (DAG). Altered levels of these second messengers trigger changes in the activity of specific signalling cascades and ultimately changes in physiological responses.

Table 14.4 Examples of neurotransmitter receptors

Transmitter	Receptor	Signal transduction
Dopamine	D ₁ family (dopamine D ₁ , D ₅) D ₂ family (dopamine D ₂ , D ₃ , D ₄)	Adenylyl cyclase (G _s) Adenylyl cyclase (G _{i/o})
Noradrenaline	α_1 family ($\alpha_{1A, B, D}$) α_2 family ($\alpha_{2A, B, C}$) β family ($\beta_{1, 2, 3}$)	Phospholipase C (G _q) Adenylyl cyclase (G _{i/o}) Adenylyl cyclase (G _s)
5-HT	5-HT ₁ family (5-HT _{1A, B, D, E, F}) 5-HT ₂ family (5-HT _{2A, B, C}) 5-HT ₃ 5-HT ₄ 5-HT ₅ family (5-HT _{5A, B}) 5-HT ₆ 5-HT ₇	Adenylyl cyclase (G _{i/o}) Phospholipase C (G _q) Cation channel Adenylyl cyclase (G _s) Not certain Adenylyl cyclase (G _s) Adenylyl cyclase (G _s)
Acetylcholine	M ₁ (muscarinic) M ₂ M ₃ M ₄ M ₅ Nicotinic ($\alpha 1-10$, $\beta 1-4$, δ , ϵ , γ)	Phospholipase C (G _q) Adenylyl cyclase (G _{i/o}) Phospholipase C (G _q) Adenylyl cyclase (G _{i/o}) Phospholipase C (G _q) Cation channel
GABA	GABA _A ($\alpha 1-6$, $\beta 1-3$, $\gamma 1-3$, $\sigma 1-3$, δ , ϵ , π , ρ) GABA _B	Chloride channel Adenylyl cyclase (G _{i/o})
Glutamate	AMPA (GluA1–4) NMDA (GluN1, GluN2A–D, GluN3A–B) Kainate (GluK1–5) Group I family (mGluR _{1/5}) Group II family (mGluR ₂₋₃) Group III family (mGluR _{4, 6, 7, 8})	Cation channel Cation channel Cation channel Phospholipase C (G _q) Adenylyl cyclase (G _{i/o}) Adenylyl cyclase (G _{i/o})
Tachykinin (including substance P)	NK ₁ NK ₂ NK ₃	Phospholipase C (G _q) Phospholipase C (G _q) Phospholipase C (G _q)
Opioid	δ κ μ	Adenylyl cyclase (G _{i/o}) Adenylyl cyclase (G _{i/o}) Adenylyl cyclase (G _{i/o})
Galanin	GAL1 GAL2 GAL3	Adenylyl cyclase (G _{i/o}) Adenylyl cyclase (G _{i/o}) Adenylyl cyclase (G _{i/o})
Adenosine	A ₁ A ₂ family (A _{2A, B}) A ₃	Adenylyl cyclase (G _{i/o}) Adenylyl cyclase (G _s) Adenylyl cyclase (G _{i/o})
ATP	P2X family (P2X ₁₋₇) P2Y ₁ P2Y ₂ P2Y ₄ P2Y ₆ P2Y ₁₁ P2Y ₁₂ P2Y ₁₃ P2Y ₁₄	Cation channel Phospholipase C (G _q) Phospholipase C (G _q) Phospholipase C (G _q) Phospholipase C (G _q) Phospholipase C (G _q) Adenylyl cyclase (G _{i/o}) Adenylyl cyclase (G _{i/o}) Phospholipase C (G _q)
Cannabinoid	CB1 CB2	Adenylyl cyclase (G _{i/o}) Adenylyl cyclase (G _{i/o})

The indirect opening of ion channels in response to neurotransmitter-induced GPCR activation leads to direct effects (excitatory or inhibitory) on the electrical properties of neurons, albeit on a longer timescale than effects produced by ligand-gated ion channels. Almost all neurotransmitter classes are able to evoke changes in ion channel opening via GPCRs, and some may be clinically important. For example, the α_2 -adrenoceptor-induced opening

of potassium ion channels on noradrenaline neurons causes a fall in noradrenergic activity and release, which may contribute to the anxiolytic and sedative properties of α_2 -adrenoceptor agonists such as clonidine. On the other hand, the 5-HT_{2A} receptor-induced closing of potassium ion channels on cortical neurons causes an increase in cortical neuron activity and may underlie the psychotropic effects of lysergic acid diethylamide (LSD) and related hallucinogens [37].

GPCR regulation

Recent discoveries of interactions between GPCRs and other intracellular proteins have led to a new understanding of how the receptors are regulated and trafficked to and from the plasma membrane. Studies commencing on the β -adrenoceptor have identified two families of regulatory proteins called β -arrestins and GPCR kinases (GRKs). Within seconds of being activated by an agonist, the GPCR is phosphorylated by a GRK on the C-terminal cytoplasmic tail and other intracellular domains. This phosphorylation promotes the interaction of β -arrestins with the GPCR, which limits the signal duration, and causes loss of sensitivity to agonist activation and then receptor internalization from the cell surface [38].

In addition to β -arrestins, the C-termini of GPCRs associate with a large variety of transmembrane or soluble proteins, termed 'GPCR-interacting proteins' (GIPs). Some GIPs are themselves

GPCRs that form homo- or heterodimers, while other GIPs are ionic channels, ionotropic receptors, and proteins that control GPCR trafficking [39]. One interesting example of a GIP is the molecule p11, which reportedly functions to traffic a 5-HT GPCR (5-HT_{1B}) to the plasma membrane. Evidence suggests that p11 expression is reduced in the post-mortem brain of patients committing suicide and that mice with a genetic deletion of p11 have a depressive-like phenotype [40].

Second messengers

The generation of the second messengers cAMP and DAG by adenylyl cyclase and PLC, respectively, leads to activation of protein kinases that add phosphate groups to specific protein targets to change their activity and ultimately trigger diverse physiological responses (Fig. 14.2). Enzymes called phosphatases, which remove phosphate groups, oppose these signalling effects. Guanylate cyclase is a cytosolic enzyme which also generates a second messenger cGMP. As noted, guanylate cyclase is activated by NO to produce effects on presynaptic function.

Based on molecular cloning studies, nine forms of adenylyl cyclase have been identified (I–IX), and each exhibits a distinct distribution in brain and peripheral tissues [41]. The full implication of this complexity is not yet understood, but it suggests that regulation of

Fig. 14.2 Diagrammatic representation of ligand-gated ion channel and G protein-coupled receptors. Ligand-gated ion channels comprise multiple protein subunits that form a central pore in the plasma membrane. On binding of the neurotransmitter, this receptor mediates fast excitatory or inhibitory transmission, depending on whether the channel gates cations or chloride ions, respectively. G protein-coupled receptors comprise a single membrane-spanning protein. On binding of the neurotransmitter, this receptor mediates slow transmission by enabling the dissociation of the G protein into an α subunit monomer and a β/γ subunit dimer, both of which may activate an effector enzyme to generate a second messenger. Also, the β/γ subunit dimer may directly interact with ion channels. Second messengers may also indirectly modulate ion channels through phosphorylation by activating protein kinases.

cAMP formation varies, depending on the form of adenylyl cyclase expressed in neuronal cells.

Both cAMP and cGMP are degraded by phosphodiesterases (PDEs), which are expressed in numerous forms (types 1–11) in brain and peripheral tissues [30]. At high concentrations, caffeine and related methylxanthines inhibit PDE and this action contributes to the pharmacological effects of these drugs. Much effort is being made to develop inhibitors that are selective for brain-specific forms of PDE. Rolipram inhibits all isoforms of PDE4; this drug showed promise as an antidepressant, but its clinical utility was limited by peripheral side effects. However, because PDE4 enzymes comprise a number of isoforms, an inhibitor of one isoform may lead to the development of an effective antidepressant without the side effects of rolipram.

GPCR-induced activation of PLC causes the breakdown of phosphatidylinositol, resulting in the generation and recycling of the second messengers IP_3 and DAG, via the phosphoinositide cycle. Both IP_3 and DAG produce downstream signalling effects, IP_3 through the mobilization of intracellular calcium stores and DAG through activating a protein kinase. There are two major isoforms of PLC in the brain— β and γ , the β isoform being predominantly responsible for mediating the effects of GPCRs linked to G_q .

After its formation, IP_3 is recycled via a series of dephosphorylations to form inositol, which is used in the regeneration of phosphatidylinositol. Lithium, which is an important drug in the treatment of bipolar disorder, inhibits one of the enzymes involved in the recycling of IP_3 [inositol-1-monophosphatase (IMPase)] and causes inositol depletion at therapeutic concentrations. Because inositol does not easily enter the blood–brain barrier, brain inositol levels are thought to fall and the production of the second messengers diminishes. It is a popular hypothesis that inositol depletion is responsible for lithium's clinical effects, but this remains unproven. The recent discovery that the organoselenium antioxidant compound ebselen inhibits IMPase has stimulated interest in the idea that this agent has potential for repurposing, and specifically for use in bipolar depression [42].

In addition to IMPase, lithium interacts (albeit often at high concentrations) with a range of other signalling systems, including various ion channels, adenylyl cyclases, and protein kinases. For example, lithium inhibits glycogen synthase kinase-3 β (GSK-3 β), which also provides a source of inositol in the brain; certain mood-stabilizing anticonvulsants, such as valproate, also have this effect [43]. This has encouraged the development of GSK-3 β inhibitors for bipolar disorder. However, GSK-3 β has a range of functions, including a role in trophic mechanisms, and the safety of GSK-3 β inhibitors is currently uncertain.

Downstream signalling cascades

The activation or inhibition of second messenger signalling cascades by GPCRs can profoundly change the intracellular environment of the neuron by regulating the activity of protein kinases and other proteins, including gene transcription factors and even enzymes involved in the regulation of chromatin structure. Consequently, these cascades may regulate gene transcription and protein synthesis and activate multiple downstream effectors, including those that form the cytoskeleton or contribute to mechanisms underlying synaptic

plasticity. Such effects can induce long-lasting changes in neuronal function. Increasing evidence suggests that the neuroadaptive responses to repeated psychotropic drug administration are underpinned by changes in gene expression that result in the remodelling of neural circuit function and structure. This thinking has been applied to explain a multitude of neuropharmacological mechanisms, ranging from compulsive use of recreational drugs to the therapeutic action of antidepressant and antipsychotic drugs.

As an example, recent research has seen the evolution of a fascinating theory to explain the delayed onset of antidepressant effect of drugs like fluoxetine and imipramine that act to inhibit plasma membrane monoamine transporters. It supposes that elevated monoamine levels (through transporter blockade) trigger GPCR signalling cascades that activate gene programmes to enhance neuronal survival and connectivity, the latter having being weakened because of the adverse effects of stress and other environmental factors [18, 44–46]. Some of the key genes involved in this process include trophic factors such as BDNF, which may be a trigger for the production of newly formed neurons and many other forms of neural plasticity that leads to the overall strengthening of synapses and increased information transfer through key neural circuits relevant to mood control. This theory is a driving force for the development of pharmacological strategies for improved antidepressant therapies, even though our knowledge of the key molecules that are changed by antidepressants to bring about the relief of the symptoms of depression is far from complete.

Non-canonical GPCR signalling

In addition to the classical (canonical) GPCR signalling, it is now recognized that GPCRs signal via a diversity of less well-known (referred to here as non-canonical) pathways, some of which are dependent on 'small G proteins' and others which are G protein-independent. Small G proteins (termed because of their low molecular weight and monomeric composition) comprise a protein superfamily, which also bind GTP and possess intrinsic GTPase activity. These G proteins function as molecular switches that control several cellular processes, ranging from vesicle trafficking and exocytosis (for example, Rab) to assembly of cytoskeletal structures (for example, Rho). Among the best characterized small G proteins are those that comprise the Ras family. Numerous types of cell signals, including those of most neurotrophic factors, converge on Ras and related proteins to regulate mitogen-activated protein (MAP) kinase pathways. Some GPCR signalling is independent of G proteins and often involves the recruitment of members of the arrestin family of proteins, which then trigger downstream pathways such as those involving MAP kinase.

This diversity in GPCR signalling is highly relevant in the context of emerging experimental evidence that different agonists acting at the same receptor can elicit different signals. This phenomenon is sometimes referred to as biased agonism or ligand-dependent signalling. Thus, agonists for a specific receptor may differ not only in terms of potency and efficacy, as given in classical pharmacological accounts, but also in terms of the signal that they elicit. Interestingly, evidence of ligand-dependent signalling through 5-HT_{2A} receptors has relevance to the psychotropic effects of 5-HT_{2A} receptor agonists, some of which are hallucinogenic, but not all, and

it may also explain the long-lasting effects of LSD which are difficult to explain on the basis of pharmacokinetics alone [47]. Biased agonism offers intriguing possibilities for therapeutic potential (for example, avoidance of adverse side effects), although this is yet to be explored.

Concluding remarks

Until recently, studies on the chemistry of synaptic neurotransmission have focused on a relatively small number of neurotransmitters and a narrow group of proteins involved in neurotransmitter function, specifically neurotransmitter receptors, transporters, and enzymes which bring about neurotransmitter synthesis or degradation. Today, powerful molecular and genetic approaches are being used to identify and understand new proteins and mechanisms involved in neurotransmitter function and control. So far, just a few tens of perhaps thousands of neurotransmitter-related proteins have been successfully targeted by pharmacological agents and translated into important treatments of psychiatric disorder, but there is promise of many more such treatments to come. Moreover, this huge diversity of neurotransmitter-related proteins is now emerging as a large resource for studies of genetic risk factors of psychiatric disorder and investigations of biological markers of illness diagnosis and progression and treatment outcome.

Psychoneuroimmunology

Juan C. Leza, Javier R. Caso, and Borja García-Bueno

Introduction

Psychoneuroimmunology (also known as psychoneuroendocrinology) is a growing scientific discipline that studies the complex bi-directional circuit between the nervous system and the immune system in health and pathological conditions. The study of these interactions requires a multi-disciplinary and convergent approach from psychology, neurosciences, immunology, pharmacology, psychiatry, behavioural medicine, infectious diseases, endocrinology, rheumatology, and other disciplines.

The term was coined around the 1970s by R. Ader and N. Cohen, studying how episodes of stress and anxiety affect a person's immune system and how this activation of the immune system affects mental processes and health in extension.

Along history, a common place for psychoneuroimmunologists is the study of stress exposure and how individuals mount proper responses to cope with it. The mechanism/s implicated in the stress-induced modification of the immune system will be briefly discussed in this chapter, as well as the consequences in the structure and function of the CNS, both at molecular and behavioural/cognitive levels. Some large meta-analytic studies indicate both activation and depression of the immune system after stress exposure, depending on the duration, intensity, and the kind of stressful event (for example, trauma or loss) [1].

Stress: cross-talk between the brain and the immune system

The term stress has been widely used since a long time ago to define a range of situations and experiences like those in which somebody is suffering from pressure, anxiety, or sadness, for example, being its use correct in all of them. Physiologically, stress is a situation produced subsequent to experiencing an alteration in an organism's homeostasis mainly due to an aversive threat. W. Cannon and H. Selye made some of the initial discoveries in this field and were the first to use the terms stress and 'stress response' [2]. This response, constituted by a three-phase mechanism and defined by Selye as *general adaptation syndrome*, is the result of an adaptation necessary to allow the overcoming of situations in which an

organism has to fight or flight to survive. Some of the physiological effects observed in this response are an increase in arousal and concentration capacity, faster cardiac rhythm, higher blood pressure, suppression of the digestive process, redirection of blood to muscles, and a reduction of sexual desire and the immune system activity, among others. All these co-operate to allow the organism to detect the danger and provide it with all the energy available, in order to achieve survival, while depriving the organism from energy necessary for other processes. However, stress is a double-faced phenomenon, since while this fast and reversible response is essential for survival, it may cause adverse effects when secretion of stress hormones is sustained. Indeed, very intense or long-lasting stress results in a new biological equilibrium that can be either beneficial (for example, exercise-induced conditioning of the cardiovascular system) or detrimental, causing damage or disease due to maladaptation. In humans, the threat might be real or not. Although stress is not a disease in itself, continuous exposure to stressful stimuli has been clearly related with the onset, progression, or outcome of many psychopathological processes [3].

Stress response affects many different organs and systems, including the CNS. In the CNS, stress over the course of weeks causes reversible atrophy of hippocampal dendrites and apoptosis, whereas overexposure for months can cause permanent loss of neurons in rodents. Importantly, accumulating evidence of such stress-induced damage in the human brain has been presented [4], particularly in people with PTSD or major depression (that is, decreasing volumes in several brain areas). Studies carried out in animal models or in humans indicate that psychological stress induces a clear inflammatory response in the brain, accompanied by the release of cytokines and oxido-nitrosative mediators and the activation of several intra- and extracellular pathways [5, 6].

Inflammation: how systemic inflammation reaches the central nervous system

Although stress-induced inflammation occurs in the brain, there is much recent evidence indicating that stress induces a systemic inflammatory response, which suggests possible inflammatory-immune cross-talk between the brain and the periphery. The CNS

has long been considered an immune-privileged organ; however, this immune status is far from absolute. There are multiple neuro-immune pathways via which systemic inflammation reaches the CNS (Fig. 15.1).

These could be directly related to behavioural (for example, sickness behaviour, social avoidance, anhedonia) and cognitive alterations (for example, memory disruption), which resemble psychiatric symptomatology. The relative relevance of each one may vary in the function of the type, duration, and severity of the stimuli.

The humoral pathway: signalling through the blood-brain barrier

The BBB structure is a complex histological, multi-layered structure, formed by a thick, continuous glycocalyx (a complex structure of proteoglycans and sialoproteins in the endothelium), non-fenestrated endothelial cells, linked by tight junctions (TJs), two basement membranes (vascular basement membrane and glia limitans), astrocytic end-feet, and two types of perivascular cells (pericytes and perivascular macrophages). All elements of this structure contribute to the functional BBB.

Neuro-immune signalling through the BBB is called the ‘*humoral pathway*’ and occurs via two mechanisms: (1) energy-dependent transportation of immune signals by means of specific/non-specific transporters in the non-fenestrated endothelium of the BBB; and (2) the endothelium and perivascular-associated cells retaining the capacity to detect changes in circulating immune signals (cytokines) and initiating appropriate brain responses by increasing the synthesis and local release of signalling molecules, notably prostaglandins such as prostaglandin E_2 (PGE_2). Release of cerebrovascular PGE_2 activates nearby catecholamine-containing neurons that project to the paraventricular hypothalamic nucleus (PVN), regulating neuroendocrine responses to stress. Like PGE_2 , nitric oxide (NO) produced by the endothelium is also considered a second messenger implicated in the *humoral pathway*.

In inflammatory conditions, passage of inflammatory cells (lymphocytes, neutrophils, and monocytes) across the BBB occurs primarily at the post-capillary venules in a process called cellular transmigration through a disrupted endothelium. Once leucocytes reach the perivascular space, a second step requires passage across the glia limitans to enter the brain parenchyma in a process regulated by perivascular cells (macrophages and pericytes).

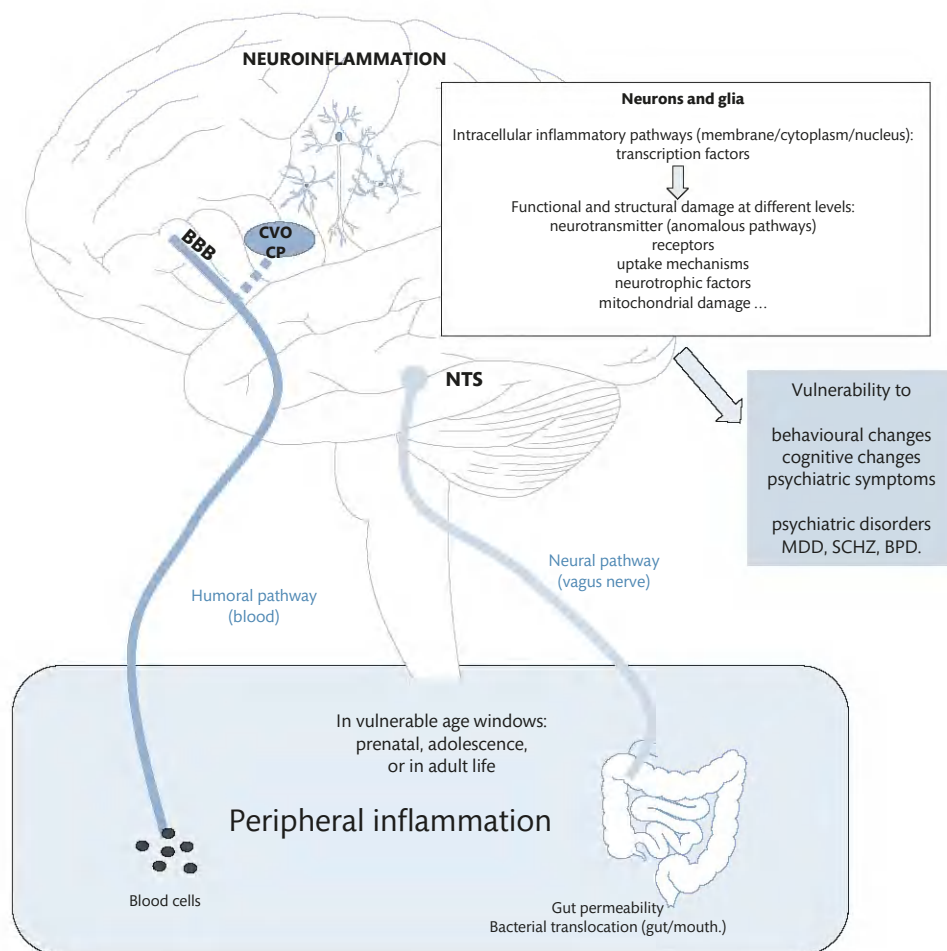

Fig. 15.1 Multiple neuro-immune pathways by which systemic inflammation can reach the CNS. Possible functional, structural, and clinical consequences. BBB: blood-brain barrier; CVO: circumventricular organs; CP: choroid plexus; NTS: nucleus tractus solitarius; MDD, major depressive disorder; SCHZ, schizophrenia; BPD: bipolar disorder.

Signalling through structures in the brain that lack a normal blood–brain barrier (circumventricular organs)

The circumventricular organs (CVOs) can be functionally divided in two major types: (1) the sensory organs, including the area postrema (AP), the subfornical organ (SFO), and the vascular organ of the *lamina terminalis*; and (2) the secretory organs, mainly including the subcommissural organ (SCO) and the median eminence. The sensory organs detect and transmit peripheral immune signals to the CNS, and conversely, the secretory organs produce signals (that is, hormones) from the CNS to modulate the activity of peripheral organs and systems. The particular and extensive fenestrated vasculature of these organs allows direct interaction between neurons and glial cells, which also form part of their structure and peripheral blood flow. These organs also possess neuroanatomical connections between them, as well as with other remote brain areas and structures involved in the regulation of the immune system such as the PVN and vagal sensory fibres. The exact contribution of each organ to transduce cytokine-dependent signalling is not known and may vary in function of the intensity of the stimulus. As occurs in the choroid plexus (CP), there are resident macrophage-like cells in the CVOs that respond to circulating stimuli by producing pro-inflammatory cytokines, and also in pathological conditions, there are increased numbers of CD45⁺ leucocytes in the CVOs, suggesting the recruitment of inflammatory cells into the parenchyma of the CVOs, probably mediated by endothelial adhesion molecules.

Signalling through the blood–cerebrospinal fluid barrier formed by the choroid plexus and meningeal arachnoid membrane (endothelium and meningeal macrophages)

The CP is located in the brain ventricles and is formed by epithelial cells [with TJs and gap junctions (GJs) between them] that rest upon a basal lamina, and a second stromal structure consisting of central connective tissue and highly fenestrated vascularized tissue populated by diverse cell types (fibroblasts, macrophages, and dendritic cells). Its main function is the production of CSF.

It is accepted that CP response to acute peripheral stimuli is fast and strong but loses magnitude on chronicity. The CP is the preferred site for initial transepithelial leucocyte trafficking from the periphery to the brain, because it contains resident immune cells (the function of CD4⁺ T cells is especially relevant in this regard) that produce pro-inflammatory cytokines and expresses major histocompatibility complex (MHC) and leucocyte adhesion molecules. The CSF passes into the subarachnoid spaces surrounding the brain and spinal cord. Part of the CSF drains into blood via arachnoid villi in venous sinuses, but the CSF also drains from the cerebral subarachnoid space to cervical lymphatic organs. This pathway also allows traffic of antigen-presenting cells between the brain parenchyma and regional lymph nodes.

Direct recruitment of immune stimulus-primed peripheral immune cells to brain parenchyma

Peripheral immune cells may act as important modulators of neuroinflammation. Under physiological conditions, several types of immune cells (monocytes, granulocytes, dendritic cells, T cells, and perivascular macrophages) of haematopoietic origin populate specific brain areas (vasculature, CP, and meninges) and exert

supportive and immunosurveillance actions. By contrast, in a state of chronic/uncontrolled neuroinflammation (for example, chronic exposure to stress), these cells are potentially detrimental due to their capacity to produce massive levels of pro-inflammatory mediators such as cytokines and chemokines.

In the resolution phase of neuroinflammation after injury, recruitment of blood-derived cells (that is, macrophages) facilitates the resolution of the neuroinflammatory response by displaying an M2-like anti-inflammatory profile. As previously commented, these monocyte-derived macrophages enter the injured brain site through a designated barrier—the CP within the blood–CSF barrier, rather than through the breached BBB.

Neural pathway

The ‘neural pathway’ is mainly constituted by the activation of primary sensory afferent nerves such as the *vagus* nerve by macrophages, increased cytokine levels, or direct activation of the innate immune receptors Toll-like receptors (TLRs) by DAMPs (damage-associated molecular patterns) or PAMPs (pathogen-associated molecular patterns). Inflammation signals reach the nucleus tractus solitarius, which interconnects with the dorsal motor nucleus where the majority of efferent vagus nerve fibres originate.

The efferent component of the vagus nerve detects signals from the periphery, and through the release of acetylcholine (ACh) and consequent activation of $\alpha 7$ nicotinic ACh receptors ($\alpha 7$ nAChRs) expressed in macrophages and T cells, the production of pro-inflammatory cytokines is markedly inhibited. In addition, stimulation of the vagus nerve induces activation of stress hypothalamus–pituitary–adrenal (HPA) axis, which results in glucocorticoid release by the adrenal cortex, with broad anti-inflammatory actions. This neuro-immune communication is termed ‘*the inflammatory reflex*’.

In conclusion, the brain and the immune system have mutual dependency. The brain regulates multiple organs, the immune system included, mainly at the level of lymphoid organs. On the other hand, immune cells help to maintain brain homeostasis and plasticity when brain-resident microglia, astroglia, and perivascular macrophages are unable to cope with an exacerbated neuroinflammatory response. Neuro-immune interactions take place through different barriers, each with specific, and often complementary, functions. Elucidation of the multiple interconnections between them will improve the development of new approaches for the treatment of neurodegenerative and psychiatric diseases.

Inflammation and depression (in animal models and humans)

A biological basis for mood disorders was described as early as the fifth century BC, when Hippocrates referred to *melancholia* as a condition associated with ‘aversion to food, despondency, sleeplessness, irritability and restlessness’. Nevertheless, the fundamental pathophysiology of depression still stays elusive. In fact, different studies are indicating that, in some cases, more than 30% of depressed patients fail to achieve remission despite multiple treatment trials [7].

Interestingly, mounting data indicate that inflammation may also play a role in the pathophysiology of major depressive disorder

(MDD). Given the accelerating development of biomarkers and treatments focused on the inflammatory response, there is tremendous promise that these advances, in addition to their relevance to general medicine, may have unique applications in psychiatry.

Different epidemiological studies have demonstrated that MDD is associated with a higher prevalence of elevated markers of inflammation [8], and different meta-analyses have shown that the levels of cytokines and other indicators of an inflammatory scenario are elevated in the periphery of patients with MDD [9–11]. In addition, a recent meta-analysis indicated that elevated peripheral levels of inflammation are contributory to treatment resistance in MDD subjects [12]. Indeed, elevated levels of inflammatory markers predict a poorer response to drugs against depression (antidepressants), and those who do not respond to AD treatments show persistently elevated inflammation.

Thus, inflammation, both in the brain and in the periphery, is being presented as an element worth considering in the aetiology of psychiatric conditions such as MDD. This conception is grounded in the strongly activated inflammatory/immune response detected in these diseases [7, 13–15] and in that patients with MDD who are otherwise medically healthy have been repeatedly observed to have activated inflammatory pathways. In addition to those pathways are worth mentioning increased levels of pro-inflammatory cytokines and acute phase proteins and increased expression of chemokines and adhesion molecules.

Long-term exposure to cytokines also has been shown to lead to marked behavioural alterations in humans. Thus, several studies in humans suggest that immune-targeted therapies may have clinical benefit. For example, medically healthy depressed patients who received the selective cyclo-oxygenase-2 (COX-2) (a key enzyme for the production of prostaglandins and other eicosanoids) inhibitor celecoxib, in combination with reboxetine, showed greater symptomatic improvement vs patients randomized to reboxetine plus placebo [16].

Antidepressant activity of anti-inflammatory therapy has also been observed in patients with autoimmune and inflammatory disorders. For example, in a large double-blind, placebo-controlled trial of the TNF α antagonist etanercept for the treatment of psoriasis, participants who received etanercept exhibited significant improvement in depressive symptoms, compared with placebo-treated subjects, an effect independent of improvement in disease activity [17].

Thus, it seems reasonable to recognize that pro-inflammatory cytokines induce not only symptoms of sickness, but also true MDDs in physically ill patients with no previous history of mental disorders.

Besides, clinical observations and epidemiological data have also demonstrated associations between suicide and inflammatory cytokines in the orbitofrontal cortex, a brain region involved in suicidal vulnerability. Interestingly, the perception of menace that directs suicidal individuals to consider suicide may trigger biological stress responses, including the inflammatory ones [18].

Aside from evidence of increased levels of inflammatory markers in patients with MDD, data from laboratory animals indicate that the administration of innate immune cytokines, including interferon (IFN)- α , or an immunological challenge induced by lipopolysaccharide (LPS) injection (major component of the outer membrane of Gram-negative bacteria which induces the secretion

of cytokines) leads to multiple behavioural changes that overlap with MDD, including depressed mood, anhedonia, psychomotor slowing, disrupted sleep, anxiety, etc. This is the so-called *sickness behaviour* [19, 20]. These findings are consistent with a vast literature on laboratory animals, indicating that cytokine antagonists or anti-inflammatory agents can block the development of behavioural changes following immune activation.

On the other hand, it seems fairly recognized nowadays that both genetic and environmental factors (such as stress) contribute to depression. Currently, experimental models of depression are based on exposure to stress, and it has been widely described that experimental stress induces pro-inflammatory actions mediated by glucocorticoids, catecholamines, glutamate, and other mediators released by stress [5]. Thus, experimental data indicate that inflammation is an important component of MDD, and in particular, pro-inflammatory cytokines that are induced by injury and infection, as well as by psychological stress, are implicated in depressive-like behaviour in rodent models.

Some of the mechanisms that might be responsible for inflammation-mediated sickness and depression have now been elucidated. These findings suggest that the brain–cytokine system, which is, in essence, a diffuse system, is the unsuspected conductor of the ensemble of neuronal circuits and neurotransmitters that organize physiological and pathological behaviour. Some of the evidence will be discussed in the next sections.

Depression, serotonin, and cytokines

Traditionally, the prevailing hypothesis is that depression is caused by some disorganization of brain serotonergic systems, perhaps a deficiency in serotonergic neurotransmission. This hypothesis is based largely on the observation that many effective drugs for depression affect serotonergic transmission. Also, serotonin receptor abnormalities are found in the brain of patients with MDD. While there is no doubt that drugs for depression increase synaptic levels of serotonin, noradrenaline, and (some of the drugs) dopamine, these compounds also suppress pro-inflammatory cytokine production (for example, IL-1 β , IL-6, TNF α) and stress hormone release and may additionally stimulate anti-inflammatory cytokine (for example, IL-10) release [21]. These data indicate again that neuro-immune and neuroendocrine system perturbations likely play an important role in the aetiology of depression.

Depression, immune system activation, and indoleamine 2,3-dioxygenase

As aforementioned, an immunological challenge, such as induced by LPS injection, leads to multiple behavioural changes that overlap with MDD. Thus, a factor which induces an immunological response (such as infection) and subsequent cytokine release could be implicated in the origin of this disease.

An interesting hypothetical mechanism by which infections might induce depression relates to the metabolism of tryptophan and serotonin (5-HT). Infections induce IFN- γ and TNF α , which are potent inducers of indoleamine 2,3-dioxygenase (IDO) in macrophages and certain other cells. This enzyme degrades tryptophan, so IDO enables the conversion of tryptophan to kynurenine. The resulting catabolism of tryptophan decreases its circulating concentrations, and lower plasma concentrations of tryptophan have been associated with depression. It has been postulated that such a decrease may

limit the availability of tryptophan to the brain, thus limiting serotonin synthesis and precipitating depression [22].

Furthermore, the induction of IDO through immune system activation could also be playing a role in other theoretical mechanisms implicated in the pathophysiology of MDD such as excitotoxicity and glutamate metabolism. As it has been already mentioned, once activated by pro-inflammatory cytokines, IDO degrades tryptophan. But IDO activation also generates potentially neurotoxic kynurenine metabolites, such as kynurenic acid and quinolinic acid, which could contribute to the pathogenesis of psychiatric diseases through their actions on the glutamate NMDA receptor (that is, kynurenic acid is an endogenous glutamate NMDA receptor antagonist, and quinolinic acid an endogenous glutamate NMDA receptor agonist) [23].

Depression, bacterial translocation, and innate immunity

Recent studies have postulated that increased gastrointestinal permeability with an increased translocation of LPS from Gram-negative bacteria may play a role in the pathophysiology of MDD. Specifically, it has been suggested that increased LPS translocation may mount an immune response, and thus an inflammatory status, in some patients with MDD and may induce specific sickness behaviour symptoms [24].

Disruptions of the intestinal epithelium allow normally poorly invasive enterobacteria to exploit lipid raft-mediated transcytotic pathways or the enlarged spaces to cross the gut wall. Thus, loss of the epithelial barrier integrity caused by inflammation and/or stress may induce an increased bacterial translocation, provoking increased serum concentrations of LPS. And as it is well known, LPS causes induction of nuclear factor κ B (NF- κ B), the major upstream intracellular mechanism which regulates inflammatory and oxidative/nitrosative stress mediators, such as COX-2 and inducible NO synthase (iNOS), and also causes cytokine release through its union to the TLR-4 [6].

TLRs are one of main actors of innate immunity, and there are a good number of preclinical studies showing that TLRs are involved in depression-like behaviour induced by experimental models of MDD. Furthermore, there is increasing evidence from the clinical arena suggesting that TLRs are involved in the pathophysiology of MDD. Recently, TLR-4 mRNA expression in peripheral blood has been identified as an independent risk factor related to the severity of MDD. In addition, studies have shown that some elements of the TLR-4 signalling pathway were upregulated at mRNA level in peripheral blood mononuclear cells (PBMCs) of patients with MDD. And importantly, these peripheral alterations of the TLR-4 signalling pathway have been corroborated in post-mortem human brain tissue (dorsolateral prefrontal cortex) from depressed and suicidal patients [25–27].

Based on this, it is plausible to conclude that increased bacterial translocation is another pathway which may explain the inflammatory pathophysiology of MDD. Thus, the TLR-4 pathway may either primarily (increased translocation of LPS inducing inflammation) or secondarily (primary inflammation that may induce bacterial translocation) be involved in the inflammatory pathophysiology of MDD.

Consequently, the study of possible bacterial translocation and the kind of bacteria present in an organism (microbiota) has a

crucial importance and represents an area of research in which further investigation is warranted.

The psychoneuroimmunology approach to the study of the pathophysiology of MDD is crucial, as it could expose related biomarkers for the identification and monitoring of potentially responsive patients. From this point of view, there are already compilations of common peripheral biomarkers measured in studies on MDD [28].

Among the inflammatory and immune response peripheral biomarkers, cytokines (for example, TNF α , IL-1 β , IL-6, IFN- γ), C-reactive protein, neopterin (released by macrophages and considered a marker of activation of cell-mediated inflammation), and tryptophan catabolites, as well as different elements of the IDO pathway, stand out.

Bearing in mind that inflammation is often followed by oxidative damage, there are other peripheral biomarkers of oxidative and nitrosative stress to consider such as malondialdehyde (a product of lipid peroxidation), superoxide dismutases (SODs) (an important antioxidant defence in nearly all cells exposed to oxidative stress), and glutathione peroxidase and reductase.

Inflammation and psychosis (in animal models and in humans)

The idea about the existence of alterations of the innate immune system taking part in the aetiology and pathophysiology of psychotic disease is long-standing but has been receiving renewed interest in the last years. Specifically, alterations of the innate immune system could contribute to the pathophysiology of these mental diseases, producing alterations in processes such as dopaminergic and serotonergic metabolism and transmission, neurotrophic factor levels, neurogenesis, and even behaviour and cognition.

There is converging evidence from different fields of knowledge and approaches (genetics, pharmacology, brain imaging, clinical trials), both in experimental animal models and in human biological samples from diverse organic compartments (serum, plasma, PBMCs, and post-mortem human brain tissue samples), as well as from subjects diagnosed with different degrees of psychotic disease.

Most of the evidence supporting peripheral inflammatory changes in schizophrenia involves elevated plasma pro-inflammatory cytokine levels (that is, IL-1 β and -6). These effects have been directly associated with certain clinical features such as cognitive impairment and brain volume loss or with negative symptoms. There is less evidence on alterations in the number, activity, and profile of peripheral immune cells in psychotic disease, but some authors have described T cell dysfunction in patients with schizophrenia and an imbalance of immune responses towards a major humoral [T helper 2 (Th2)] response in plasma, correlated with a worse prognosis. In addition, recent studies have reported the existence of anti-NMDA receptor antibodies and surface dopamine-2 receptor antibodies in serum and CSF of subgroups of individuals with psychotic disease.

Inflammatory evidence is also present in the brain. Abnormal CSF cytokine and leucocyte levels have been identified in the brain of schizophrenia patients. Post-mortem evidence for inflammation is growing. Brain microglial activation and abnormal lymphocyte levels have been suggested in post-mortem and PET studies, although novel, highly specific PET ligands for activated microglia are needed. Alterations in other immunity-related systems at the

CNS level have been also reported, such as the case of prostanoids (that is, prostaglandins and related lipid-derived compounds), endocannabinoids, and the tryptophan-degrading enzyme indoleamine 2,3-dioxygenase (IDO) generating potentially neurotoxic kynurenine metabolites such as kynurenic and quinolinic acids. Schizophrenia manifest interrelated peripheral and central symptomatology. Determining the relationship between peripheral and central changes in inflammation-related molecules in subjects with a psychotic disorder could be useful not only for diagnosis and monitoring of the natural course of the disease (trait or state biomarkers, risk/protective factors), but also to reveal possible mechanisms with aetio-pathophysiological relevance.

One relevant question to address is the mechanism/s whereby inflammation leads to brain cell damage in psychotic disease. Some of the putative mechanisms involved include: (1) microglial overactivation or increased microglial cellular density; (2) oxidative/nitrosative stress; (3) uncontrolled activation of the HPA stress axis (hypercortisolism); (4) excitotoxicity and disrupted glutamate metabolism; (5) mitochondrial dysfunction and energy deficits; (6) reduced levels of neurotrophins (that is, BDNF, NGF); (7) impaired neurogenesis; (8) apoptosis; (9) demyelination; (10) impaired glucose transport and metabolism; and (11) functional BBB breakdown and ultrastructural abnormalities affecting a number of brain functions, including excitatory/inhibitory neurotransmission, stress and alarm phase responses, and synaptic plasticity.

Another issue to elucidate is the possible origin of increased inflammation in psychotic disease. There are multiple theories dealing with the origin of increased inflammation in schizophrenia. Five major categories exist:

1. Inflammatory changes before birth (due to prenatal or maternal infections and/or obstetric complications). The common notion is that these factors 'prime' an immature fetal immune system that will remain impaired for a lifetime. This idea is gaining momentum, and schizophrenia is now strongly related to anomalies in neurodevelopment. Currently, the use of maternal immune activation models in rodents is receiving increasing attention in translational psychiatry. These models are relevant because they reproduce in the progeny some functional and structural anomalies in the brain, as well as behavioural alterations and cognitive deficits, characteristic of the pathophysiology of schizophrenia.
2. Inflammatory changes in crucial stages of brain development and maturation (early adulthood) [29]. During early adulthood, the brain undergoes decisive changes, completing the myelination of axon fibres and synaptic pruning in particular areas. These neurodevelopmental changes coincide with the maturation of dopaminergic neurotransmission in cortical structures and may be crucially affected by stimuli triggering potentially detrimental innate immune responses.
3. Inflammatory lifetime changes produced by diverse environmental factors such as episodes of psychosocial stress, infections (viral reactivations, poor hygiene, periodontal problems), dietary deficiencies, alcohol, tobacco, metabolic and autoimmune disorders, medications, etc. In this regard, the family of TLRs have emerged as a possible mechanism involved. TLRs are the first line of defence against invading microorganisms and other immune stimuli. Their expression is modulated in response to pathogens and other environmental stresses. The most studied

member of the family TLR-4 orchestrates neuroinflammation in animal models, and its expression is regulated by stress-induced bacterial translocation of gut microflora. Alterations in peripheral TLR activity have been described in schizophrenia and other psychiatric disorders such as depression.

4. Inflammatory changes produced as a consequence of genetic susceptibility due to the existence of hypo-/hyperpolymorphisms in certain immune/inflammatory-related genes as risk factors for this disorder. Genome-wide association studies have identified genes involved in the immune response (MHC, etc.) that correlate with schizophrenia diagnosis.
5. Loss or impairment of protective function in at-risk cell types, such as parvalbumin-expressing cortical interneurons, in relation to oxidative/nitrosative stress.

Several studies have shown that peripheral inflammatory markers may vary with the clinical status of patients and can be used as possible trait/state biomarkers for early diagnosis and also for monitoring disease progression and treatment response. Excellent candidates are pro-/anti-inflammatory cytokines (IL-1 β , IL-6, and transforming growth factor- β), oxidative/nitrosative stress mediators [thiobarbituric acid reactive substances (TBARS), SOD], and even some lymphocyte phenotypes (CD4/CD8, CD56). The existence of a 'golden marker' for the disease is highly improbable; rather, studying complete and robust pathways with all elements of intracellular and intercellular pathways, including elements of balancing mechanisms and their relationship with positive/negative symptomatology and cognition deficits, is an interesting approach.

Besides studies for the search of biomarkers, inflammation can be pharmacologically modulated to improve the clinical picture. There are some completed and ongoing double-blind, randomized, placebo-controlled clinical trials with anti-inflammatory augmentation in schizophrenia, but the results are modest and only affecting specific subgroups of patients with schizophrenia. Based on this evidence, future studies should have a change of focus. Current studies propose the control of inflammation via direct inhibition of pro-inflammatory mediators, but pharmacological stimulation of antioxidant/anti-inflammatory pathways to potentiate the endogenous response against disease is emerging as a promising strategy. Complementary pharmacological studies have demonstrated an anti-inflammatory profile of some antipsychotics (that is, paliperidone, clozapine) with reduced expression and release of pro-inflammatory cytokine and stimulated production of anti-inflammatory cytokines such as IL-4, -10, and -17.

We are still far from having a general idea of the role/s of innate immune system/inflammation in the aetiology and pathophysiology of psychotic disease, and consequently from offering an effective and safe treatment for patients based on the modulation of the inflammatory response. There is still a long way to go, with some questions and limitations to resolve:

1. The inflammatory state may vary, depending on the course of the disease. There may be compensatory mechanisms or exhaustion, so it is needed to study different states of psychotic disease, from prodromal stages to first episode to psychosis to full-blown, chronic schizophrenia. Efforts should be made to determine if symptomatic onset of the disease occurs in a vulnerable brain (immunologically/inflammation-primed months/years before

symptoms manifest) or if a genetically prone subject develops symptoms that will increase the deleterious effects of inflammation and/or infection. The search for ‘immunophenotypes’ is a nascent approach to take into account for the future.

2. The inflammatory response is highly non-specific and is activated in response to multiple endogenous and exogenous factors in the context of psychiatric diseases [30]. Some of the parameters that need to be controlled and considered are: genetic/epigenetic susceptibility, disease state/duration, stress exposure, tobacco/cannabis use, body mass index, type and duration of antipsychotic medication, presence of ongoing infections, etc.
3. The great degree of comorbidity between psychotic disease and inflammation-related diseases, such as depression, obesity, and diabetes, or psychotropic substance abuse, further complicates the scenario.

The microbiota–gut–brain axis and immunopathogenesis of psychiatric diseases

There is evidence indicating that there is a bi-directional communication between the brain and the enteric nervous system, including the microbiota, which uses neural, hormonal, and immunological routes.

Thus, the microbiota–gut–brain (MGB) axis would be constituted by a complex system of communication between the microbiota, the gut, and the CNS, which would be able to regulate gastrointestinal, immune, and CNS functions. Among those paths of communication between the gut and the CNS are the vagus nerve, the HPA axis, the cytokine network, and tryptophan absorption from the gut into the peripheral bloodstream, as well as the passage of short-chain fatty acids (SCFAs) into the circulatory system [31].

There are multiple pathways guiding the descending and ascending directions of the MGB axis in health and disease. In particular, from the gut to the CNS, studies have revealed that brain activity can be regulated through neural activation of neurons by the gut microbiome, and through endocrine (for example, release of serotonin), metabolic (for example, microbiota synthesis of neuroactive molecules), and immune (for example, systemic inflammation and CNS-infiltrating immune cells) pathways.

The MGB axis is also a key player in neurodevelopment, and consequently it is plausible to consider that the microbiome, and in particular early-life events during initial colonization and microbiota development, can determine general and mental health in later life, which could be playing a crucial role in psychiatric diseases with a neurodevelopmental component such as autism spectrum disorders and schizophrenia.

Furthermore, in inflammatory bowel disease (IBD), comorbidity with mood disorders, such as depression and anxiety, is common, and chronic low-grade inflammation or immune activation that underlies the aetiology of IBD is also a driving risk factor in mood disorders [32]. Importantly, patients with schizophrenia quite often present with gut problems, and irritable bowel syndrome commonly co-occurs with psychiatric disorders. Thus, through diverse mechanisms that can include bacterial translocation, the microbiota from the gut would be able to affect both local and distal locations within the host organism.

Stress, which is a main risk factor for psychiatric diseases, induces intestinal dysfunction and can increase intestinal permeability. But this is not the only factor to consider. Changes in microbiota may lead to brain dysfunction through the production of harmful bacterial products that compromise the integrity of the intestinal tract (permeable intestine or leaky gut syndrome). Here appears a very important concept—the gut microbiota dysbiosis; shifts in microbiota composition and functions from physiological/beneficial states to those pernicious to the host’s health are termed dysbiosis, and gut dysbiosis may exert a deleterious impact on brain functioning via the MGB axis. Moreover, it has been recently proposed that dysbiosis might contribute to abnormal brain development, immune regulation, and metabolic function in psychiatric diseases. However, the composition of the gut microbiota has yet to be fully characterized in psychiatric patients, and further research is very much needed.

Hypersensitivity to food antigens

Among the factors influencing the functioning of the MGB axis, there is one that shows up—hypersensitivity to food antigens. Several studies have found increased immune sensitivity to food-based antigens, namely gluten and milk casein, in psychiatric diseases and, in particular, in patients with schizophrenia [33].

Gluten-dependent disorders have been recently classified into three main groups, based on their pathogenesis [34]: autoimmune reactions, including coeliac disease; allergic reactions, including wheat allergy; and non-autoimmune and non-allergic (innate immunity), which includes non-coeliac gluten sensitivity (NCGS) or intolerance. Schizophrenia has been repeatedly associated with both coeliac disease and NCGS [35]. Indeed, the average prevalence of coeliac disease among patients with schizophrenia is higher than that estimated in the general population [36]. In fact, there are already meta-analyses showing significantly higher levels of some serum biomarkers of gluten hypersensitivity in patients with schizophrenia, although more research is very much needed in this field [37].

On the other hand, elevations in antibodies to milk casein have also been described in subjects with psychiatric diseases, mainly in patients with schizophrenia. The mechanisms mediating the association between heightened antibodies to gluten/casein and the risk of psychiatric disease are not fully understood. For example, in some individuals with a psychotic disorder, comorbidity with coeliac disease/NCGS may disrupt intestinal permeability (that is, ‘leaky gut’), thereby allowing these antigens to enter the systemic circulation and generate a humoral immune response, which, in turn, would lead to psychotic symptoms. Indeed, gluten stimulates zonulin release, probably because it is mistaken for a microbial agent and therefore increases gut permeability in humans.

In summary, there is growing evidence supporting that some of the key pathways that are dysfunctional in psychiatric diseases may also be regulated by the MGB axis. Microbiota-targeted therapeutic interventions may include dietary approaches, probiotics, prebiotics, anti-biotherapy, and faecal transplantation. Preclinical studies suggest that strategies manipulating the gut microbiota hold potential preventive applications in psychiatric disorders. Thus, this is a very promising field of research. At this time, human interventions in

psychiatry are still scarce and have focused on diet modification, probiotics, and antibiotics. Importantly, all these interventions are currently considered as adjunctive treatments to standard care (for example, drugs for depression, antipsychotics).

Pharmacology

We are still far from having ideally effective and safe treatments to offer to patients with affective disorders and psychosis. There is therefore a need for a change in the drug discovery strategy, mainly based on a better understanding of the pathophysiology, while, of course, taking into account the overwhelming experimental, epidemiological, and clinical evidence suggesting that prolonged increases in the levels of pro-inflammatory and oxido-nitrosative mediators occur in depression, schizophrenia, and other neuropsychiatric diseases. This fact justifies the ongoing clinical trials on adjunctive therapies with anti-inflammatory and antioxidant drugs in these diseases, including non-steroidal anti-inflammatory drugs and anti-cytokine and antioxidant compounds [38, 39] (that is, aspirin, COX-2 inhibitors, *N*-acetylcysteine, omega-3 fatty acids, and others). Although none of these combinations have demonstrated to be clearly beneficial, much effort has to be made, from basic to clinical research, to address how inflammation and immune dysfunction affect psychopathology. This would contribute to a better understanding of the disease mechanism and to the development of new effective interventions [40].

Functional genomics

Caleb Webber

Introduction

The term functional genomics represents an approach to molecular biology that seeks to generate and exploit a wealth of diverse information about the function of genes in order to understand the relationship between genotype and phenotype. As a genomics approach, the methods employed usually involve efforts to systematically survey every gene or gene product in the genome and thus provide a global view on aspects of gene function. Unlike the static genome, gene function is a dynamic process and thus varies in terms of both space (for example, cell type) and time (for example, development). For example, we may wish to know both which set of genes are switched on in a particular type of neuron and how this set of genes changes with age.

As is often the case in science, our ability to measure is driven largely by technological development. For genomics approaches where scale is important, it is not just the development of technologies that enables us to measure a particular feature, but also further developments that enable us to economically apply this measurement systematically across the genome. Importantly, our ability to measure at the scale of the genome fundamentally changes the nature of the questions we can ask, leading to a step change in discovery. For example, while a quantitative polymerase chain reaction assay allows us to detect changes in the expression of a *pre-specified* gene in diseased tissue, the advent of microarray methodologies enabled us to measure the change in expression across thousands of genes simultaneously. Changing the question from ‘*is that* different?’ to ‘*is anything* different?’ enables us to discover disease-associated variation that we might not have thought to look for. This approach has been adopted across psychiatric disorders in recent years and will be covered in detail in the relevant chapters on genetics in this volume. It will form the prelude to understanding the variation in function that is likely to constitute the characteristics of disordered phenotypes.

While functional genomics approaches are often simply scaling up the detection of a known phenomenon, the technologies developed can also extend our knowledge of the basic functional repertoire of the cell. For example, next-generation sequencing approaches enabled the unbiased detection of all expressed RNA molecules in the cell, revealing the existence of tens of thousands of new genes that do not encode proteins and whose roles are currently being elucidated

[1]. Nonetheless, while many genes express RNA molecules that are not templates for translation, the vast majority of our knowledge about the roles of genes comes from studying the functions of proteins, and thus our knowledge is focused towards the subset of genes that encode them. This is an illustration of one bias, and although genomics approaches are innately *less* biased, the biases in each approach to measuring function should be considered when designing and interpreting studies, as discussed in the following sections.

This chapter provides a gene-centric introduction to functional genomics, each section introducing the aspect of gene function being measured and then contextualizing variation in the context of neuropsychiatric disease studies (Fig. 16.1). Each section, namely ‘Epigenomics’, ‘Gene expression’, ‘Proteomics’, and ‘Functional annotations’, is, in themselves, the subject of dedicated textbooks and dozens of reviews, and thus this chapter provides only a succinct introduction to several large and rapidly growing fields of study.

Epigenomics

Epigenetic modifications are defined as reversible modifications of DNA or DNA-associated proteins which affect gene expression without altering the DNA sequence. Epigenetics explains why two different cell types possessing exactly the same genetic code execute distinct gene expression programmes and diverge in their roles.

There are two important classes of epigenetics modifications: DNA methylation and histone modification. The transcriptional accessibility of DNA is determined by the condensation state of chromatin, which is formed from structural units called nucleosomes, in which the DNA is wrapped around eight core histone proteins. Post-transcriptional modifications of these histones can alter the regional chromatin state between a transcriptionally active open *euchromatic* state and a transcriptionally silenced closed *heterochromatic* state, thereby impacting gene expression [2, 3]. Active and repressive histone marks delineate coding regions, non-coding regulatory elements including promoter regions near transcriptional initiation sites, and proximal and distal enhancers (Fig. 16.2). In parallel to histone modifications, methylation of the DNA base cytosine within promoter and enhancer regions acts to repress transcription (Fig. 16.2).

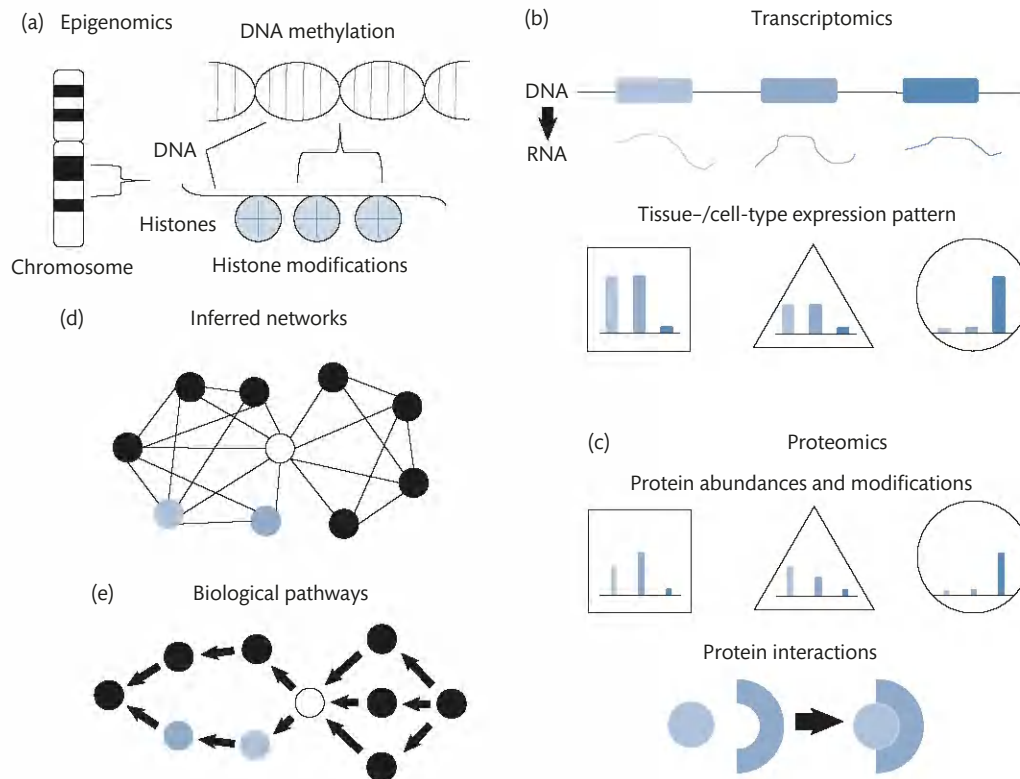

Fig. 16.1 An overview of functional genomics. (a) Epigenomic analyses can indicate how poised different genes are being transcribed. Different chemical modifications of histones, the proteins that form the scaffold around DNA, and variation in the accessibility of the DNA to proteins that regulate and execute gene expression are associated with active or repressed genes (Fig. 16.2). (b) The variation in gene expression by cell type or with disease state informs on function. Where the expression pattern of genes are similar, it may reflect their co-ordinated regulation as part of the same biological process. (c) While correlated with gene expression level, the abundance of the protein product of a gene can vary due to translational regulation and degradation, while the functioning of a protein can be significantly altered by a range of post-translational chemical modification. A physical interaction detected between two proteins can indicate that they function together in a common role. (d) Functional genomics information, such as the co-ordinated expression of genes, the knowledge that their protein products physically interact, or large-scale information gathered from published literature can be used to infer sets of genes likely to function together in the same biological pathway (e).

Using high-throughput approaches, the Roadmap and ENCODE projects have delivered genome-wide human epigenetic maps that highlight cell-specific regulatory elements, providing a valuable resource for the interpretation of genetic variation [4, 5]. These maps reveal that a large majority of common genetic risk variants identified do not affect the protein-coding sequence but are instead localized in non-coding regions regulating gene expression which these variants are likely to alter. Knowledge of the cell-specific utilization of these regulatory elements enables the identification of the cell type(s) likely affected by variants within them. For example, the 108 genetic risk loci reported so far for schizophrenia (SCZ) are enriched in brain-specific enhancer regions, suggesting these variants affect the expression of genes in the brain, but also within enhancer elements utilized by CD20/CD19 lymphocytes, in turn suggesting a link between SCZ and the immune system [6].

Inter-individual variation in DNA methylation found in fetal brain tissue coincides with SCZ risk loci [7]. However, epigenetic variation is dynamic, varying not just with the cell type, but also over the life of a cell. A study identifying regions of DNA that were differentially methylated in the prefrontal cortex between individuals with and those without SCZ found that these differentially methylated regions were associated with changes in DNA methylation that occurred during the transition from the second fetal trimester

to postnatal life, implicating this transition as a key developmental point in the development of the disorder [8].

Gene expression

The spatiotemporal expression profile of a gene is particularly informative. Knowing when (for example, in development, in disease progression) and where (in which cell types) a gene is switched on, or expressed, is key to understanding both its normal and its aberrant functioning (Fig. 16.1b). Genomic technologies that simultaneously report the expression of thousands of different RNA molecules have advanced rapidly and include microarrays that detect pre-specified RNA molecules and RNA-seq that can sequence the entire population of RNA molecules without pre-selection. However, for neuropsychiatric disorders, access to the relevant living tissue sample or cell population remains challenging. Nonetheless, using post-mortem brains, detailed maps of spatiotemporal gene expression are now available. For example, the BrainSpan atlas of the Developing Human Brain has examined 42 brains to provide the gene expression profiles of up to 16 targeted cortical and subcortical structures across the full course of human brain development [9].

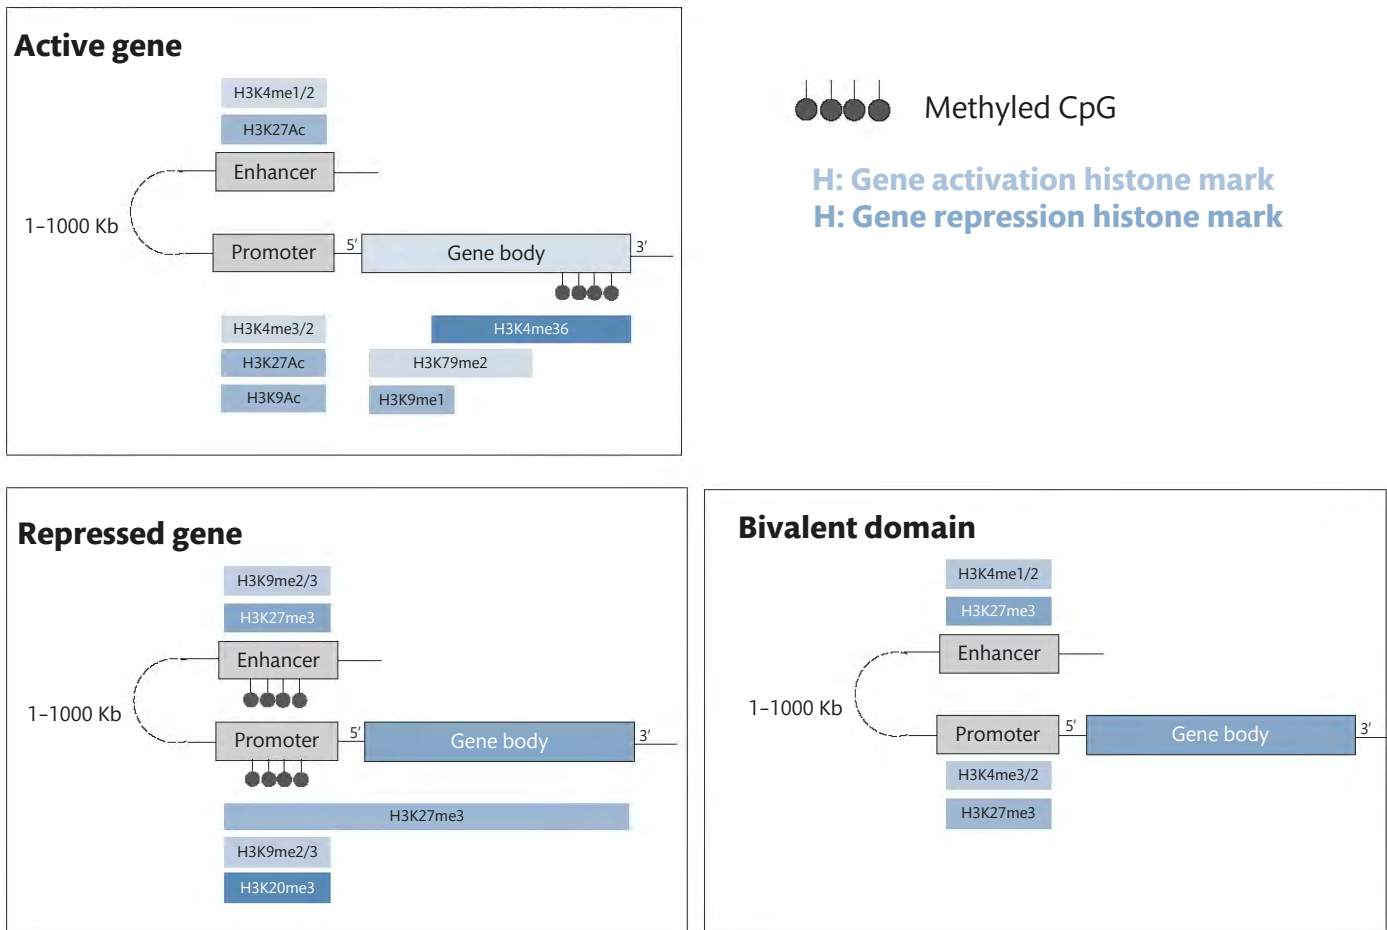

Fig. 16.2 Epigenetics marks and gene regulation. Different sets of epigenetic modifications, or marks, are associated with three states of gene regulation. The epigenetic marks can map to the full gene body or only the 5' part or 3' part to the promoter region or to a (distal or proximal) enhancer [98]. (a) Histone modifications (methylation and acetylations marks) for a transcriptionally active gene. (b) DNA methylation and histone H3 methylation are found in the promoter and enhancer region and surrounding the TSS in transcriptionally repressed genes. (c) Bivalent chromatin domain defined by the simultaneous presence of histone modifications associated with both gene activation and repression [99].

Knowledge of a gene's expression profile helps the causal interpretation of genetic variation observed in patients with neuropsychiatric disorders. In SCZ, for example, newly arising genetic variants that were observed in patients, but not in either parent, and that affected protein-coding sequence tended to affect genes that were expressed prenatally in the dorsolateral prefrontal cortex (DFC) and the hippocampus, with both regions previously implicated in SCZ [10]. Gene expression variation can also be detected directly in the analyses of post-mortem patient brain tissue. Large-scale studies of hippocampal tissue obtained from SCZ, bipolar disorder (BPD), and major depressive disorder (MDD) patients have found evidence for decreased expression of genes involved in antigen processing, GABA signalling, and endocytosis [11]. More specifically for BPD, but also reported in some SCZ studies, an upregulation of metallothionein genes has been observed in the DFC, while reductions in neuropeptide gene expression has been associated with psychosis [12, 13].

Notably, there is little consistency in the observed variation in gene expression for the same disorder across different regions of the brain. Moreover, even within the same region, there is considerable variability among post-mortem gene expression studies, likely due to experimental variation, the relatively small numbers

of samples used, and the effects of varying patient medications. For post-mortem studies on neuropsychiatric disorders, and especially so for neurodegenerative disorders, it is also unclear what point in the progression of a disease is being studied, and thus whether any observed variation in gene expression relates to the upstream causes or the downstream consequences. Genetic and epigenetic evidence discussed above points to key prenatal or early postnatal aetiological events for many neuropsychiatric disorders which may be undetectable in adult post-mortem brain tissue. For neurodegenerative disorders, onset precedes the diagnosis by many years, making it hard to discern whether upregulated processes, such as neuroinflammation, are contributing causally to the pathology or are instead protective mechanisms, a vital distinction when targeting therapeutic interventions. Furthermore, the cell type composition can change as a consequence of a disorder, for example with the death of neurons in neurodegeneration, which can then dominate the comparison with healthy tissue [14]. Accordingly, it is reassuring when variation in gene expression in post-mortem tissue can be linked to predisposing genetic variation. For example, genetic variation in *CACNA1C* is associated with an increased risk of BPD, while the expression of this gene has also been found to be downregulated in BPD patients'

brains [15, 16]. In other cases, the genetic support can be indirect; *TYROBP* has been found to be upregulated in the brain of late-onset Alzheimer's disease patients and interacts with the Alzheimer's disease-risk gene *TREM2* [17, 18].

Co-expression networks

The expression of multiple genes can be co-ordinated within the cell, for example in order to deliver all the required subunits necessary to form a functioning protein complex or to put in place all of the enzymes required at each step in a biosynthetic pathway. Thus, the co-expression of genes, that is genes whose variation in expression levels is correlated, is a commonly used approach to divine genes that might function together with a common purpose [19]. The degree of co-expression is measured largely as the correlation coefficient of those gene expressions, as measured at multiple instances, for example their correlated expression across multiple tissues over time during a biological process such as development/ageing or disease progression, or simply from repeated recordings over multiple replicates of the same experiment. Often, co-expression is represented in a network diagram, with genes depicted as nodes and where connections, or edges, between nodes represent the fact that the connected genes are co-expressed (Fig. 16.1d). A group of genes connected together within a network through their correlated expression patterns is often referred to as a co-expression *module* [20]. As compared to variation in a single gene's expression, examining the variation of a group of co-expressed genes that form a module is both more robust to noise affecting the variation of individual genes and also enables the study of variation of the shared functionality captured by the module. Furthermore, following the reasoning that genes that are co-expressed are more likely to function together, genes within a module whose functions are unknown can be inferred from those genes with known functions [21]. This process of inferring function is commonly termed 'guilt by association' and is an often used approach for filling in gaps in knowledge in functional genomics (for example, see the section on protein-protein interactions in this chapter).

Study designs for exploiting gene co-expression methods to understand disease have taken one of two approaches. In the first, gene co-expression modules may be formed from healthy individuals and then changes in expression level of multiple genes within a module within diseased tissue are used to infer up- or downregulation of that pathway. Large-scale gene expression data sets, such as the BrainSpan database, enable the identification of genes whose expression patterns are co-ordinated across regions of the brain and throughout development, enabling the construction of gene-co-expression modules, capturing spatiotemporally co-ordinated gene modules in the healthy developing brain. Mapping mutations observed in SCZ patients onto the genes within these modules identified that these mutations often disrupted module functioning during fetal development within dorsolateral and ventrolateral prefrontal cortex [22]. Within Alzheimer's disease, co-expression analyses of post-mortem tissue have recurrently identified disrupted modules of genes associated with decreasing synaptic plasticity, while those associated with immunity and microglia increased [23, 24]. As noted, care must be taken in the interpretation, as a decrease in the expression of genes across a cell type-specific pathway might be due to the loss of the cell type expressing that pathway, rather than the downregulation of genes within that pathway within the relevant cell type.

In an alternative approach, studies can consider differential co-expression, which looks for changes in the co-ordination of gene expression that suggest that the regulatory relationships between genes that were co-expressed in healthy tissue have been altered in the diseased tissue [25]. For Alzheimer's disease, this approach to identify the rewiring of gene regulation in disease found that many gene modules involved in immunity and microglia function were differentially regulated in patient post-mortem brain tissue [24].

Proteomics

Proteins are the enactors of the central dogma, and our efforts to measure the expression of genes are largely in order to estimate the abundances of these genes' protein products. The relationship between mRNA abundance and protein abundance is confounded by several factors, including the rates of translation and protein degradation, both of which are highly variable, depending upon the cell state. Nonetheless, in a steady state, studies suggest that gene-gene variation in protein abundances within a cell are primarily determined by those genes' relative mRNA expression. Specifically, upwards of 40% of the variance in protein abundances can be explained by mRNA levels [26–28]. After accounting for the delay between gene expression and protein synthesis, variation in mRNA levels explain around 80% of the change in protein abundance when a cell transitions between states [29, 30]. While this correlation is encouraging, protein activity is not solely determined by abundance. Dynamic post-translational modifications, such as cleavage or reversible covalent additions of chemical side groups or lipids, are key regulators of their activity that are not captured by the transcriptome. For example, as described earlier, acetylation and methylation of histone proteins significantly modify their functional association with DNA. Furthermore, identification of the cellular location(s) of a protein and its molecular partners can reveal much about its role.

Compared to reading the transcriptome, measuring protein abundance is far more challenging due to the diverse physiochemical properties of the constituent amino acids. Nonetheless, over the last 10 years, advances in mass spectrometry-based approaches have enabled the simultaneous estimation of the abundances of over 10,000 proteins. A clear example contributing to the understanding of neuropsychiatric disorders is the proteomic profiling of the neuronal post-synaptic density (PSD) from the human neocortex [31]. While some of the identified PSD proteins were known at the time of the study to have roles in neurological disorders, subsequent genetic studies identifying genes found to be disrupted in individuals with SCZ have found that many of these genes' proteins are found in the PSD, giving a clear indication of the aetiology [32, 33].

As with transcriptomics, the differential abundances of proteins within post-mortem neuronal tissue yield insights into the causes and consequences of neuropsychiatric disease. For the neuropsychiatric disorders SCZ, BPD, and MDD, these studies have revealed hundreds of proteins differentially abundant in patient brain tissue. In common, a meta-study identified a small number of proteins involved in forming and maintaining the myelin sheath, supporting a role for oligodendrocyte dysfunction in these disorders [34–36]. For SCZ more specifically, variation in the abundance of 14-3-3 mediated-signalling proteins was found, for BPD variation in mitochondrial function, and for MDD in oxidative phosphorylation

pathways [34]. As with transcriptomics, there is significant variation between individual studies and between the particular brain regions studied, but for proteomics, this is likely amplified by the current variability in multiple reaction monitoring-based proteomic methodologies [28, 37].

Protein–protein interactions

Knowing which proteins physically interact with each other helps to identify groups of proteins that are functioning together in the same biological process. The set of protein interactions within the cell is commonly referred to as the *interactome*. These interactions can be transient, for example a receptor reversibly binding a ligand, or obligate such as the persistent binding between subunits of a stable protein complex. The causal implication in a disease of multiple genes whose protein products interact provides insight into the perturbed molecular process(es), and the functional concordances between implicated genes give added confidence to their role in the same disease. There are many methods to experimentally determine protein–protein interactions (PPIs) [38–40]. *In vitro* methods often involve the use of a bait or tagged protein that is drawn out of a cell extract, along with any other proteins that are directly or indirectly attached to it [for example, tandem affinity purification and mass spectrometry (TAP-MS), affinity chromatography, co-immunoprecipitation]. *In vivo* methods include the Yeast 2 Hybrid (Y2H) approach. Here, a transcription factor is cleaved into a binding domain and a separated activating domain, and each of a pair of query proteins is fused to one of the two domains. If the two query proteins interact, the two transcription factor domains are brought close to each other and transcription is initiated. However, current methods for detecting PPIs are prone to noise and high rates of false positives, for example due to artefactual interactions detected between proteins that do not reside in the same cellular compartment, and thus corroborative support is often sought to validate PPIs [41, 42].

An early example of the utility of PPIs in providing insights into neuropsychiatric genetics is an interactome study performed for the Disrupted in Schizophrenia 1 (DISC1) protein [43]. Proteins that interacted with DISC1 were identified using Y2H assays, and then a subset of these interactors were selected and their interactors similarly identified. Many of the proteins within the extended DISC1 interactome had roles in synaptic-associated functions such as cytoskeletal stability and organization and intracellular transport, thereby implicating DISC1 in these processes through ‘guilt by association’ whereby the functionality of a protein is inferred through the known functions of the proteins with which it interacts.

PPIs detected in large- and small-scale studies have been collated within several large, publicly available databases [for example, human protein reference database (HPRD) [44], BioGrid [45]]. Although fewer than 100,000 interactions are currently known, which represents a fraction of the estimated complete interactome [46], these experimentally determined interactions can be supplemented by computationally predicted interactions to provide a key resource for identifying common functions between genes implicated in neurological disease [39]. For example, genome-wide association (GWA) studies have been phenomenally successful in identifying regions of the genome that are associated with the risk of developing SCZ. However, these regions often contain many genes, and so identifying which of these genes is more specifically

associated with disease risk remains a current bottleneck in translating these genetic findings into actionable drug targets. By examining the interactions of the proteins expressed by genes within risk loci identified with SCZ GWA studies with the proteins of genes that have been implicated in SCZ in past studies, one study identified interactions between 76 GWA genes and 25 previously implicated SCZ genes [47]. Such studies are able to both propose the causally associated gene within these GWA regions and identify common functions among the sets of interacting proteins, here for example synaptic plasticity, neurotransmission, and inflammation, that may be disrupted in the disease.

The vast majority of human genes express not just one transcript but instead can selectively include or exclude different exons, to generate multiple alternatively spliced transcripts. Alternatively spliced transcripts are expressed in a tissue-specific manner, with many genes expressing a dominant transcript in a particular tissue. Of particular relevance, tissue-specific splicing are most often observed in brain cells with roles in both development and ageing [48–54]. By varying the protein sequence, the set of resulting protein isoforms expressed by a single gene can demonstrate remarkable variation that impacts on function. For example, by varying the inclusion of interaction surface, protein isoforms can interact with alternative sets of proteins, changing the topology of the network [50, 55, 56]. Such tissue-specific, isoform-specific interaction networks are important in understanding cell type-specific gene function, and therefore in understanding the functional impact of genetic variation underlying neuropsychiatric disorders [57].

Literature annotations

Every day, hundreds of research articles are published, with each article reporting the results of molecular and/or genetic experiments, adding to a body of knowledge about the function of a single gene or a small number of genes. We are unable to read them all and we are unable to remember all that we have read, and what we can remember is highly biased. There is a huge diversity in experimental approaches, reflecting the many questions that might be asked. For example, these articles might report on a study that localizes a protein to a particular cellular structure, identifies a role for a protein within a specific biological function, or details the phenotypic consequences arising from the protein’s disruption within a cellular model, a model organism, or a human patient. However, in order to ask questions about groups of genes, such as whether a set of genes found to be disrupted in patients with a particular disease are associated with a particular function, the information about gene function, the language of function, must be consistent between genes.

Functional annotations

There have been several attempts to organize the wealth of heterogenous information about the function of genes and their expressed proteins. Most commonly, this involves the creation of an ontology, a defined vocabulary that describes a set of entities, or properties, and the interrelationships between them. The most successful and commonly used in molecular biology is Gene Ontology (GO) [58, 59]. Here, the properties of gene products, most commonly proteins, are defined within three ontologies. A protein’s action at the molecular level, such as binding or catalysis, is described

within *Molecular Function* ontology; where it is located within (or outside) a cell, it is described with *Cellular Component* ontology, while terms within the more abstractly defined *Biological Process* ontology are used to describe the higher-level functioning of a protein such as signal transduction or regulation of gene expression. For example, if we consider the key metabolic enzyme malate dehydrogenase, its *Molecular Function* terms include *oxidoreductase activity*; its *Cellular Component* terms include *mitochondrion*, while its *Biological Process* terms include *tricarboxylic acid cycle*. The relationships between terms within the ontology allow proteins to logically acquire additional annotation terms. For example, the GO molecular function ontology defines that the mitochondrion

is a *cytoplasmic part*, which is an *intracellular part*, and thus a gene whose protein is assigned with the GO property of mitochondrion logically inherits both the GO properties of *cytoplasmic part* and *intracellular part*. A fraction of the GO annotation tree for the Biological Process term 'positive regulation of transmission of nerve impulse' is illustrated in Fig. 16.3 where the inherited annotation terms can be seen.

While GO successfully captures a huge amount of information about human gene function, unarguably more than any other single information resource, users exploiting GO functional annotations should be aware of the evidence for a functional annotation. Each GO annotation is associated with an evidence code,

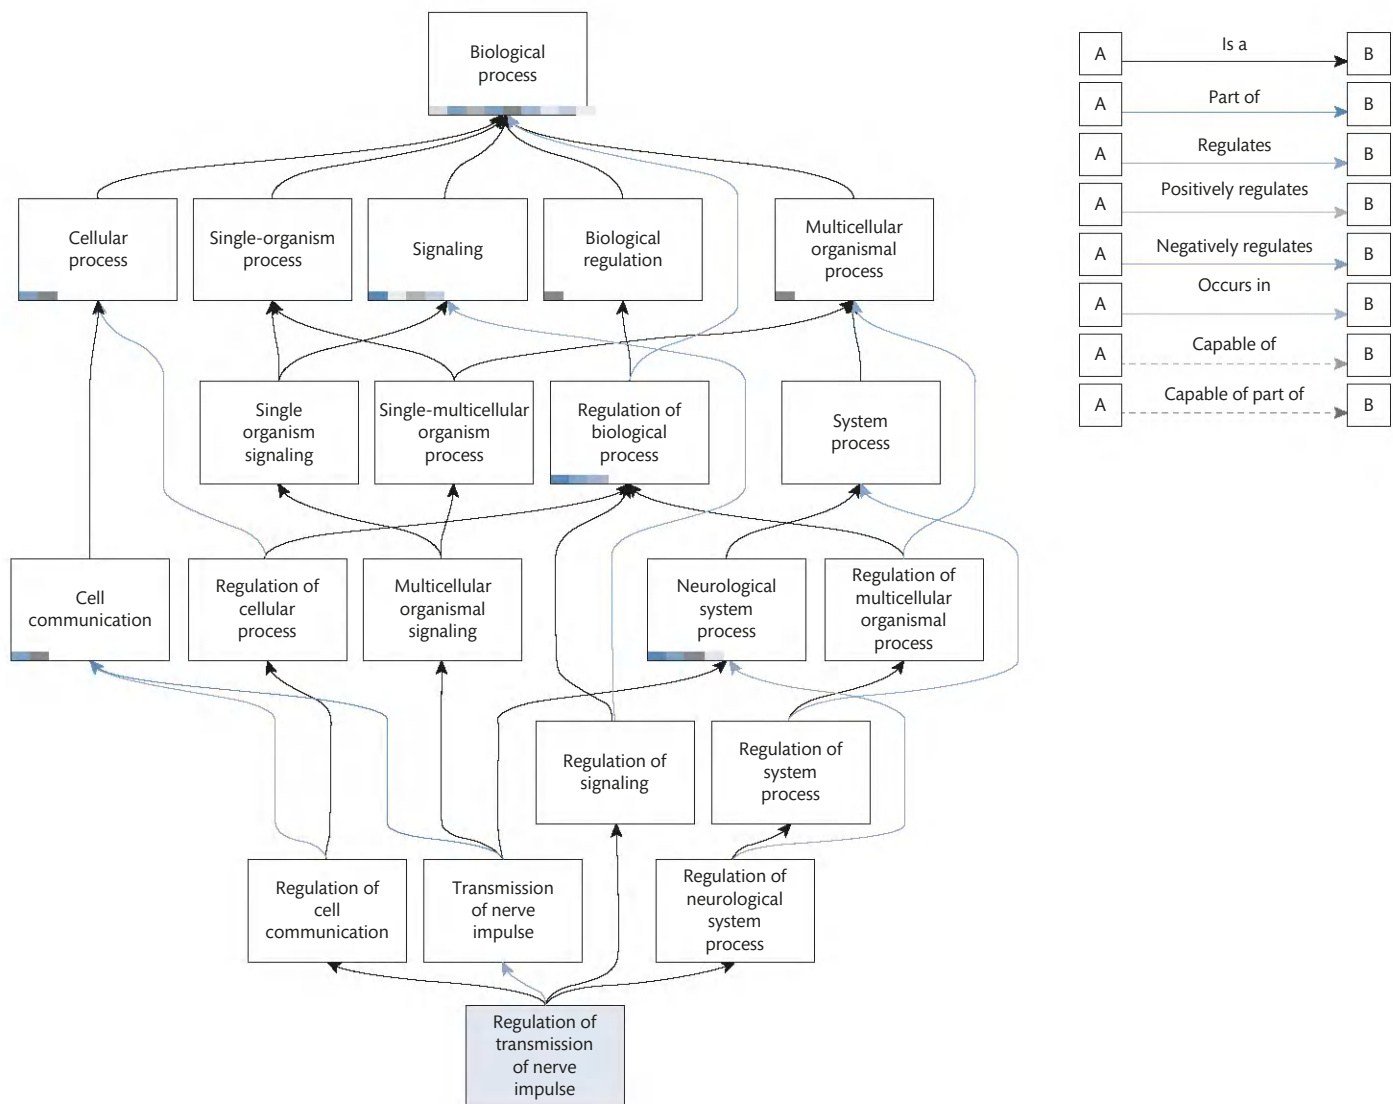

Fig. 16.3 (see Colour Plate section) An example of hierarchical relationships in the Gene Ontology (GO) [58]. In this example, we show the GO annotation terms that lie above the term 'regulation of transmission of nerve impulse'. Following this GO hierarchy, a gene that was ascribed the function of *regulation of transmission of nerve impulse* would automatically also be assigned all of the functional terms listed. As with other structured ontologies discussed in the main text, an explicit understanding of knowledge relationships between annotation terms makes it possible to identify similarities between gene functions. For example, if we were comparing a gene assigned with the term *regulation of cell communication* to another gene assigned the term *transmission of nerve impulse*, the graph identifies *cell communication* as a common role. Although many of these relationships may seem obvious to a researcher, ontologies are computable, such that we can rapidly compute the similarity between thousands of genes enabling us to statistically identify unusually common functions among sets of genes, for example those found to be dysregulated in a diseased tissue.

which can be broadly split into those codes derived from published experiments and those derived by computational predictions. As of writing, almost 16,000 out of a total of 22,000 human protein-coding genes are annotated with at least one GO annotation that has been derived from published experiments. However, for almost 5000 human protein-coding genes, only computationally predicted functional evidence is available, which should be viewed with less confidence. For 1500 genes, GO provides no functional evidence at all, experimental or inferred. Furthermore, while there is thus some functional information ascribed to over 20,000 protein-coding genes, this evidence is likely very incomplete for all but a small fraction of genes, with genes of more interest to the community (for example, those involved in disease) receiving far more experimental attention, and thus acquiring more functional annotations, than those attracting less interest. It is often necessarily assumed in functional genomics that genes that are not annotated with a particular function do not perform that function, but this assumption is flawed: *The absence of evidence is not evidence of absence*. Compounding this, there is a strong bias towards publishing positive, rather than negative, findings, in this case showing what a gene does, rather than what it does not do. Accordingly, more systematically collected functional evidence, such as a genome-wide survey of gene expression, can provide a more robust, albeit significantly less functionally detailed, information source. Despite these concerns, GO remains the current standard for ascribing gene function, and almost all the functional associations of genes with disease described in this chapter, for example sets of genes whose expression or protein abundances are found to be different or dysregulated in diseased tissue, have been identified from the GO annotations of these genes.

Pathway databases

Although GO aims to capture the function of a gene, it does not embody well the functional relationships between genes. While GO will annotate several genes as belonging to the same biological process, for example the *tricarboxylic acid cycle*, it does not inform on the order in which the enzymes in this fundamental energy cycle act, which is key to understanding the biological process. To address this, pathway databases have been created that map out the constitutive genes, describing a set of interacting genes/products that together perform a particular biological function. Historically, the most well-used of these is the *Kyoto Encyclopaedia of Genes and Genomes* (KEGG), which attempts to map out the literature-reported relationships between genes within a diverse collection of metabolic and cellular processes, including processes associated with specific diseases [60]. More recently initiated databases, for example *Reactome* [61], attempt to more systematically map out the molecular operations of gene products into a hierarchical level of detail, similar to that described previously for GO. However, as discussed for GO annotations, pathway annotations are very incomplete and suffer from significant ascertainment biases. Furthermore, the biological processes that these pathway concepts seek to describe are often active under specific conditions and/or within particular cell types [62], information that is often missing. Nonetheless, from a deterministic perspective, where the aim is to understand the consequences of a genetic variant, understanding the relationship of that gene to the biological process(es) in which it participates will clearly aid in the interpretation.

Model organism databases

Although far beyond the remit of this chapter to discuss the utility of model organisms for individual neuropsychiatric disorders (for reviews, see [63–70]), the ability to determinedly introduce genetic variation into an organism is a robust approach to understanding the relationship between genotype and phenotype. The evolutionary conservation of the protein-coding sequence of orthologues between two species implies that the function of these genes is similarly conserved between those species, and thus knowledge of the gene in one species can be transferred to the other. This conjecture holds best between unique 1:1 orthologous genes, defined as genes in two species that have been maintained without duplication since those species diverged from a common ancestor [71–73]. While the functional genomics resources described in this chapter thus far are focused on molecular and cellular annotations, from the expression of genes through to the functional roles of their protein products, often it is not immediately obvious how the disruption of a cellular process might manifest a complex behavioural abnormality. Thus, model organisms offer a more direct description of the influence of genetics and environment upon behaviour.

Due to their ready genetic manipulation, easy laboratory management, and study scalability, genotype/phenotype relationships have been extensively explored in the lower model organisms, namely the fruit fly *Drosophila melanogaster*, the nematode *Caenorhabditis elegans*, and the yeast *Saccharomyces cerevisiae*. From a functional genomics perspective, the knowledge amassed about the function of individual genes from studying these model organisms has contributed to a genome-wide body of knowledge that has been collated for each model into community-supported databases (namely FlyBase [74], WormBase [75], *Saccharomyces* Genome Database [76], and Zfin [77]). Much of this knowledge forms a major contribution to functional and pathway annotation resources.

From a neuropsychiatric perspective, rodent models are pre-eminent in the study of relevant disorders, due both to their more comparable neuroanatomy and to behaviours that are more comparable to neuropsychiatric presentations. From a functional genomics perspective, the systematic collation from published reports by the Mouse Genome Database (MGD) of the phenotypes resulting from determined genetic manipulation of several thousands of mouse genes offers an excellent resource for neurological associations [78]. Currently, the MGD holds phenotypic associations for the unique orthologue of over 9000 human genes and reports this phenotypic information within structured ontology, enabling computational analyses [79]. As with other literature sources of gene functional information, the original studies upon which these data are based were hypothesis-led, and thus only a specific set of phenotypes would have been examined in each study and reported on. Nonetheless, aetiological insights into neuropsychiatric disorders can be robustly obtained, for example an excess of genes whose orthologues' disruption in the mouse yielded synaptic dysfunction has been identified among genes found to be deleted or duplicated in individuals with autism [80, 81]. Of note, for functional genomics approaches, significant efforts are ongoing by the International Mouse Phenotyping Consortium (IMPC) to systematically pass each mutant mouse line through a series of standardized phenotypic tests of broad relevance to human disease, with results from the first 1750 knockout mouse models recently reported [82–85]. A key criticism of functional

annotation resources amassed from individual studies is that where a gene is not annotated with a particular function, researchers might assume that that gene is not associated with that function when, in fact, the association has never been tested. Thus, although the phenotyping of these models is inevitably incomplete, the IMPC's efforts to annotate gene function are hugely powerful, as the systematic testing also provides evidence that a phenotype is not associated with a given gene.

Future perspectives

Functional genomics is a particularly technology-driven field. New methods are frequently published, enabling new properties of the genome to be assayed or known properties to be examined on an increasing scale. The overwhelming volume of biological data being generated consequently challenges bioinformaticians to develop new analytical techniques able to integrate these diverse data types and make these data coherently available for researchers to query. Thus, while the promises of new technologies are often noisily trumpeted, our organization and standardization of data, for example gene function within GO or organismal phenotype within the Mammalian Phenotype Ontology or the Human Phenotype Ontology, are also important in gaining new biological understanding.

Several current technologies are promising to revolutionize molecular biology and functional genomics and are worth drawing attention to in the context of neuropsychiatric disease. An outstanding problem in the study of the brain is accessibility to brain tissue. As discussed, post-mortem tissue may better reflect the consequences of disease, rather than yield insights into the causes. The development of induced pluripotent stem cells (iPSCs) is enabling researchers to create cultures of patient-derived neurons in the laboratory [86–88]. Here, an accessible non-neuronal tissue is sampled from a patient and then these cells are coerced, through a cocktail of bioagents, into a pluripotent state, able to be subsequently driven down a cell lineage towards a neuronal cell identity. While there are many significant differences between iPSC-derived neurons and native adult neurons, these cell models are promising significant insights into neuropsychiatric disorders, for example, mimicking the differential lithium responsiveness of bipolar patients [89, 90].

While epigenomic, transcriptomic, and proteomic studies have yielded many insights into neuropsychiatric disease, a criticism already discussed when comparing healthy and diseased tissues is that differences in the underlying cell types that form these tissues are obscured when measuring across the whole tissue combined. Recently developed single-cell approaches allow the epigenetic and transcriptomic profiles of individual cells to be obtained, enabling the cell type to be determined from the cell type-specific marker genes and particular and specific populations of cells to be examined [91–93]. Elsewhere, our ability to manipulate the genetic sequence in disease models to introduce or remove, and thus explore the effects of, disease-predisposing mutations has been revolutionized in terms of ease and scale by the development of the clustered regularly interspaced short palindromic repeat (CRISPR)/Cas system, a prokaryotic antiviral defence mechanism whose constituent proteins are remarkably adept at introducing genome edits [94–96]. By combining these approaches, we might, for example, derive a culture of neuronal cells via iPSCs from a patient. If we have a candidate disease-predisposing genetic variant in that patient, then we

could edit the genome of the cells in a parallel culture to remove this variant and then compare the effect of this variant on the individual neuronal cell types (neurons, glial cells). This experiment is certainly not trivial, but remarkably it is now possible.

While these, and many other, developments are exciting, we should resist the urge to generate data simply because we can. These new techniques bring substantial challenges to the bioinformatics interpretation of the data, for example huge variability in cell models and high noise in the single-cell readouts [97], and thus answers may not simply drop out. We must make sure that our applications of functional genomics are both well powered and hypothesis-led and, in particular, that we increase the informatics, mathematic, computational, and statistical expertise required to interpret these fantastical experiments.

Cognitive neuroscience

Principles and methods

Anna Christina Nobre

Introduction

Cognitive neuroscience is the scientific discipline concerned with understanding the neural mechanisms involved in supporting human mental function. The discipline therefore rests on a reductionistic stance, or at least on the assumption that there are principled relationships between the objective, physical brain and the subjective, functional mind. The overarching aim is to build mechanistic bridges connecting the mind to the workings of the organ from which it arises and to the behaviours that arise from it.

Cognitive neuroscience has two primal roots. The first consisted in the observation that damage to the brain can lead to highly selective deficits in high-level human cognitive behaviours such as reasoning and comportment [1], language production and comprehension [2, 3], the recognition of complex objects [4–6], and the comprehension of spatial relations [7, 8]. The second was the development of rigorous quantitative scientific experimental methods to identify and measure elemental processes in human behaviour [9–11]. The two roots came together in the elegant research in neuropsychology and behavioural neurology, which used rigorous psychophysics and cognitive psychology to understand associations and dissociations in elemental cognitive functions in individuals with different patterns of brain damage [12–14].

A third root was being established at around the same time but took longer to mature—the development of methods to measure activity in the human brain. Early attempts were made to measure blood circulation, based on the belief that it was linked to brain activity [15–17]. The coupling between brain activity and local circulatory changes was subsequently scientifically proven [18] and eventually supported the development of effective methods to measure haemodynamic responses using PET [19–21] and fMRI [22]. A complementary set of methods was developed to measure the electrical signals of the brain directly [23, 24]. Once established, modern-day brain imaging and neurophysiological methods provided a significant impetus for the establishment of cognitive neuroscience.

The term ‘cognitive neuroscience’ was famously coined in a New York taxi in the late 1970s when a renowned neuroscientist (Michael Gazzaniga) and cognitive psychologist (George Miller)

were on the way to a dinner meeting aimed at promoting studies into how the brain enables the mind (<https://www.cogneurosociety.org/background/>). The name stuck, and the field thrives.

The enormous scope of cognitive neuroscience prevents a comprehensive review. The chapter therefore focuses on highlighting the emerging principles of the brain–mind relationship and the ever improving methods with which to investigate them. The conceptual and methodological breakthroughs provide a foundation for an experimental medicine approach into understanding the neural basis of psychiatric conditions and their treatment.

Principles

Levels of organization

The neural mechanisms that contribute to mental function (and dysfunction) can be investigated at various levels of organization. Starting from the most basic unit, it is possible to look for contributing factors linked to molecules, biochemical cascades, cellular structures (for example, synapses), cells, local microcircuits, brain regions, large-scale brain networks, behaviour of individuals, social groups, and culture. There is no leading candidate for the most relevant level of organization. Instead, it is clear that factors at any of these levels can provide important insights into understanding the brain–mind relationship.

As an example, consider the case of human memory. The properties of the NMDA receptor *molecule* are essential for enabling changes in synaptic strength as a function of association between the activities of two interconnected neurons [25, 26]. Donald Hebb [27] had famously proposed such a mechanism to be able to support long-term associative learning in the brain. Similar, though less technically detailed, proposals had also been put forth earlier [28]. *Biochemical cascades*, such as those involving calcium/calmodulin-dependent protein kinase II (CaMKII) are essential for transforming the calcium signal entering via the NMDA receptor channel into stable changes in synaptic transmission and structure [29]. The *synapse* serves as the unit of change, and different algorithms for plasticity may be manifest at different types of synapses, with different

consequences for memory. For example, the rules for plasticity differ at the synapse between Schaeffer collaterals between CA3 and CA1 pyramidal neurons vs at the synapse between the mossy fibres from the granule cells of the dentate gyrus and the CA3 pyramidal neurons. What learning properties arise is highly dependent on the way both principle cells and interneurons are interconnected in the *local microcircuitry* of brain regions (for example, entorhinal cortex, dentate gyrus, CA3, and CA1) [30, 31]. For example, in the CA3 region, the sparse pattern of potent connections between mossy fibres and pyramidal cells, together with the dense pattern of recurrent connections among CA3 pyramidal neurons, has been proposed to support sequential learning and auto-associative memory [32, 33]. Different brain *areas* are essential for supporting different types of memory. The hippocampus is essential for forming new long-term episodic memories [12, 34], whereas the cerebellum is required for certain types of sensorimotor forms of conditioning [35]. These brain areas do not operate in isolation, but within large-scale *networks* of brain regions, in which activity injected by other brain areas can modulate the qualities and strength of memories. For example, the prefrontal cortex, which is linked to the hippocampal region, can influence the integrity of source and temporal context of memories [36–38]. None of these neural insights would have come about without the observations of human *behaviour*. The patterns of dissociation among affected vs preserved memory functions in individuals after brain damage were essential to reveal the plurality of memory and to guide its taxonomy. Social, and ultimately cultural, factors strongly influence what individuals end up encoding and storing in memory [39, 40], revealing the fact that memory is biased towards items and events that are relevant to individuals, and therefore proactive and adaptive, rather than passive and impartial.

Given that all levels of organization are informative, research at different levels is equally valid. The ambition is to abstract and formalize the relevant computations at different levels and incorporate their contributions as we move to increasing scales. This is not yet possible with any certainty of capturing the true essence of all biological mechanisms involved, though the use of biophysical and mathematical models is a powerful way to test and refine ideas about computations at different levels. For the empirical scientist conducting research at a given level, the most prudent way forward is to recognize the important constraints and influences brought to bear by the other levels of organization. In the case of human cognitive neuroscience, most of the methods provide access to macroscopic levels of organization, ranging from brain areas to human behaviour. However, these can also be deployed to understand neural changes as a result of molecular manipulations or changes, as in the case of genetic risk factors or pharmacological interventions.

Structure and function

At all levels of brain organization, structure and function are bound. Thus, in order to understand neural mechanisms of cognition, one must consider the anatomy, physiology, and pharmacology. On a macroscopic scale, the anatomical pathways and connections between areas provide the scaffolding on which neural computations unfold. Furthermore, the anatomical pattern of connections to and from a given brain area is a primary determinant of its functional role [41, 42] for contemporary partitioning of human brain anatomy. The nature, intensity, and timing of physiological signals exchanged within and among brain areas through the anatomical

highways carry the contents of neural information. These determine our behaviours and our mental experience. The carriers of the physiological signals are neurotransmitters and neuromodulators acting through their various receptors. The main excitatory neurotransmitters in the brain—glutamate and GABA—are responsible for the bulk of neuronal communication in the human brain, but neuromodulators such as dopamine, serotonin, noradrenaline, and acetylcholine play essential roles in shaping the specificity, gain, and plasticity of the communications. Thus, when considering the neural basis of psychological functions, it is essential to consider the anatomy, physiology, and pharmacology. As a corollary, when attempting to understand psychological or psychiatric disorders, it is necessary to understand the interplay of these three essential ingredients.

Networks

The intuitive approach to understanding brain–mind relationships remains stuck in phrenology [43]. We gravitate towards understanding the contributions of individual brain areas to complex cognitive functions, and many scientists continue to focus on individual areas. But it is clear that brain areas are not independent functional modules within the brain. Instead, they are interconnected within large-scale networks. Functional specializations of individual brain areas come together and interact within networks.

Networks can be considered effective functional units in their own right, the integrity of which correlates with complex human psychological functions most directly [3, 44, 45]. Functional brain networks are supported by the patterns of anatomical connectivity in the brain but are also assembled flexibly according to the context of the incoming stimulation and task demands. Some groups of brain areas have a strong and close allegiance with one another, working closely together to support given functions. Examples would be the left hemisphere-dominant language network for speech comprehension and production [46, 47] and the right hemisphere-dominant network for the control of spatial attention [48, 49]. However, new allegiances can be formed flexibly and specific brain areas may be co-opted, depending on the nature of information or computations required for the current task. Indeed, brain areas need not be exclusively dedicated to one network and may contribute to multiple networks that make use of their elemental computational functions. One example is the inferotemporal cortex, noted to contribute to networks involved in visual, working memory, and semantic tasks [50–53].

Large-scale networks have important and distinctive properties. Within networks, the categorical differences between the functions of contributing brain areas can become blurred and difficult to pinpoint. The network architecture can provide resilience to loss of function by providing compensatory mechanisms, unless critical or multiple nodes are damaged. When behavioural deficits occur, these can result from lesions that damage critical brain areas within the network or from lesions that disrupt their connections to other regions. Because of the multiple specialized nodes and their interconnections, behavioural symptoms can be varied and dissociable [49, 54].

The network pattern of organization is recapitulated at lower levels of organization. Individual neurons are embedded within functional ensembles and circuits. In many cases, neuronal ensembles may be assembled flexibly, though constrained by their anatomical

connectivity. At an even finer grain, active synapses form dynamic network structures that can support specific patterns of communication and plasticity [55].

Functional specialization

Although it is no longer sensible to think of brain areas as being fully responsible of delivering specific mental capacities in a phrenological sense, it is clear that brain areas contribute specialized functions to the networks within which they are embedded. The shift from functional localization to functional specialization may appear subtle, but it is fundamental. Functional specialization of brain areas is determined by multiple factors: the pattern of inputs it receives from its various afferent regions, the neuromodulatory influences, the mappings of functional units within the region, the intrinsic microcircuitry that determines how information is transformed locally, and the pattern of outputs to its various efferent regions. Though we have made tremendous progress in sketching the functional contributions of many brain areas, our knowledge of their functional specialization is largely still incomplete.

Functional specialization occurs at different levels of organization. Previously, we considered how brain areas have specialized functions, but the same is true at higher and lower levels of organization. At higher levels of organization, we have functional brain networks that perform different transformations of their characteristic patterns of stimulation. Higher still, in humans, we observe specialization at the level of brain hemispheres. Though the precise origins and determinants of hemispheric specialization remain mysterious, certain brain networks and functions display patterns of hemispheric dominance across the population. Language, for example, tends to be left hemisphere-dominant [2, 15], whereas spatial attention tends to be right hemisphere-dominant [48, 56, 57]. Anatomical differences, such as the torque [58], accompany these functional differences, and disruption during the development of normal hemisphere dominance has been suggested as a possible cause for disorders of mental health [59].

At lower levels of organization, functional specialization occurs within subregions of brain areas, and at cellular and molecular levels. Let us focus on the hippocampal system as an illustration. In the main afferent to the hippocampus proper—the entorhinal cortex—spatial responses of neurons are organized in a grid-like fashion, which has been proposed to provide a scaffolding for constructing maps of spatial relations out of external stimulation [60]. Within individual regions of the hippocampus and closely related structures, neurons display different types of functional specialization, coding for spatial locations within the environment [61, 62], interval durations [63], or head direction [64]. Subcomponents of hippocampal cells are also specialized such as the giant synapses between the dentate mossy fibres and the ‘thorny excrescences’ on the proximal dendrites of the CA3 neurons and the exuberant pattern of recurrent collaterals within the CA3 region itself. At the molecular level, the NMDA receptor channel, densely packed in some hippocampal subregions, provides a unique molecular logical ‘AND’ gate, sensing the coincidences of presynaptic and post-synaptic activity, and is thus well suited for gating synaptic plasticity [25, 26, 65]. The computational contributions and implications of these various levels of specialization are not fully understood and remain an area of active research. Interestingly, cognitive neuroscientists are beginning

to explore whether some of these specializations, which have been observed within the context of spatial navigation and memory in animal models, may also contribute to the mapping of other types of functional relationships, and therefore underpin cognition more broadly [66–68].

Concurrent processing

Another hallmark of network organization is the rich, multidirectional, and concurrent flow of information among its various nodes. It is intuitive to think of the brain as operating on simple signals extracted from the external stream of information in an orderly way, reconstructing increasingly more complex and abstracted features and dimensions, and stitching these together into cohesive episodes. But, at best, this is an oversimplification. For example, although there is evidence for increasingly integrated and sophisticated information being coded along sensory hierarchies, it is also well known that information processing does not progress neatly in series through these hierarchies. There are many bifurcations, shortcuts, and re-entrant pathways of information. In vision, the best studied case, multiple paths of visual signal are established already at the first relay. Activity flows from the retina both to the lateral geniculate nucleus of the thalamus and to the superior colliculus. In the cortex, massive interconnections among visual areas are well documented [42, 69]. Bifurcations result in massive concurrent processing. Processing at multiple specialized brain areas proceeds concurrently to extract information about the colour, motion, identity, and spatial relations among items. Analysis in these areas cannot be said to be fully parallel, since many interconnections exist, with the possibility of mutual interaction and cross-talk during concurrent analysis. Re-entrant pathways are also abundant, so that higher-order areas receiving early signals can influence stimulus processing at hierarchically lower-order areas. For example, in vision, prefrontal areas have some of the earliest latencies of stimulation and may influence lower-order areas [70]. One interesting observation, for example, is that there are many times more feedback connections between V1 and the lateral geniculate nucleus than there are feed-forward connections [71]. Information flow in the reverse hierarchical direction may be as important as that in the forward direction [72].

The computational architecture combining functional specialization with distributed, concurrent processing is highly efficient, greatly speeding up perceptual analysis and providing some fault tolerance through compensatory pathways. However, it also poses a major problem, known as the ‘binding problem’. How does the brain correctly integrate the various attributes of the individual objects of perception (or thought) to form a cohesive episode? To date, no specific brain repository of fully integrated objects fit for conscious experience has been identified. Most theories posit that the binding problem is solved through the co-ordination of activity across large-scale networks in the brain [73, 74]. These theories are often also invoked to explain the neural basis of perceptual awareness [75, 76]. However, it is fair to say that we still lack an understanding for the exact way in which activity is co-ordinated and integrated throughout brain networks. The questions become particularly thorny when one considers the different timings for information to reach the brain from the different sensory modalities and remembers that we experience the world dynamically as it changes and we move through it.

Proactive and dynamic modulation

Our conceptualization of the brain is evolving. Instinctively, we have considered the brain as an organ to mirror, or at least construct a good internal model of reality. In this interpretation, the brain is usually a passive organ that reacts to external stimulation, creating a mental percept or construct anew, from scratch, at each moment. Yet, advances in research reveal the brain to be of a very different character. It is a complex dynamical system, ever restless, full of content used proactively and dynamically to interpret incoming signal perturbations to guide adaptive behaviour.

From the very first measurements of electrical signals in the human brain, this organ was found to be full of structured activity [23]. Far from idle, brain activity had rhythms that changed in intensity and frequency with the individuals' state or pursuit. With the advent of modern haemodynamic brain imaging methods, researchers observed that, even at rest, the brain alternates among activated functionally specialized networks [77, 78]. Contemporary electrophysiological methods with good spatial and temporal resolution reveal rapid transitions, with multiple network states per second [79, 80]. At the level of neuronal ensembles, the ebbing and flowing of rhythmic fluctuations in voltage levels is thought to affect neuronal excitability, influencing the timing of neuronal spiking and, ultimately, their communication [81–83].

The earliest psychophysical studies of human behaviour also cast strong doubt on a reactive and bottom-up construction of perception and cognition. For example, when multiple stimuli compete for attention, the resulting percept is strongly dictated by where one wilfully chooses to focus, independently of where one is looking [10]. Over the years, experimental psychology has taught us that, contrary to how it seems, we do not take in the complete and continuous stream of events unfolding around us. Instead, we sample at most a handful of items at any given moment. What ends up being perceived, and subsequently remembered, depends largely on our current task goals, motivations, memories, and emotions [84]. These internal factors influence perception and cognition proactively and dynamically. By combining behavioural studies with measurements of brain activity, cognitive neuroscientists have been charting the brain networks and mechanisms involved in the top-down control of information processing in the brain. Anticipatory signals based on internal states (for example, task goals or memories) carry information about multiple attributes (for example, locations, features, or timings) of expected relevant events. These, in turn, influence multiple stages of sensory and motor processing to determine the objects of perception that occupy the mind or guide action [85].

This continual orchestration of human perception and cognition by internal factors has important repercussions for understanding and treating mental disorders. The delicate regulation and optimization of our mental experience is achieved through fine orchestration of activity in multiple brain areas by large-scale networks involved in attention, memory, motivation, and emotion—often working together. Biased patterns of memories or deficits in motivation can lead to suboptimal or distorted pickup of external information from the environment, for example by prioritizing and selecting items that reinforce negative expectations. In this way, cognitive and emotional biases can compromise the very first exchanges with reality. Furthermore, because these selected items then come to occupy the mind and guide action, they fuel a cognitive vicious cycle that can become difficult to break.

Research into how disruption of proactive top-down control by various types of internal factors contributes to disorders of mental health has great promise. Some researchers are beginning to investigate how mood disorders compromise attention to emotional stimuli [86, 87]. The results are promising and are already leading to some useful cognitive interventions [88, 89]. However, the opportunities remaining to be explored are vast. To make incisive progress, it will help for cognitive neuroscientists to expand their inquiry of attention-related mechanisms to more ecological contexts and to consider the influence of internal factors highlighted by the clinical condition.

Methods

The last few decades have produced methods for investigating the human brain that would have seemed unimaginable when researchers first started empirical investigations of the brain–mind relationship. Each of the methods has its characteristic strengths and limitations, and so none is superior to others. In order to make advances in understanding how the brain supports cognition, it is always prudent to keep methodological limitations in mind and to employ multiple methods in a complementary fashion, to overcome limitations and guide accurate interpretation. A similar approach should be used to develop biomarkers and treatments for disorders of mental health.

Psychophysics

Psychophysics is a key term introduced to launch the empirical study of mental functions and to establish psychology as a scientific discipline [90]. Through psychophysics, the researcher investigates how systematic alterations in physical stimulation change an individual's private perceptual experience and behaviour. The use of the term is often confined to studies of perceptual systems, but the methodology applies equally well to investigations of higher-order cognitive functions, such as attention, memory, and emotion, through the systematic manipulation of stimulation.

Careful psychophysical experimentation should be brought to the forefront of understanding the causes of mental health disorders. Their primary and defining symptoms are psychological functions, yet many of the scientific efforts to develop biomarkers and treatments include only coarse psychological assessments or sidestep cognition altogether. Instead, few approaches would make greater inroads to understanding mental disorders than careful psychological testing, enabling reliable, sensitive, and selective quantification of specific cognitive functions.

The establishment of experimental psychology as a scientific field has transformed our understanding of the landscape of mental functions. The constituent elements of cognition are distilled with increasing granularity, and their dissociations, associations, and mutual influences charted. We no longer think of cognitive domains, such as memory, language, executive control, or emotion, as monolithic constructs defined in folk psychological terms. Each of these domains comprises functions with characteristic input streams, functional variables, behavioural consequences, and relationships to other psychological functions.

To dissect the psychological mechanisms of granular cognitive functions, experimental variables are manipulated systematically to

measure behavioural consequences. In addition to behavioural responses that explicitly tap into the variables of interest, it is also possible to use indirect behavioural measures, which are altered by the implicit use of the cognitive construct in question. Implicit measures can be very sensitive and circumvent problems related to strategic responding by participants. For example, rather than asking individuals about their reactions to emotional stimuli, it is possible to measure their response times to targets that follow emotional vs neutral stimuli [91] or to name the colour in which emotional vs neutral words are written [92]. The implicit association task [93] is a good example of how implicit measures can reveal instinctive psychological attitudes of prejudice, which would be difficult to assess through explicit judgements. Most behavioural tasks still rely on unitary responses, such as a button response related to detection, discrimination, or choice of a stimulus. In addition to accuracy, response times often add valuable information about the quality of performance. It is possible, however, to obtain much more detailed measures of behavioural performance by using continuous responses in behavioural tasks and by recording the precision and trajectories of responses [94, 95]. For example, rather than indicating whether a particular stimulus held in working memory was on the left or right side of the screen, participants can place the stimulus at its remembered location on the screen. In this way, over trials, it is possible to verify the precision of memory by the dispersion of responses around the correct value, to detect whether participants swap the location of items in mind, or to test whether the response trajectory is influenced by the presence of other stimuli that may have had particular salience or significance [96, 97]. In addition to relying on manual responses, recording eye movements, body movements, facial expressions, and muscle contraction can further add valuable sensitivity to the content and transformation of mental operations. The precise delineation of boundaries among functions, as well as their full characterization, is still a living science and subject to refinement, but current knowledge is sufficiently mature to make significant contributions to the study of mental health.

Our growing insights into psychological functions have not made their way very effectively into the batteries of psychological tasks used for diagnosing mental functions. The challenge is to develop a time-efficient set of tasks that are sensitive, selective, reliable, validated, and easy to administer and quantify. The requirement to use well-validated tasks keeps us tethered to old ways. Some of the most popular neuropsychological tasks combine many psychological functions of different sorts, making interpretation at the granular level problematic. Take, for example, the Wisconsin Card Sorting Task (WCST), used for diagnosing frontal lobe dysfunction. On each trial, participants view three items that can vary along multiple dimensions—colour, shape, and number. They have to learn the rule determining which two items go together. After a series of trials, the categorization rule changes without instruction. Participants must understand that the rule has changed, learn and use the new rule, and inhibit using the previous rule. This simple task therefore requires verbal comprehension, attention to individual features, categorization, learning sensorimotor correspondences, rule switching, inhibition, working memory for the active rule, sustained attention, and more. Most of the favourite neuropsychological tasks, like the WCST, are blunt or, at best, messy tasks from which to interpret the precise functions that may be compromised. But they are also quick and powerful methods for revealing a deficit in the first place, and

over the years, their interpretation has become a science in its own right [98].

Effective behavioural testing is essential. The quality of inference about a given molecular biomarker, brain dysfunction, or experimental treatment for a mental disorder will depend heavily on the quality of behavioural testing. Researchers argue about the best neuropsychological tasks, or combination of tasks, to chart the mental landscape of individuals. The use of a consistent set of tasks is important in order to link research findings from various laboratories around the world. For this reason, efforts are increasingly made to harmonize the use of neuropsychological tasks across research centres, with groups of researchers coming together to thrash out what constitutes the most effective task battery [99]. But even these distilled test batteries still combine old-fashioned and complex tasks that do not isolate and quantify relevant psychological functions with a high level of granularity. Given the state of experimental psychology, much cleaner and more detailed assessments should be possible.

So how do we strike the right level of innovation vs validation? It would be foolish to throw away the old faithful tests, with their many decades of validation. It seems equally foolish not to benefit from the power of precise psychological phenotyping that is currently possible. Multiple components should be considered for striking the right balance. The first step is to acknowledge the importance of cognitive and behavioural phenotyping. Occasionally, major research initiatives or trials of mental disorders use only perfunctory measures of cognition such as administering one of the standard cognitive batteries. What is the logic in downgrading the importance of obtaining high-quality psychological data relative to obtaining other body-based measures? Could this be a lingering prejudice against psychological science? If so, it is high time that we leave this behind. Another contributor could be the lack of access to high-quality cognitive neuroscience, and for this, more cross-fertilization between clinical and basic science training would be highly effective.

Once the importance of sophisticated psychological phenotyping is accepted, it will prove exciting to realize the enormous breakthrough potential that can be achieved through its incorporation into large-scale studies. At this juncture, multiple research approaches should be pursued and interrelated. We should continue to use standardized and well-validated batteries of proven neuropsychological tasks. These are effective at revealing the neuropsychological deficits and tether new studies to the established literature, thus allowing for comparisons. In parallel, we should use contemporary cognitive neuroscience to zoom in on potentially compromised areas in much greater detail. In many cases, it will be worth investing the time to obtain reliable and precise measures through extensive psychological testing that enable the characterization and quantification of cognitive functions at a sufficiently granular level for mapping onto functional brain networks. Granular psychological testing should be ported to digital platforms, which enables testing on massive scales, and therefore greatly accelerates their validation and the development of norms. These tests can be delivered in an engaging, game-like fashion, in short testing bursts. The opportunity to conduct testing over multiple sessions, such as in a daily fashion, has the added benefit of producing measures of variability, rates of learning, and functions of amelioration or decline. Developing games to measure and track mental health during healthy lifespan development and in the context of disorders is becoming a major enterprise

in digital health [100–102]. Finally, we should start using digital technology to measure psychological functions from ongoing natural behaviour in the real world. Patterns and variations in speech, response times, balance, movement, navigation, social contexts, sleep, for example, are likely to provide much more information than constrained psychological tests or games. To understand how the various variables within any one of these behaviours map onto cognitive and brain systems, however, it will be necessary to correlate performance variables during natural behaviour and carefully designed experimental tasks in the first instance.

Neuropsychology

The first major insights about the relationship between the human mind and brain came from observations of behavioural and cognitive deficits after brain damage. Cases of Phineas Gage [1], Leborgne (Tan) [2, 15], and HM [12, 34], for example, were pivotal to situating higher-order comportment, language production, and episodic memory in the brain.

Interpreting the functional role of a brain area from a lesion is complicated. The first complication is that naturally occurring lesions, such as after a haemorrhagic stroke, do not follow the boundaries of functional brain areas. Multiple areas may be compromised, and portions of individual areas may be spared. In many cases, therefore, it is impossible to know what exact functional areas have been affected and to what extent. Importantly, lesions also often damage white matter, breaking connections between other, often remote, brain areas.

Lesion location aside, there exist other complications. Psychological functions arise through the co-ordinated activity of large-scale brain networks. In this context, it is important to consider functional inputs and outputs, connections among areas, and possible redundancies or alternative pathways to achieve given functions. It is not possible therefore to conclude that the lesioned area performed the lost function. Instead, one can only infer that the brain cannot support that function in the absence of that area. Rather than the compromised psychological function under observation, a lesioned area could be performing a necessary upstream or downstream function. It is also not possible to conclude that the lesioned brain area does not contribute to a function that remains unaffected, since the given function may also be (or become) supported by an alternative set of brain areas. Lesions to the white matter may disconnect brain areas from their critical inputs and/or outputs. Some have argued that major neurological syndromes result from disconnections caused by lesions to key white matter hubs for inter-areal connections, such as neglect [103], aphasia [44], or amnesia [104].

To complicate matters further, the effects of lesions change over time. Damage to a given area may change the pattern of inputs or outputs to and from other areas, thus changing the levels of effective stimulation at these distant sites. Loss of normal function at these sites can result in neurological damage and atrophy. When studying the effects of chronic lesions, therefore, it is important to consider how other areas and networks have been affected through diaschisis [105, 106]. Complementing the erosion of function in damaged and interconnected areas, there can also be compensatory plasticity in preserved and complementary brain areas.

Despite all its shortcomings and complications, neuropsychology is an essential method for mapping the functional architecture of

the human mind and for understanding how brain areas and networks support its various functions. Associations and dissociations among psychological functions affected by different brain lesions are invaluable for identifying the natural kinds of psychological functions, separating those that are strongly interdependent from those that are naturally segregated in the brain. Patterns of dissociation have broken down the previously monolithic constructs into complex systems of constituent functions. Double dissociations are an especially powerful method for identifying neurally independent psychological functions [107]. These have helped us chart the relative independence between syntax and semantics [108], perceptual and motor learning [109–111], and perception for guiding recognition and for guiding action [112]. In addition to carving the psychological landscape at its joints, neuropsychology is also essential to linking psychological function to brain structure. Disruption of a psychological function after damage to a particular area provides confirmation that this area plays a necessary and causal role in supporting the given function. Although it can be problematic to infer the psychological function performed by a given brain area based solely on neuropsychological observation in the first place, for the reasons given, neuropsychological observation is the ultimate testing ground for hypotheses concerning the causal contribution of a brain area to a psychological function.

Most of the neuropsychological literature considers focal brain lesions resulting from haemorrhagic or ischaemic strokes. However, it is also possible to apply neuropsychological methods to understand psychological deficits that result from dysfunctions in brain networks in neurodegenerative and neuropsychiatric conditions. One may argue that network-level neuropsychology is more natural and appropriate, given that psychological functions arise from activity in large-scale networks in the first place. Furthermore, patterns of neurodegeneration and network dysfunction in psychiatric conditions tend to follow the patterns of intrinsic brain connectivity. Patterns of degeneration and dysfunction within networks can be graded along their core nodes and occasionally display focal points. This can reveal interesting focal patterns of relative specialization within large-scale networks. An example is the breakdown of primary progressive aphasia into agrammatic, semantic, and logopenic subtypes, which compromise different aspects of language after pathology weighted to lateral frontal, medial temporal, or lateral temporal regions, respectively [113].

Though, in principle, investigating the cognitive deficits after network-level dysfunction in neuropsychiatric conditions using a neuropsychological approach should be straightforward, in reality, it is very challenging. Some of the reason for the difficulty is that it has taken longer to accept that psychiatric conditions have neural causes. Most efforts in developing neuropsychological methods therefore occurred in the context of neurological disorders. The psychological tests and batteries we have are therefore most sensitive to the psychological consequences of damage in neurological conditions, and especially stroke. Efforts should be increasingly dedicated therefore to develop test batteries that are sensitive to patterns of cognitive and affective breakdown in psychological and psychiatric conditions [114]. The other major difficulty is in identifying the patterns of damage in brain structure, connectivity, and function in psychiatric cases. Without reliable markers of brain dysfunction, the power of the neuropsychological approach is diminished. Identification and quantification of neural markers are likely to

improve substantially, as methods for imaging the human brain develop to provide increasing sensitivity to alterations in cortical microstructure, neuromodulation, fine-scale structural connectivity, and integrity and vitality of activity in functional networks.

Brain stimulation

Transcranial magnetic stimulation (TMS) is a non-invasive method that can simulate the transient effect of a brain lesion [115, 116]. By briefly passing a current through a coil of wires, forming a high-field magnet with a very focal gradient, a strong and rapidly fluctuating magnetic field is formed, which generates electrical currents in the underlying neural tissue and affects the membrane potential of nearby neurons. The result is a brief stimulation of action potentials and interference with the natural pattern of regional neuronal activity. In some cases, TMS elicits positive effects such as the generation of sensations or of motor responses by stimulation of primary sensory or motor areas. Most of the time, however, the result of TMS pulses is to interfere with ongoing neural activity, thus acting as a brief virtual lesion. Virtual TMS lesions have the advantage of being spatially and temporally circumscribed and targeted under experimental control. TMS can be applied in repetitive trains or as single pulses, with varying consequences on the excitability of the targeted region [117]. Because magnetic fields decay rapidly, only superficial cortical brain regions can usually be targeted. The method therefore avoids issues linked to diaschisis and reorganization of function that follow from chronic stroke lesions. However, stimulating one brain area using TMS may also influence activity across the whole network of regions to which the stimulated area is functionally interconnected. By using TMS, it is also possible to get evidence about whether a brain area is causally involved in the psychological function under investigation. By using multiple stimulators, or by combining TMS with brain imaging and recording methods, it also becomes possible to investigate how brain areas causally influence activity in other brain regions and how these modulatory connections, in turn, modify behaviour [118]. Increasingly, other related brain stimulation methods are being developed, which are capable of modifying cortical excitability in subtler and different ways (for example, transcranial direct current stimulation, transcranial alternating current stimulation, and transcranial random noise stimulation) [119]. In addition to their use in testing the causal involvement of brain areas and circuits in particular psychological functions, these methods are being increasingly used to induce plasticity in specific areas and circuits within rehabilitative contexts [120].

Brain imaging

Methods for imaging structure and function in the human brain *in vivo* and non-invasively have revolutionized the study of psychological function and dysfunction.

The first major technique to be developed was PET [19, 20, 77]. PET measures the concentration of a radioactive substance at different locations within the brain. PET scanners use arrays of detectors to sense the coincidence of gamma rays emitted upon the annihilation of positrons emitted from a radioactive substance. PET can resolve signals at the level of functional brain areas, but its spatial resolution is limited by the dispersion of positrons from their original source. The temporal resolution of PET is dictated by the half-life of the specific radioactive substance being measured.

Some commonly used substances decay very rapidly and thus have a relatively high temporal resolution, while others decay much more slowly and thus have a low temporal resolution.

By using radioactively labelled tracers that mimic or alter the function of neurotransmitters or neuromodulators [for example, 6-¹⁸F-fluorodopa (FDOPA)], it is possible to investigate neuropharmacological dysfunctions related to psychiatric conditions. PET and the related method of SPECT are the best methods for investigating neuropharmacological alterations associated with psychiatric conditions. The growing availability and specificity of tracers make it possible to study neuropharmacological parameters with ever increasing specificity. In the case of the dopamine system, for example, it is possible to measure synthesis [for example, 6-¹⁸F-FDOPA and 6-¹⁸F-fluoro-L-m-tyrosine (FMT)] and transport (for example, ¹¹C/¹⁸F-labelled tropane analogues) of dopamine and to isolate multiple dopamine receptor subtypes in the nigrostriatal, mesolimbic, and mesocortical systems (for example, ¹¹C-SCH 23390 for D1 receptors or ¹¹C-raclopride for D2/3 receptors).

By using tracers linked to glucose metabolism [for example, 2-deoxyglucose (2-DG) or blood flow (for example, 15-O₂)], it is possible to investigate patterns of brain activity correlated with psychological states or functions. Neuronal activity is metabolically costly, leading to local increase in glucose metabolism and blood flow. Tracers of glucose metabolism offer the most direct marker of brain activity using brain imaging methods. 2-DG is a glucose analogue that cannot be metabolized. It is taken up by cells with high metabolic demands and remains trapped. The half-life of 2-DG is about 2 hours, and images are typically acquired over 20 minutes. Therefore, although 2-DG imaging provides a good proximal measure of neuronal activity, the time resolution is insufficient for resolving modulations of brain activity within psychological tasks. Measures of blood flow using PET made up some of the first images of brain performing different activities [121]. The most commonly used tracer is 15-O₂, which is absorbed into water in blood. It has a short half-life (about 2 minutes), allowing for multiple measurements (usually 8–12) to be taken from one individual during one experimental session, with a temporal resolution of approximately 30 seconds. This method enabled researchers to quantify and compare brain activity within brain regions and to correlate it across task conditions and groups of participants. Haemodynamic-based imaging with 15O₂-PET ushered in cognitive neuroscience as we know it today.

PET-based haemodynamic brain imaging was soon to be superseded by fMRI. Most fMRI experiments measure the BOLD signal, which mainly reflects changes in blood flow associated with neuronal activity [22]. The development of the BOLD signal combined many pieces of knowledge about the nature of the MRI signal and its susceptibility to local distortions in the magnetic field. Distortions in the field by the deoxygenated form of haemoglobin [122] lead to signal loss, so that the resulting signal strength is proportional to the ratio of oxygenated-to-deoxygenated haemoglobin [123]. The net increased blood flow into an active brain region leads to an overall increase in the proportion of local oxygenated blood, and therefore of the MRI signal [124]. In addition to being a superb method for investigating brain activity, MRI image sequences can also be used to measure different aspects of brain structure and connectivity (see Chapter 12). This one method—MRI—therefore provides various complementary modalities of brain imaging.

fMRI offers much better spatial and temporal resolution than 15O2-PET, and it allows for many more images to be taken within a given experimental session, thus providing much greater reliability and flexibility. The theoretical spatial resolution of MRI is unlimited, though, in practice, the resolution is limited by coupling between the active neuronal pool and the local source of blood flow, as well as by the requirement to pool over space to increase signal strength. MRI images can be acquired very rapidly, and methodological developments are constantly pushing the time requirements down [125]. However, ultimately, the temporal resolution of fMRI is constrained by the haemodynamic function linking neuronal activity to subsequent changes in the level of oxygenated blood linked to the influx of blood and adjustments to other haemodynamic parameters. Whereas it is possible to obtain a magnetic resonance image within the time frame of local field potentials related to synaptic activity (tens of milliseconds), the haemodynamic response function lags far behind, tracking brain activity with a delay of seconds. Even though the HRF is much slower than its driving impetus by neuronal activity, it is still possible to individuate the responses elicited by different events occurring in rapid succession, if these are appropriately timed and intermixed [126]. Furthermore, the extent to which haemodynamic responses are suppressed by successive stimulation can provide an index of overlap in the neuronal populations activated by these events [127]. MRI-based imaging has been highly successful, and the method is constantly improving, with new hardware advances, imaging sequences, and analysis tools. Arguably, MRI has played a major role in the paradigm shift from a view of the brain as a reactive organ with phrenological units to that of the brain as a proactive dynamical system of complex networks. Initial studies using fMRI in the 1990s focused primarily on brain areas [128, 129]. Soon researchers began investigating the relationships between activity in different brain areas and refining measures of their functional connectivity and interaction [130–132]. Changes in brain activity and functional connectivity by pharmacological manipulations further nuanced our appreciation of modulatory functional interactions in the brain [133]. MRI then enabled the observation that functional brain networks are spontaneously active, even during periods of rest [77, 78]. Resting state networks (RSNs) emphasize the dynamic and active nature of the brain.

Advances in analysis techniques have substantially increased our statistical power and resolution to study the human brain across spatial scales. Going beyond univariate analyses of changes in the magnitude of regional BOLD responses, multivariate analyses can compare patterns of subtle signal variation across voxels [134, 135]. Furthermore, computational approaches are increasingly applied to understand the relationship between patterns of brain activity and their representational content [136], and to arbitrate among competing models about the nature of neural coding supporting psychological functions [137]. At the network level, analyses based on graph theory and network science are increasingly used to estimate parameters related to the patterns and strength of connectivity among various functional nodes on multiple scales [138, 139].

Electrophysiological recordings

Electrophysiological methods are the most direct way to measure human brain activity. Rather than relying on the relationships between brain activity and metabolic demands and between metabolic demands and blood flow, electrophysiological methods pick

up unmediated electrical correlates of neuronal activity. In doing so, these methods have the ability to register changes in brain activity with high temporal fidelity.

Electrical signals generated in the brain were first measured from the exposed animal brain by Richard Caton (1875) [140]. He designed an ingenious voltage-sensitive mechanism to move mirrors—a reflecting galvanometer—and demonstrated systematic changes in the pattern of reflected light upon variation of light stimulation to the eye. Some decades later, Hans Berger (1929) [23] developed the ‘electroencephalogram’ (EEG), a non-invasive method for recording electrical signals originating from the human brain. The EEG measures fluctuations in voltage over time through electrodes placed on the scalp and a reference electrode. Using his method, Berger described the characteristic frequencies of voltage changes recorded from the human brain in different functional states (for example, sleep, relaxation, intellectual effort, administration of cocaine) and neurological conditions (for example, epilepsy).

Although the EEG records voltage directly, the signals available at the scalp are a macroscopic and distorted summary of activity over large populations of neurons. Voltage signals at the scalp originate mainly from the summation of synaptic potentials of synchronously active neurons that are well aligned spatially [141, 142]. Because voltage decays logarithmically with distance, the measures are heavily biased towards neuronal populations that are close to the active electrode. The orientation of the active neuronal population relative to the electrodes also influences the polarity and amplitude of the signals. The resulting signal therefore reflects the spatial summation of co-active neurons, biased by the degree of co-alignment of contributing neurons, as well as the orientation of the active region within the brain. The skull and scalp further strongly blur the signals before they are recorded [143]. Given these principles, the EEG recordings tend to be biased towards picking up excitatory synaptic potentials from pyramidal neurons in the neocortex [141, 144]. Signals at the scalp have been estimated to reflect the activity in thousands to millions of co-activated neurons [144]. The precise polarity and amplitude of the signals recorded at any given scalp electrode are heavily dependent on the location of the reference electrode.

Magnetoencephalography (MEG) is a more recent electrophysiological method, which uses superconducting quantum interference devices (SQUIDS) to record the magnetic fields that accompany the neuronal voltage signals [145, 146]. Magnetic fields have different properties to voltage potentials, which confer greater spatial resolution to the recordings. The underlying origin of the signal measures with EEG and MEG is the same—summed synaptic potentials over large populations of well-aligned, co-active neurons, but some important details differ in the signals that are measured.

MEG sensors detect local changes in the magnetic field, so the recordings are reference-free. Magnetic fields are unaffected by the conductivity of the skull and scalp, eliminating the problem with blurring and resulting in much sharper gradients of activity measured from the scalp. Magnetic fields decay more sharply than electrical fields with distance, further focusing the activity measured to superficial neocortical sources. Furthermore, the sensors are more sensitive to neuronal activity in sulci, resulting in magnetic fields that are tangentially oriented to the scalp. Altogether, MEG therefore provides more spatially resolved measures of active neuronal populations. The main drawback of MEG, relative to EEG, is its reliance on expensive superconducting technology and on the scarce

resource of liquid helium. However, new generations of sensors are being developed to measure MEG with more accessible technologies such as optically pumped magnetometers (OPMs) [147], hybrid quantum interference devices [148], and nitrogen vacancy magnetometers [149].

Compared to haemodynamic imaging methods, EEG and MEG have poorer spatial resolution. Their spatial sensitivity comes from the distribution of voltage or magnetic-field gradients at the scalp, which can be sampled with dense arrays of sensors. It has been known since Helmholtz (1853) [150] that the problem of estimating the sources of signals from within a three-dimensional volume from a pattern on a two-dimensional surface is ill posed. The problem is mathematically underdetermined and impossible to solve uniquely. An infinite number of possible configurations of sources can account for any given surface pattern. Mathematical impossibilities aside, increasingly powerful methods of source reconstruction are being developed, which incorporate knowledge about brain structure and physiology, convergent findings from methods with high spatial resolution, and analytical methods to quantify likelihoods of different possible solutions [151–154].

The direct and time-resolved measures of brain activity from MEG and EEG (M/EEG) can be used to address many important questions relevant to psychiatry [155]. As in Berger's original use of EEG, it is possible to extract useful information just from the raw M/EEG signal. At rest, brains display characteristic patterns of activity within different frequency ranges, thought to reflect the levels of excitability in different neural circuits and on different spatial scales [156]. Disruptions in synaptic function or in the interactions among brain areas within large-scale networks associated with psychiatric conditions can lead to systematic alterations in the characteristic frequencies and power of oscillatory activity. Abnormal patterns of oscillations have been linked to conditions such as schizophrenia [157], autism spectrum disorder [158], and Alzheimer's disease [159]. In addition to characterizing the frequency profile of activity in raw M/EEG, it is also possible to resolve activity in functional networks from the raw MEG signal when individuals are at rest [79]. Investigating the strength in RSNs and connectivity among constituent regions can provide a powerful method to investigate network dysfunctions associated with psychiatric disorders or their risk factors [160, 161]. New analytical methods that identify which functional network is most likely to be active at a given time point enable researchers to quantify the dynamics within functional RSNs [162]. Using such methods, it becomes possible to compare the vitality of networks in psychiatric conditions, for example by determining whether the dwell time of networks indicates excessive rigidity or instability in network states

In addition to general measures of brain activity at rest, M/EEG provide rich information about the brain's response to specific events within tasks. Traditionally, brain activity linked to a perceptual stimulus, a cognitive operation, or a motor response has been studied using event-related potentials (ERPs) or fields (ERFs). These are averages of waveforms triggered by several repetitions of such events, which reinforce the aspects of the signal that are systematically related to the event and average away other artefacts and unrelated brain activity. The resulting waveforms have characteristic patterns of peaks and troughs, known as 'components'. Components are defined by their latency, amplitude, voltage topography over the scalp, and functional modulation by experimental variables

[141, 163]. Their relations to the underlying neural events can be complex. In many cases, there may be no specific single intracranial component, but instead multiple overlapping neural processes that give rise to a macroscopic component at the scalp. These are therefore best understood as sources of controlled observable variability [164] that provide rich, dependent variables to study information processing in the brain during that time period.

Using ERPs and ERFs, it is possible to investigate changes in information processing in the brain on a millisecond-by-millisecond time frame. Such temporal resolution can reveal whether a given psychiatric condition affects early perceptual pickup of information or only later deliberative processes. For example, ERP studies have pointed to early visual deficits in conditions such as schizophrenia [165]. Such conclusions could not be derived from haemodynamic imaging studies showing alterations in the visual cortex, since it would not be clear whether the modulation came from early visual processing or from late feedback modulation of visual areas by re-entrant activity after extensive processing in other areas. Another nice feature of electrophysiological recording methods is that brain responses can be studied without requiring participants to respond. In this way, it is possible to study the extent to which patients with different conditions process irrelevant, distracting stimuli. Such studies can reveal deficits in inhibiting irrelevant information [166] or exaggerated engagement with irrelevant emotional stimuli [167, 168] in different psychiatric and psychological conditions. By focusing on ERPs and ERFs at various stages of processing and by careful experimental design, it is possible to investigate how different psychiatric conditions affect attentional capture, emotional processing, semantic access and integration, memory retrieval, etc, arguably in a more specific and direct way by using brain imaging.

More recently, an increasing number of measures and approaches are being developed to derive and analyse brain signals linked to event processing from raw M/EEG. By relying on trial-by-trial fluctuations in stimulus and behavioural parameters, it is possible to analyse task-related brain signals without having to average brain activity [169], thus providing even greater sensitivity to identify deficits within particular stages of information processing. In addition, task-based analyses are increasingly separating the M/EEG signal into its various frequency components. Changes in the intrinsic oscillatory rhythms induced by stimuli or cognitive operations can suggest alterations in circuit-level activity or connectivity in psychiatric conditions such as schizophrenia and autism spectrum disorders [170, 171].

Because MEG and EEG provide a direct measure of brain activity, unmediated by haemodynamic parameters, they are well suited for investigating pharmacological effects. The powerful combination of pharmacological manipulations with electrophysiology remains under-exploited but is likely to play a major role in investigating pharmacological contributions to psychiatric conditions, as well as developing drug-related treatments [172, 173].

Biomarkers

By combining neuropsychological batteries and focused cognitive testing with non-invasive measures to image and record brain activity, one dramatically increases the likelihood of identifying relevant biomarkers associated with risk or early stages of psychiatric

disorders. It becomes possible to enhance characteristic cognitive profiles with sensitive and selective quantitative measures of speed, accuracy, and variability in specific, relevant cognitive domains. These rich psychological measures can be accompanied by variations in the structure and function of brain areas, their structural and functional connectivity, the strength in activation of large-scale brain networks, the vitality and temporal characteristics of networks, markers of neuronal integration, and communication, the speed and strength of neural responses at various stages of information processing, and altered patterns of information processing at various stages.

Two general approaches can be considered when developing psychiatric biomarkers. The various behavioural and neural measures can be used in a data-driven way to pull out combinations of measures that are predictive of psychiatric risk, condition, or recovery. New multivariate decoding and machine-learning modelling methods are increasingly powerful in identifying combinations of factors associated with particular outcomes. While this chapter strongly endorses the inclusion of factors directly related to cognitive and brain structure and function in biomarker development, it does not exclude the utility of other factors linked to molecular and cellular characteristics. The multivariate decoding approach can easily assimilate all such factors to find the most promising combinations of factors, thus generating high-level composite biomarkers. Much progress can be made in patient stratification, diagnosis, and treatment by using data-driven biomarkers, even without a clear understanding of the mechanisms that link each cognitive or brain factor to the outcome in question. Additionally, these data-driven biomarker candidates can become subjects of enquiry in their own right, yielding new mechanistic hypotheses to be explored.

The other approach is the more traditional, hypothesis-driven experimental-medicine model. In this case, candidate mechanisms of cognitive or brain deficits can be investigated directly. By expanding the methods with which these are investigated, it becomes possible to gain a fuller mechanistic understanding of how a hypothesized deficit is expressed at different levels of analysis, as well as to learn about the breadth of implications of a given deficit and how best to develop treatments.

Good examples of successful hypothesis-driven approaches to psychiatric conditions are found in the context of mood disorders. In the context of depression, Harmer and colleagues [174, 175] have investigated the role of cognitive emotional biases in mediating the effects of drugs for depression (often referred to as antidepressants). By using a sensitive battery of cognitive tests to assess emotional recognition and emotional biases, the researchers have suggested that monoamine reuptake inhibitors influence emotional and social cognition directly, which, in turn, re-dress the mood disorder over time. The proposed mechanism explains why clinical actions of drugs for depression are delayed. By combining cognitive and pharmacological studies with brain imaging methods, the researchers have revealed the neural systems affected by drugs affecting different neuromodulatory systems and have been able to develop effective means to predict individual responses to antidepressant treatment.

A similar experimental medicine approach is being developed in the context of bipolar disorder, which is also benefiting from data-driven discoveries [176]. The guiding hypothesis for this programme of research came as a combination of data-driven and clinical

observations. Long-term prospective weekly monitoring of mood levels by patients [177, 178] revealed that individuals with bipolar disorder display high levels of mood instability, rather than the textbook pattern of alternating discrete episodes of mania, depression, and euthymia. Such results from remote monitoring of mood states complement clinical observations and conventional questionnaire findings [179, 180], and also provide rich quantitative data for modelling with machine-learning methods, as well as with novel mathematical techniques [181–183]. These findings raised the intriguing possibility that mood instability may provide a central feature that contributes to bipolar disorder. It occurs in individuals at high risk for bipolar disorder [184], predicts its onset [185], occurs during the prodrome of the disorder [186, 187], and is independently associated with poor prognoses [188–190]. Mood instability may also contribute to other mood disorders, such as borderline personality disorder [191], and may further do so in different ways.

A cognitive neuroscience experimental-medicine programme of work has been launched to characterize the pattern of mood instability associated with the risk for bipolar disorder, to investigate how mood instability is associated with changes in particular cognitive functions and to reveal how altered brain network dynamics may contribute to mood instability and cognitive deficits [176]. If successful, such a programme of research will identify effective biomarkers that will enable the stratification of individuals for trials to investigate the effects of mood-stabilizing drugs, as well as predict and measure their efficacy within individuals. By building on this approach, a double-blind, randomized, placebo-controlled study is investigating changes in mood, cognition, and brain network dynamics after 6 weeks of lithium treatment in participants with bipolar disorder and mood instability [192].

The field can get caught up in debating whether data-driven or hypothesis-driven approaches are the way forward. The answer is simple. They are both useful and can work together effectively, in complementary ways. Ultimately, hypothesis-driven research is essential for developing a deep and nuanced understanding of the mechanism. However, the approach requires building on good initial assumptions and ideas. In any scientific field, there is a danger of building experimental edifices on false starts. The additional challenges in psychiatry related to the lack of simple and tangible phenotypes for grounding the research exacerbate the problem. Data-driven discoveries can help set scientists back on track for better hypothesis-driven research. The process can be iterative, and information can flow in both directions, with data-driven findings informing hypothesis-driven work and results from focused experiments contributing to the pool of data for further mining.

Ageing and the human brain

Verena Heise, Enikő Zsoldos, and Klaus P. Ebmeier

Introduction

Age is an acknowledged confounder in psychiatric research, most apparent in younger and in older patient groups. There is hardly any study that does not address this variable, usually by matching controls and patients by chronological age, by separating psychiatric disciplines into age groups (viz. child and adolescent or old age psychiatry), or by entering the chronological age as a covariate into regression analyses. Time as a physical category, whether defined as multiples of 9,192,631,770 cycles of radiation (the transition between two energy levels of the caesium-133 atom at rest at a temperature of 0 K (= 1 second [1]) or by the emptying of an hourglass, clearly has no direct mechanistic impact on a person's biological age, nor does our perception of time [2], although chronological time is used as a proxy of ageing. It is understood, moreover, that there is good ageing and bad ageing, depending on genetic and non-genetic factors, which add variability to the association of biological changes with the linear progress of time. This chapter will attempt to identify the time-dependent, that is, cumulative, processes that interfere with the function of the body and, in particular, manifest with changes in behaviour and experience. It will cover genetic and epigenetic mechanisms, the intermediate metabolic changes associated with ageing, as well as changes at a system level that increase the allostatic load and lead to overload. We will pay particular attention to age-related changes in the brain that are likely to be associated with psychiatric disease and that are becoming more and more amenable to examination with *in vivo* imaging techniques. Empirical biology of psychiatric ageing will require a chain of evidence from predisposing variables, longitudinally throughout life to observable brain changes that are associated with changed behaviour and psychiatric illness. We will illustrate this principle with a few examples.

Mechanisms of ageing

Cellular ageing

Chronological age is the best predictor of many chronic diseases such as atherosclerosis, type 2 diabetes, most cancers, and neurodegenerative diseases [3]. But how does the passing of time affect the human body? There are many different pathways underlying

ageing, but the common denominator is that they affect the accumulation of damage in DNA, proteins, and lipids over time, and thus in organelles, cells, and tissues [4]. This somatic body cell clock determines the fate of individual organisms over weeks, months, and years and is based on mechanisms similar to the germ cell molecular clock that allows us to reconstruct the history of species over hundreds of millennia [5]. It is the balance of two processes that defines how quickly damage occurs—on the one side, external and internal processes that cause cellular damage, and on the other side, systems for maintenance, repair, and turnover.

One example of internal processes associated with age-related damage is the production of reactive oxygen species (ROS). ROS are a normal by-product of cell energy metabolism and are mainly produced in the mitochondria, the power generator of the cell. ROS are chemically very unstable and cause oxidative damage to DNA, proteins, and lipids. This damage, in turn, causes malfunctioning of cells, and ultimately cell death if cells cannot recover [6]. However, there are many systems in the cell to combat oxidative damage, from antioxidants that act as scavengers of ROS to DNA repair mechanisms and degradation pathways for faulty proteins [7]. Accumulation of oxidative damage in cells is the cause of ageing, according to the 'free radical theory' of ageing [8]. However, there is conflicting evidence on the involvement of ROS in shortening or extending the lifespan [9].

Pathways that play a role in the pace of ageing have been extensively studied in the four main model organisms for ageing research: the budding yeast *Saccharomyces cerevisiae*, the nematode worm *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster*, and the house mouse *Mus musculus musculus/domesticus*. There seem to be converging pathways in these model organisms and humans that not only lead to an extension of the lifespan, but also an improvement of health during ageing—an increased 'health span' [4]. One of the best studied ways of extending life in model organisms is to introduce dietary restriction. This led to the discovery that pathways involved in nutrient sensing are important players in ageing. These pathways are regulated by different proteins: target of rapamycin (TOR), adenosine monophosphate-activated protein (AMP) kinase, sirtuins, and insulin/insulin-like growth factor 1 (IGF-1) [9]. On the one hand, these pathways affect cellular metabolism, which intuitively makes sense; when food is scarce, the organism needs to be able to enter a standby mode of energy-saving

to support only those processes that are vital for survival [10]. On the other hand, there is also a link between these pathways and cellular damage because they affect the production of antioxidants and proteins involved in cellular maintenance and repair mechanisms [9]. While it is difficult to establish links between dietary restriction and ageing in humans, studies in rhesus monkeys have shown that it affects ageing in non-human primates as well. Dietary restriction leads to improved insulin sensitivity and inflammatory profiles and protects from age-related diseases such as sarcopenia, cardiovascular disease (CVD), type 2 diabetes, neoplasia, endometriosis, and brain atrophy [11].

Cellular brain ageing

The brain is particularly susceptible to cellular damage because of its limited capacity for regeneration and its high metabolic demand, which leads to increased ROS production [12]. Many neurodegenerative diseases have in common the fact that post-mortem studies show increased oxidative stress and reduced levels of antioxidants in brain regions affected by pathology [6]. Whether this is cause or effect of pathology and the contribution of oxidative stress to brain ageing *per se*, however, is a matter of intense research [12]. Nevertheless, nutrient-signalling pathways provide a link between cellular damage and the brain. They not only play a role in the periphery, but also mediate signalling in the brain. For example, insulin receptors can be found in the hippocampus and their function depends on insulin transport from the periphery to the brain [13].

One of the direct effects of dietary restriction on the brain is increased production of neurotrophic factors and neurogenesis in the hippocampus [14]. The hippocampus is one of the few areas in the adult human brain that show integration of newly generated neurons into brain circuits. While most studies on neurogenesis have been conducted in rodents, it is reasonable to assume that adult neurogenesis in the human hippocampus serves similar purposes, supporting memory processes and contributing to brain plasticity. Neurogenesis decreases with age, so measures that contribute to increased neurogenesis are thought to be protective [15, 16]. Another mechanism of brain plasticity that decreases with age is synaptic plasticity. It has been extensively studied in non-human primates where age-related cognitive decline is more associated with alterations in synaptic connectivity, particularly highly plastic synapses, than loss of neurons *per se* [17]. Similar effects have been shown in humans, and research into Alzheimer's disease has shown a high degree of synapse loss, rather than neuron loss at early disease stages, which correlates with cognitive symptoms [18, 19]. Therefore, the loss of synaptic plasticity and connectivity plays a role in the ageing human brain as well. Insights into the mechanisms driving ageing and longevity in humans have focused on two main contributors: genetics and lifestyle and other environmental factors.

Genetics and epigenetics

The simple concept that some people 'look young' for their age, or vice versa, shows that chronological age, the time that has passed since birth, and biological age, in this case defined by features such as smoothness of the skin, posture, etc., are not necessarily the same. Research into genetic factors that drive the pace of ageing have focused on two extreme ends of the spectrum: those who show accelerated ageing phenotypes due to progeroid syndromes and

centenarians who show exceptional longevity. One example of a progeroid syndrome is Werner syndrome, which is characterized by the development of age-related diseases such as osteoporosis, CVD, and cancer from the age of 20. Research into the genetics of many of these progeroid syndromes has shown the importance of DNA repair and maintenance in ageing [20]. The debate of whether or not familial forms of neurodegenerative diseases, such as Alzheimer's disease, constitute an 'accelerated ageing' phenotype later in life [20] is beyond the scope of this chapter. It is striking, however, that individuals with exceptional longevity seem to escape age-related disorders, including neurodegenerative disorders, altogether and live mostly disease-free until late in life [21]. Longevity clusters in families point towards a link between genetics and lifespan. Additionally, studies have shown that centenarians do not lead a healthier life than the rest of the population, which makes it more likely that it is their genetic makeup that protects them from the development of age-related diseases [21]. However, genome-wide association studies (GWAS) have not yielded very promising results, apart from an association between the apolipoprotein E (APOE) $\epsilon 2$ allele and longevity, which is most likely due to the link between a reduced risk of Alzheimer's disease in carriers of this allele [21]. Some studies have also reported that centenarians are more likely to carry protective alleles for age-related diseases such as cancer, CVD, and type 2 diabetes. However, this appears to depend on the sample source of centenarians because other studies found that centenarians were healthy, even though they carried risk genes for these diseases [21]. More targeted genetic approaches have also shown associations between longevity and genes that are associated with ageing pathways such as forkhead box O3A (FOXO3A) and IGF-1 signalling, genomic stability, in particular telomere protection, and genes that encode antioxidants [21]. The contribution of mitochondria and oxidative stress may implicate mitochondrial DNA. For example, two-thirds of Japanese centenarians were found to carry a mitochondrial gene variant that is possibly associated with decreased mitochondrial leakage of ROS [22]. For an updated list of genes associated with ageing, see The Ageing Gene Database available at: <http://genomics.senescence.info/genes/>.

One problem with the genetic approaches described is that it is probably too simplistic to assume that all centenarians have the same genetic profile. One could hypothesize that it is again the balance of processes that cause damage vs repair and maintenance pathways that will determine the lifespan in humans. While some centenarians live long and healthy lives because they are resistant to damage in the first place, others profit from systems that efficiently repair damage and allow them to be resilient.

It is not necessarily only the genotype that determines longevity, but also which parts of the DNA are actually transcribed. Epigenetic modifications, such as histone modifications, DNA methylation, and chromatin remodelling, change with age and provide a link between genetics and lifestyle or environmental factors that affect ageing. Members of the sirtuin family of proteins, for example, have been extensively studied as epigenetic factors that influence longevity in model organisms [23]. However, it is unclear whether these proteins also play a role in human longevity [21]. Studies in monozygotic twins have shown that lifestyle or environmental factors contribute to epigenetic differences between twins that increase with age [24]. These factors and the mechanisms underlying their effects on ageing are the subject of extensive research.

Environmental and lifestyle factors

Studies in model organisms, as mentioned previously, have already provided links between metabolism and ageing. While it is difficult to determine the effects of dietary restriction in randomized controlled trials in humans, several short-term studies have shown beneficial effects, for example a reduction in risk factors for atherosclerosis, that are similar to those observed in animal studies [4]. There are strong links between hypertension, dyslipidaemia, and oxidative stress, with studies showing increased ROS production and decreased antioxidant activity in CVD patients. Indeed, some antihypertensive drugs and cholesterol-lowering statins probably act, at least partly, via decreasing ROS production [25]. As CVD can be seen as a sign of 'unsuccessful' ageing, factors that affect CVD risk, such as diet [26], will also, in turn, affect mechanisms of ageing. Physical activity affects ageing, possibly partly by acting on CVD risk. Even at low levels, physical activity decreases mortality and thus leads to more 'successful' ageing [27]. On a mechanistic level, there is an association between physical activity and leucocyte telomere length, which indicates the effects on pathways that are important for genomic stability [28]. Physical activity also has direct effects on the brain where it leads to increased hippocampal neurogenesis [15]. Another link between the environment and ageing is the immune system. Ageing is associated with upregulated inflammatory markers, possibly because the immune system has to deal with recurrent or chronic systemic infections and imbalances between pro- and anti-inflammatory networks [29]. Following an injury or infection, the immune response to systemic insults is not restricted to the periphery, but also affects the brain. This becomes evident in the associated behavioural symptoms of sickness such as lethargy and poor concentration [30]. Systemic inflammation accompanies many chronic diseases such as rheumatological conditions and CVD. There is also a link between metabolism and the immune system, because increased peripheral insulin levels are associated with increased pro-inflammatory

markers in the cerebrospinal fluid (CSF) [31]. Chronic inflammation leads to an increased state of activation of the brain immune response that accompanies ageing and might, in turn, contribute to neurodegeneration [32]. Not surprisingly, altered immune responses have been described consistently in depressive disorders later in life [33] (see also Chapter 16). Another important lifestyle factor that affects brain ageing is stress, which will be discussed in the next section.

Stress and ageing (allostatic load)

From first principles, our chance of developing physical and psychological illness increases with time. Any change or challenge within the internal or external environment, no matter how minor it may be, requires temporary adaptations of the internal milieu and a shift in its homeostasis (a process termed allostasis). The repeated demand for allostasis over time can lead to syndromes that are associated with peripheral organ damage, as well as structural and functional brain changes [34], which, in turn, further damage the dysregulated stress response system. These maladaptive responses reflect the 'allostatic load' (AL) and 'overload' [35], physiological dysregulation, and the wear-and-tear of the body, thus representing biological ageing [36, 37] (Fig. 18.1). Common psychological stress, if perceived negatively, rather than as an incentive to strive, is said to accelerate biological ageing and precipitate the onset of age-related diseases [38]. Individual variability in the progressive loss of the ability to deal with stress and the development of age-related distress [39] may also reflect differences in individual potential for brain plasticity and resilience [40].

Chronic stress-related changes accumulate across the lifespan, and challenges faced in later life are associated with intermediate composite markers of AL such as the metabolic syndrome [41]. These, in turn, increase the risk of pathological brain changes and

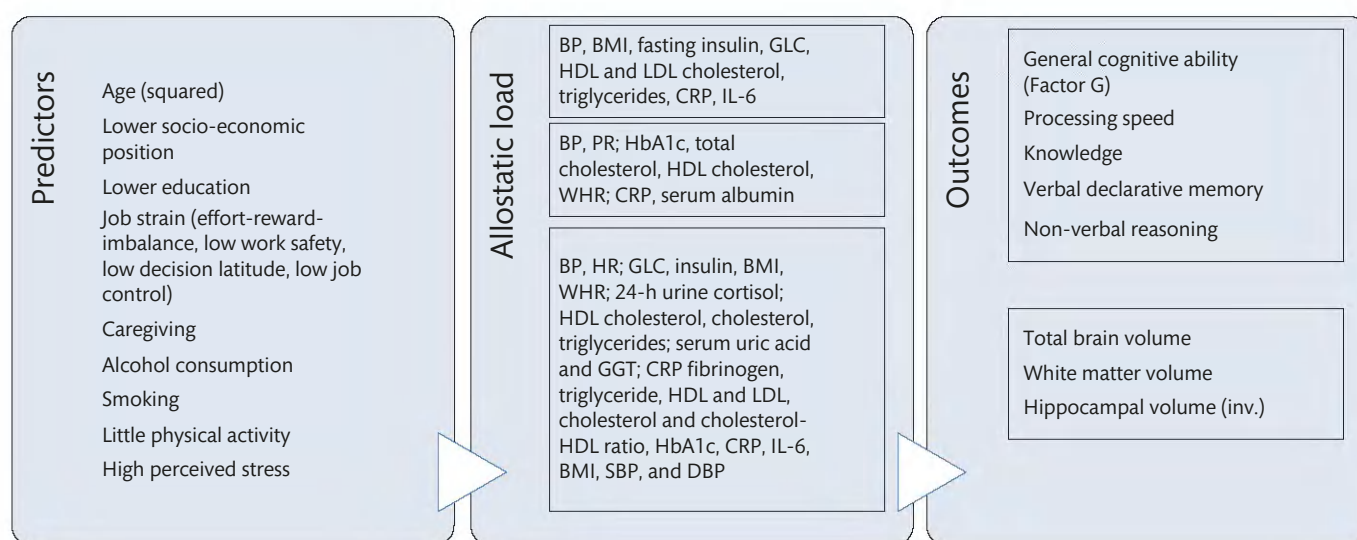

Fig. 18.1 The secondary stress marker 'allostatic load' with predictors and behavioural and brain outcomes. Three versions of computing the allostatic load from abnormal physiological measures and cited based on the underlying papers [70–75]. BMI, body mass index; BP, blood pressure; CRP, C-reactive protein; DBP, diastolic blood pressure; GGT, gamma-glutamyltranspeptidase; GLC, glucose; HbA1c, glycated haemoglobin; HDL, high-density lipoproteins; HR, heart rate; IL-6, interleukin 6; LDL, low-density lipoproteins; PR, pulse rate; SBP, systolic blood pressure; WHR, waist-to-hip ratio.

age-related diseases such as depression [42], impaired cognitive function [43, 44], and Alzheimer's disease [45].

Composite measures of biological ageing

The release of stress hormones and their antagonists, along with pro- and anti-inflammatory cytokines, triggers the cardiovascular, metabolic, and inflammatory systems through the HPA axis and the autonomic nervous system to shift their operational ranges in order to sustain allostasis (Table 18.1). While this is adaptive in the short run, prolonged activity results in an increase of AL markers, which predict stress-related illness. Markers include cardiovascular, metabolic, and inflammatory measures, such as summarized in the Framingham risk scores [46] (see also Fig. 18.1), metabolic syndrome [47], or AL index [41], and are better predictors of physical, mental, and cognitive health and mortality risk than individual component measures [48, 49].

Table 18.1 Composite measures of biological ageing

		Allostatic load index [41]	Framingham stroke risk [46]	Metabolic syndrome [47]
Cardiovascular	Systolic BP	X	X	X
	Diastolic BP	X		X
	CVD		X	
	Atrial fibrillation		X	
	Left ventricular hypertrophy		X	
	BP medication		X	
Metabolic	Diabetes	X		X
	Diabetes medication		X	
	Fasting glucose		X	
	Waist circumference		X	
	Weight		X	
	Fat mass		X	
	% body fat		X	
	Serum triglycerides	X		X
	HDL			X
	LDL	X		
	Cholesterol	X

	Sex		X	X
	Smoking		X	
	Cortisol	X		

BP, blood pressure; BMI, body mass index; CVD, cardiovascular disease; HbA1C, glycated haemoglobin; LDL, low-density lipoprotein. Allostatic load index below is based on markers available in the Whitehall II study [139, 140].

The effects of psychosocial stress have been most extensively studied in association with cardiovascular health and disease risk in the context of the workplace [50]. Mid-life hypertension is associated with an increased risk of late-onset depression [49] and dementia [51]. It has been linked to atrophy in both occipital and frontal cortical regions [52] and in the hippocampus [53] in cognitively healthy older adults. Consistently high blood pressure across adulthood also predicts structural brain changes in the deep white matter in healthy older adults [54]. Multifactorial cardiovascular and stroke risk scores, such as the Framingham Coronary Heart Disease [55] and stroke risk [46] scores, are associated with cognitive decline [56, 57] and structural brain changes such as grey matter volume reduction [58] and white matter hyperintensities [59]. In turn, patterns of structural brain changes discriminate between those with high vs those with low coronary heart disease risk, as measured by the Framingham Coronary Heart Disease Risk score, even after taking into account the genetic risk for Alzheimer's disease [60].

Metabolic syndrome [47] is a combination of cardiovascular and neuroendocrine factors. It is defined by a number of biomarkers: increased abdominal circumference, increased levels of triglycerides, decreased levels of high-density lipoprotein (HDL) cholesterol, elevated blood pressure (including prehypertension), and fasting glucose levels (prediabetes). A diagnosis of the syndrome is given if at least three of these markers are above their defined thresholds. The effects of workplace psychosocial stress have been shown to manifest as metabolic syndrome [61], besides adverse cardiovascular health, as mentioned in this chapter. In turn, metabolic syndrome is associated with a risk of stroke and CVD mortality [62], telomere shortening [38], and poor mental and cognitive functioning [42, 43, 63]. Our understanding of the association between metabolic syndrome and brain changes, however, is limited [64]. Reduced cortical thickness in distinct areas of both hemispheres, as well as volume reductions in the right nucleus accumbens of middle- to older-aged participants with metabolic syndrome, have been documented [65]. Vascular brain damage in the form of periventricular white matter hyperintensities and subcortical white matter lesions in middle-aged individuals [64], reduced white matter integrity in fronto-temporal regions [66], and silent brain infarction in older individuals [64] have also been reported.

The exact combination of biomarkers that define the AL index is subject to debate [41], as is the way it is computed [67, 68], but it tends to include a combination of stress hormones, inflammatory, cardiovascular, metabolic, dyslipidaemia, and neuroendocrine markers. In combination, they are better predictors of health outcomes and mortality than on their own [69]. Chronological age is a strong predictor of AL increase, and a combination of psychosocial factors, including those at work, predict high levels of the index [70]. A recent systematic review of 16 cross-sectional studies found that occupational stress was positively associated with AL index, in spite of the lack of consensus on its computation and the heterogeneity in study methods and quality [71]. Low socio-economic status is associated with higher AL index across the lifespan [72], which is not surprising, given that the prevalence of stressors is higher in low socio-economic groups. A recent community-based prospective cohort study of middle-aged adults found that material possessions (car and house ownership) and smoking, but not other health behaviours, such as physical activity or alcohol consumption, or psychological factors, mediated the relationship between low

socio-economic status and high AL index [73]. Sex differences are present in the association of both socio-economic status and lifestyle with AL index—low occupational position and alcohol abstinence, compared to moderate drinking, is associated with higher AL index levels in women, but the opposite is true for men. Education level, physical activity, and low salt intake seem to be protective against high AL in both sexes [74]. The AL index is a significant predictor of cognitive and physical decline, CVD, and mortality in older adults [48]. In a birth-year cohort, Booth *et al.* [75] reported a negative association of AL index with total brain and white matter volumes, and no association with grey matter volume in participants aged 73 years. In addition, the index was negatively associated with general cognitive ability, processing speed, and knowledge, but not with memory or non-verbal reasoning. Although it is argued that combinations of physiological markers of wear-and-tear are better predictors of brain structure and function than any one of the AL markers [48], the mechanisms in which primary and secondary markers come together to predict cognitive decline are yet to be understood [76].

Central role of the brain

Several brain structures have a central role in the regulation of the stress response (Fig. 18.2). These regions include the hippocampus,

amygdala, and prefrontal cortex. They are important effectors, responding to mediators of allostasis, as well as targets of allostasis, so that chronic dysregulation can result in AL and damage to certain brain structures. Furthermore, they can become central to such dysregulation, stress-related vulnerability, and pathological plasticity [34]. Identifying the precise mechanisms that lead to the wear-and-tear of specific brain structures may lead to effective interventions [37].

The subcortical limbic brain structures, the hippocampus and amygdala, process information arising from less developed brain regions in the diencephalon (such as the hypothalamus) and myelencephalon (parts of the brainstem), along with higher cortical areas, particularly in the prefrontal cortex, to regulate physiological and behavioural responses of allostasis [34]. The formation of synapses and long-term potentiation to facilitate memory can make these responses adaptive. However, neuronal damage caused by chronic elevated glucocorticoid levels can lead to (hippocampal) neuronal death via further dysregulation of glucocorticoid secretion [77]. Although a lack of longitudinal studies makes it challenging to determine the mechanism for this, for example, higher sensitivity to glucocorticoids in PTSD may contribute to hippocampal atrophy [78]. Individuals with smaller hippocampi, on the other hand, may

Fig. 18.2 (see Colour Plate section) Negative association of vascular risk (Framingham Stroke Risk Score) averaged over 20 years from mid- to later life and grey matter density (GMD) in members of the Whitehall II cohort ($N = 405$). Images were analysed using FSL-VBM, an optimized voxel-based morphometry (VBM) protocol (for more details, see [140]). Using randomized and correcting for multiple comparisons, a voxel-wise general linear model (GLM) was applied between average Framingham Stroke Risk Scores and GMDs, correcting for age and sex. Significance threshold was set at $P < 0.05$, using the threshold-free cluster enhancement (TFCE) method. Significant negative association is present in the right cerebral cortex: in the medial temporal lobe, temporal pole, planum polare (a), and post-central gyrus (b). A = anterior; R = right.

be more vulnerable to developing PTSD [79]. In older adults, a continuous rise in resting glucocorticoid levels with age seems to be associated with loss of hippocampal volume and memory decline [40]. Changes in white matter microstructure are also present with elevated diurnal and reactive glucocorticoid levels in elderly males [80].

Psychosocial and severe stress

Common stressful psychosocial and environmental factors, such as socio-economic status and workplace stressors, are predictors of cardiovascular outcomes [81, 82] and mortality [83]. Although attempts to relate specific stressors to specific medical problems have been unsuccessful, stress remains an underlying theme in the development and course of virtually all physical illness [84]. Socio-economic status both in childhood and adulthood is associated with chronic stress [85] and has been linked with negative health outcomes and mortality in later life [86]. Composite measures of AL are often associated with low social status in childhood and adulthood, capturing the long-term effect of chronic stressors, which have a higher prevalence in low socio-economic strata [37]. There is some evidence for the negative association between psychosocial stress in childhood and adulthood [87, 88] and shorter telomere length, which may mediate impaired health in adulthood. Socio-economic status in childhood, however, is not unequivocally associated with telomere length [87]. Negative circumstances in both early and adult life independently predict higher AL index, and so does negative emotional response to stressful life events [89, 90]. There is some evidence that chronic perceived stress and the number of stressful life events is associated with decreased grey matter volumes in the limbic and prefrontal areas in adults without specific psychopathology [91–93]. However, studies like these are scarce and difficult to interpret. In principle, mild or moderately aversive conditions during childhood can shape an individual to be optimally adapted to similar conditions later in life [94] but can also potentiate the effects of further negative events and circumstances—albeit current evidence for this only exists in men [89].

Crises or unexpected traumatic events exerting acute, sudden, or intense stress not only overwhelm coping mechanisms, but may also be associated with psychopathology, such as PTSD [95] or major depression [96]. Extreme life stressors can affect brain structures related to allostasis, such as the hippocampus, amygdala, anterior cingulate cortex, and medial frontal gyrus [93], especially in people with depression [36] and PTSD [78]. In people with major depression or PTSD, childhood neglect or trauma can result in structural and functional brain changes [97]. However, psychopathology itself may already cause these [98, 99].

Not all stress is bad: potentials for resilience and the slowing of ageing

Mild or moderately aversive conditions during childhood can shape an individual to be optimally adapted to similar conditions later in life [94]. The benefits of mild and limited stressors that result in physiological benefits (so-called ‘eustress’ or ‘hermetic stress’) are well documented in laboratory animal studies and can be supportive of successful biological ageing [100, 101]. The relationship between the animal’s response to stress and the rate of ageing is extremely complex, and successful translation into human experiments are rare [102]. While the relationship between stressful circumstances (such as daily hassles, workplace stress) and physiological pathways

is plausible, demonstrating and measuring this aspect of biological ageing, independent of disease pathology, is challenged by laboratory and ethical limitations [103]. Healthy eating, including caloric restriction, physical exercise, and gene expression in response to certain stressors, are recommended targets of future biological ageing studies [103]. The advent of longitudinal cohort studies and non-invasive multimodal imaging techniques presents a window of opportunity to bridge the gap between basic and clinical scientific enquiries.

There is some evidence that cumulative adverse circumstances across the lifespan predict physiological dysregulation, measured by the AL index [89]. There is also evidence that this relationship is mediated by the negative emotional response to stressful events [90]. Stress mindset, the extent to which an individual thinks a stressor is debilitating or enhancing is said to be instrumental in the manifestation of the stress response and the acceleration of biological ageing [104]. A key feature of dysfunctional stress adaptation is loss of resilience, which manifests in the form of anxiety and depression. (Mal-)adaptive stress-related brain plasticity, such as dendritic remodelling or shrinkage of dentate gyrus-CA3 pyramidal neurons in the hippocampus or medial prefrontal cortex, dendritic growth in the amygdala, neuronal replacement, and synapse turnover, if reversible, that is, prior to permanent excitotoxic damage [105], can underpin treatment or slowing of age-related changes [106].

Ageing and the brain

Structural changes with ageing

That brains change with age has been observed for a long time in the general population. Until recently, this may even have contributed to the clinical neglect of brain imaging in the assessment of pathological changes in higher age groups [107]. Brain size changes with age, declining by 1% every 5 years from the ages of 20 to 80 [108]. Correspondingly, certain domains of cognition, such as memory, reasoning, phonemic and semantic fluency, but not vocabulary, deteriorate from age of 45 at different speeds [109] (see also [110]). Distinct aspects of frontal lobe structure mediate age-related differences in fluid intelligence and multitasking [111]. Structural and functional differences in the medial prefrontal cortex underlie the known distractibility and suppression deficits in ageing [112], known to everybody who has played ‘Taboo’ with older and younger relatives. This family game requires one player to describe a concept to all other co-players, without using certain given keywords that are commonly linked to the concept, that is, the player has to suppress the ‘obvious’ responses (the ‘performance cut-off’ appears to be in the 30s [113]). Objective markers of ageing, such as leucocyte telomere length, have been found to be associated with total and regional brain volumes, in particular the hippocampus, amygdala, and inferior temporal region, in a large population-based cohort [114]. Not only the grey matter, but also the white matter, deteriorates with age [115]. Widespread age-related differences in brain microstructure are demonstrated by quantitative MRI, with an anterior–posterior gradient, for example, more changes in the genu than in the splenium corporis callosi [116]. The aetiology of these changes is not entirely clear, but an important contribution must be from vascular ageing that is also thought to contribute significantly to the development of dementia in Alzheimer’s disease [117, 118].

Fig. 18.3 (see Colour Plate section) Associations of *large vessel elasticity* (from pulse wave velocity data supplied by Eric Brunner, University College London) with mean diffusivity in white matter (a, b, c: negative association) and grey matter density (d: positive association) ($N = 444$). Model: sex, education, mean arterial pressure, alcohol, antihypertensive medication, chronic illness, ethnicity, social class, and FRS (for image acquisition and analysis, see [140]).

Increases in 24-hour systolic blood pressure are associated with arteriolar fragility of the cerebral white matter in people aged over 65. The clinical relevance of such abnormalities in asymptomatic and moderate cardiovascular risk populations is unclear [119].

Figs. 18.2 and 18.3 demonstrate the associations of vascular risk (Framingham stroke risk score) and large vessel elasticity with grey matter density ($N = 405$). Alternative mechanisms underlying age-related white matter changes include excitotoxicity and mitochondrial dysfunction [120]. Also, less decrease over 6 years in C-reactive protein, that is, persistent inflammatory reaction, was significantly associated in octogenarians with poorer white matter integrity in the dorsal and temporal superior longitudinal and uncinate fasciculi ($N = 276$ [121]). **Figs. 18.4 and 18.5** summarize the negative associations of grey matter intensity and white matter integrity (fractional isotropy) with age.

Brain reserve in ageing

Atrophic or regressive brain changes are, however, only half the story [122]—the brain retains plasticity and is able to adapt to

damage by reorganization and recruitment of alternative circuits for impaired tasks [123, 124]. A number of mechanisms have been described. Functional activity tends to shift anteriorly with advancing age ('posterior to anterior shift' [125]). This may explain the devastating effect of additionally impaired executive function on patients with primary temporo-parietal lesions in Alzheimer's disease. Particularly within frontal lobes, activation that is lateralized in younger people (as, for example, for verbal and spatial working memory) tends to be distributed more symmetrically with advancing age [126]. This Hemispheric Asymmetry Reduction in Old Adults (HAROLD) model [127] has support in the domains of episodic, semantic, and working memory, perception, and inhibitory control. The large resting brain network that is active when no task is engaged (default mode network) and suppressed during tasks tends to be disrupted with age, in that the link between anterior and posterior sections is weakened [128, 129]. Such changes are associated with poor white matter integrity and cognitive function. While such anterior and posterior uncoupling already occurs in the absence of amyloid [129], it is emphasized in those with amyloid deposits in,

Fig. 18.4 (see Colour Plate section) Widespread negative association of grey matter density (GMD) with age in members of the Whitehall II cohort ($N = 405$). Images were analysed using FSL-VBM, an optimized voxel-based morphometry (VBM) protocol. Using randomized and correcting for multiple comparisons, a voxel-wise general linear model (GLM) was applied between age and GMD, correcting for sex and socio-economic status defined by employment grade. Significance threshold was set at $P < 0.05$, using the threshold-free cluster enhancement (TFCE) method [140]. A = anterior; R = right.

Image courtesy of Dr Enikő Zsoldos.

for example, the posterior cingulate gyrus, whether dementing or not [130, 131] (Fig. 18.6).

Cognitive impairment associated with such changes is therefore likely to be due to disruption of brain reserve, rather than damage to networks primarily involved in certain tasks. Apart from functional connectivity documented by PET or resting fMRI, white matter integrity, as recorded by T_2 -weighted MRI and DTI, is likely to contribute to brain functional reserve [132].

While correlational studies are relatively easy to come by and may reflect a relatively static or pre-existing brain reserve, the mechanisms of brain plasticity supporting cognitive function are more difficult to identify. Valkanova *et al.* [124] cite 36 studies employing a variety of training modalities such as juggling, working memory training, meditation, learning abstract information, and aerobic

exercise. There were training-related structural changes, increases or decreases in grey matter volume, a combination of increases and decreases in different brain regions, or no change at all. There was increased white matter integrity (fractional anisotropy) following training, but other patterns of results were also reported. Apart from study-dependent variations in outcome, a number of questions arise in the interpretation of such results. Are changes in the grey or white matter structure simply due to use, or are they associated with learning as such? What are the underlying neural correlates of learning, the temporal dynamics of changes, the relations between structure and function, and the upper limits of improvement? How can gains be maintained [124]? If and how exactly use and training of brain-related skills can contribute to counteract the effect of ageing therefore still awaits clarification.

Fig. 18.5 (see Colour Plate section) Widespread negative association of white matter integrity [fractional anisotropy (FA)] with age (in blue overlaid on green white matter skeleton) in members of the Whitehall II cohort ($N = 395$). Images were analysed using FSL-TBSS, an optimized tract-based spatial statistics (TBSS) protocol. Using randomized and correcting for multiple comparisons, a voxel-wise general linear model (GLM) was applied between age and FA, correcting for sex and socio-economic status defined by employment grade. Significance threshold was set at $P < 0.05$, using the threshold-free cluster enhancement (TFCE) method [140]. A = anterior; R = right.

Treatment implications

It is tempting to assume that it might be possible to prevent age-related changes in brain structure and function and cognitive decline by targeting the mechanisms of brain ageing. Indeed, an effect on ageing per se might have knock-on benefits for the host of diseases associated with the ageing process. There are several strategies that are under investigation. Some are aimed at slowing brain ageing with physical exercise, which has been shown in animal models to have beneficial effects on neurogenesis and cerebrovascular health [133]. Cognitive exercise is another preventive strategy that is thought to increase resilience to age-related brain changes [134]. Several pharmacological studies are also under way that target some of the molecular pathways of ageing, such as the TOR or IGF-1 pathways, using repurposed drugs that have already been approved for treatment of other diseases, for example the diabetes drugs metformin and pioglitazone [135,136]. In mouse models, it has been shown that blood transfusions from young mice might lead to rejuvenation of older mouse brains [137], and translation into humans is being tested. However, there is currently not enough evidence to show that any of these strategies can prevent or slow down brain ageing in humans.

Conclusions

With the advent of sophisticated *in vivo* imaging methods, brain ageing can now be investigated. Naturally, the first available studies are cross-sectional, while large longitudinal studies will be a lifetime

in coming. Hypotheses regarding molecular, cellular, and system-level ageing allow for us to start interrogating the available data in a specific fashion. Such multiple testing will always suffer from ‘residual confounding’—all samples collected for imaging will be selected in some fashion (willingness to participate, able to enter an MRI scanner), even if they are picked at random from the general population (which most are not). The large number of possible factors contributing to ageing, as well as secular changes in the nature and pattern of causation, will keep researchers busy for decades to come [138].

Development of brain stimulation

Andrea Crowell, Patricio Riva-Posse, and Helen S. Mayberg

History and rationale

The emergence of deep brain stimulation (DBS) as an intervention for treatment-resistant psychiatric disorders is the result of an evolution of understanding of brain function and disease mechanisms across a variety of disciplines within neuroscience and medicine. Refinement of brain imaging strategies has increasingly linked specific symptoms or behaviours with discrete brain regions. Highly sophisticated neuroscience techniques, such as optogenetics, have allowed for an increased understanding of neurocircuitry in awake and behaving animals and the development of more sophisticated translational animal models linking brain and behaviour to human disease. Refinement of neurosurgical techniques led to its expansion into neuropsychiatric disorders, most notably movement disorders. The success of lesioning techniques in Parkinson's disease gave rise to the use of high-frequency DBS at the same target sites, with the initial conception of DBS as a reversible lesion ([Fig. 19.1](#)). As these various disciplines evolved in parallel, there is no single rationale for using DBS to treat psychiatric disorders. (See [Table 19.1](#) and [Fig. 19.2](#) [1] for a summary of targets.) For example, use of DBS in the region of the internal capsule for obsessive-compulsive disorder (OCD) and depression largely grew out of the history of performing anterior capsulotomy and other surgical lesions for severe, treatment-resistant cases. Targeting the subcallosal cingulate cortex (SCC) with DBS was the direct extension of neuroimaging findings demonstrating SCC hyperactivity in depression and subsequent normalization of activity following successful treatment, irrespective of treatment modality. Consideration of the nucleus accumbens (NAC) and medial forebrain bundle (MFB) as DBS targets relied heavily on the work in animal models to understand limbic circuitry and reward, implicating the NAC and associated monoaminergic inputs in drive, motivation, and positive reinforcement, all of which are important aspects of nearly any psychiatric syndrome.

Regardless of the target or rationale, all of the data reviewed here represent experimental attempts to treat a subset of patients for whom standard treatments have failed (OCD, depression, eating disorders, addiction) or who suffer from an illness for which there is no treatment that significantly modifies the disease trajectory [Alzheimer's disease (AD)]. Treatment resistance is defined differently for each disorder, although typically it includes non-response

or loss of response to multiple medication categories and a validated psychotherapy trial. DBS for OCD does have the CE Mark approval for use in Europe. In the United States, DBS is not US Food and Drug Administration (FDA)-approved for any psychiatric disorder, although the FDA did grant a humanitarian device exemption (HDE) for use in OCD. (For comparison, DBS is FDA-approved for Parkinson's disease and essential tremor, and there is an HDE for dystonia.) The current state of DBS for psychiatric disorders is therefore still very early and largely experimental, driven by the absence of any effective treatment in this subset of patients with severe and treatment-refractory illness. With continued research on brain circuit abnormalities in other conditions, the breadth of potential applications of targeted neuromodulation is likely to increase.

Disorders and targets

Obsessive-compulsive disorder

OCD affects approximately 2% of the population. It is a chronic psychiatric disorder, with an estimated 10–20% of affected individuals considered treatment-resistant. Standard treatment includes SSRIs, the tricyclic drug clomipramine, and cognitive behavioural therapy (CBT). Symptoms typically fall into themes such as obsessions, checking, contamination, symmetry, harming, and hoarding. Most patients diagnosed with OCD will also meet criteria for another psychiatric disorder at some point, with major depressive disorder being the most frequent.

The cortico-striato-thalamo-cortical (CSTC) loop has been widely implicated in the pathology of OCD ([Fig. 19.3](#)) [2]. This loop includes the lateral orbitofrontal cortex (OFC) projecting, via fibres of the anterior limb of the internal capsule (ALIC), to the head of the caudate, in turn projecting to the globus pallidus and on to the thalamus, which, in turn, projects back to the OFC via fibres of the inferior thalamic peduncle (ITP). In imaging studies of OCD, hyperactivity in the OFC and caudate has been commonly demonstrated and decreases with medication or psychotherapy. Previously, anterior capsulotomy and gamma knife capsulotomy have been used to interrupt fibres reciprocally connecting the mediodorsal thalamus and prefrontal cortex. DBS for treatment of OCD developed from this understanding of the neural circuitry underlying disease pathology, as well as from evidence of effectiveness of other

Fig. 19.1 Radiographs showing DBS leads implanted in the brain (left), with subcutaneous lead extensions connecting the brain leads to the internal pulse generator implanted subcutaneously in the chest wall (right). Image courtesy of Dr. Helen Mayberg.

neurosurgical procedures that have improved OCD symptoms either intentionally or serendipitously.

Anterior limb of the internal capsule, ventral striatum/ventral capsule

The most frequent DBS target for OCD is the ventral portion of the internal capsule, extending into the ventral striatum. The anatomical target of the first DBS for OCD was the ALIC, following the literature on anterior capsulotomy lesions. Initial data came from 15

patients across four studies and case reports [3]; 45% of 11 patients for whom data were tracked showed at least 35% improvement from their baseline Yale-Brown Obsessive Compulsive Scale (Y-BOCS) score, the threshold most commonly used to define treatment response. Collaboration among four work groups at this target demonstrated the effect of a learning curve, such that over time, the target shifted posteriorly to include the ventral internal capsule, caudate nucleus, and NAC [ventral capsule/ventral striatum (VC/VS)]. Results from 34 patients receiving high-frequency stimulation for 36 months showed a 62% response rate. Imaging and animal studies suggest that this more posterior position may more effectively stimulate fibres of the CSTC circuit. In the most recently published cohort of patients, 4 of 6 were responders at 1 year [4]. Full effects of stimulation typically take about 3 months to evolve and plateau. Reports from long-term observational cohorts describe a sustained benefit from VC/VS DBS in OCD.

Stimulation-related side effects are common, at least transiently during stimulation parameter testing. Hypomania affects 35–65% of patients, resolves with changes in parameters, and usually is not severe. Transient sensory effects have also commonly been reported. Other reported effects include: euphoria, giddiness, anxiety, panic attacks, sadness, and stimulation-induced contralateral smile.

DBS at VC/VS appears to be differentially effective on specific symptom subtypes. DBS was 100% effective ($n = 5$) for predominant obsessions and checking, 56% effective ($n = 5/9$) for symmetry and ordering symptoms, and 45% effective ($n = 5/11$) for cleanliness and washing symptoms.

Nucleus accumbens

The rationale for targeting the NAC directly, rather than as part of the VC/VS approach, stems from evidence of reward system dysfunction in OCD, as well as its role as a relay structure between limbic and cortical areas [5]. Hyperactivity of the NAC specifically, or more generally of limbic activity relative to cortical activity, may lead to fixed thought/action patterns overcoming more flexible and

Table 19.1 Psychiatric disorders and DBS targets

Depression	Subcallosal cingulate
	Nucleus accumbens
	Ventral capsule/ventral striatum
	Medial forebrain bundle
	Inferior thalamic peduncle
	Lateral habenula
Obsessive-compulsive disorder	Ventral capsule/ventral striatum
	Nucleus accumbens

appropriate behaviour patterns. Disruption of this aberrant activity with NAC DBS could thus restore behavioural flexibility [5, 6].

Fourteen patients have received right unilateral NAC stimulation; 19 patients have received bilateral NAC DBS. A positive effect of right unilateral NAC stimulation in three of the first four patients reported led investigators to undertake a larger and more rigorous trial, though only one patient in ten met the response criteria of 35% Y-BOCS improvement after 1 year of stimulation. Five additional subjects demonstrated at least 25% improvement [7]. Three case reports of bilateral NAC DBS describe 38–52% improvement after 15–24 months of stimulation. In the largest study of NAC DBS for OCD, 9 of 16 patients (56%) were treatment responders after 8 months of stimulation [8]. Further improvement was seen when CBT was subsequently added, despite the fact that patients had failed CBT prior to DBS [9]. Importantly, four patients with ego-syntonic symptoms of perfectionism, a need for symmetry, reassurance-seeking, and hoarding averaged only a 10% improvement on Y-BOCS, providing additional information about the differential effects of this treatment on different clinical subtypes of OCD.

Similar to VC/VS stimulation, hypomania is the most commonly reported side effect. Transient olfactory phenomena and increased libido were also reported. In the right unilateral cohort, three patients experienced transient agitation due to stimulation. Notably across studies, discontinuation of stimulation was associated with a rapid and poorly tolerated return of negative mood beyond baseline depression ratings, disproportionate to the return of OCD

symptoms. This reversed rapidly with resumption of stimulation. The necessity of dose adjustments or evidence of long-term stability of response are not yet reported.

Medial forebrain bundle

The MFB is a white matter tract that connects the ventral tegmental area and NAC. Based on the rapid antidepressant effects observed with MFB DBS for depression (see next section), two patients with OCD underwent MFB DBS surgery [10]. Both were reported to have acute improvement in affect and compulsions. While one patient met and maintained >35% improvement in Y-BOCS from the first month through the first year of stimulation, the other did not meet response criteria until month 12 of stimulation. In both cases, transient increased heart rate and oculomotor effects typical of stimulation at this target were observed, but hypomania was not.

Subthalamic nucleus

DBS of the subthalamic nucleus (STN) is an accepted treatment for Parkinson's disease. In a 2002 report on two patients with Parkinson's disease and comorbid OCD who were treated with STN DBS, Parkinson's symptoms improved, as did obsessions and compulsions, with Y-BOCS reductions of 58–64% 2 weeks after surgery and remaining improved over 1 year later. A third, independent case report described similar outcomes.

In a randomized, double-blind trial of STN DBS for patients with severe OCD *without* Parkinson's disease, 12 of 16 patients

randomized to treatment (75%) experienced improvement of at least 25% after 3 months of active stimulation. Three of eight patients in the sham stimulation group responded similarly [11]. Transient mania or hypomania was reported in 6 of 16 (38%). Other side effects were anxiety, dyskinesias/motor effects, and depressed mood and suicidal ideation, which occurred in one patient. Although most adverse events were transient, serious adverse events occurred in 65% of implanted patients. No long-term efficacy data are available. That OCD symptoms improved rapidly in Parkinson's disease, unlike the slower course in OCD patients, across DBS targets likely reflects the pathophysiology of the syndrome in each illness.

Inferior thalamic peduncle

The ITP was conceived of as a DBS target for OCD because of its location in the CSTC loop, connecting the thalamus to the OFC. A positive experience with ITP DBS in a single patient with MDD who experienced good antidepressant effect for years following DBS surgery, and the fact that many pharmacological and surgical treatments for MDD also treat OCD, also influenced a proof-of-concept study of ITP DBS. Unlike other DBS targets for OCD, the ITP has the advantage of being well defined anatomically and readily identifiable neurosurgically, based on electrophysiological properties. Six patients (100%) with severe, treatment-resistant OCD responded to ITP stimulation, with a 50% average decrease in Y-BOCS scores over 1 year [12]. Improvement

was largely stable after 3 months of stimulation. Three patients were still enrolled in the study 3 years after implantation, all having maintained responder status. No side effects were reported for stimulation on the target contact. However, stimulation above the target, near the fornix, induced confusion in one patient, which resolved when stimulation at that contact was stopped. Additionally, stimulation below the target, at or near the hypothalamus, routinely induced anxiety and dysautonomia. Hypomania was not observed at this target.

Across targets, there is clear evidence that high-frequency stimulation of the orbitofrontal basal ganglia loop system can improve some symptoms of OCD. There has yet to be a systematic study comparing responders to non-responders at a given target or a comparison of the different targets, although OCD symptom subtype appears to be important. PET studies of implanted patients showing increased perfusion in the OFC, subgenual anterior cingulate, striatum, pallidum, and thalamus [13] support CSTC modulation generally as underlying the DBS effect; however, there is not yet a clear understanding of which pathways within the CSTC network mediate either clinical efficacy or side effects.

Major depressive disorder

MDD is a chronic illness with an episodic course. International surveys have estimated the lifetime prevalence of MDD to be 8–12% typically, although this varies by country, with the lifetime

prevalence as high as 17% in the United States. An estimated 27% of individuals will have three or more episodes, while approximately 20% will experience a chronic, unremitting course. An estimated one-third of patients demonstrate some degree of treatment resistance. Definitions of treatment-resistant depression (TRD) include failure to respond to antidepressant medications of adequate dose and duration from multiple pharmacologic classes and/or ECT. The risk of a suicide attempt in patients with MDD is estimated to be 15%, with a 2–12% risk of suicide completion, a risk that increases 7-fold with lack of remission or recurrence of a major depressive episode [14], highlighting the mortality risk in TRD particularly.

The CSTC loop system has also been implicated in the underlying pathology of depression, but involving different cortical components than in OCD. Volumetric and functional abnormalities have been observed in the SCC and ventromedial and dorsolateral prefrontal cortices (DLPFC), as well as the amygdala, hippocampus, and habenula [15]. Studies in non-human primates show white matter connections from medial prefrontal regions to visceromotor output regions, such as the hypothalamus and periaqueductal grey, to limbic areas, including the amygdala and NAC, and to midline thalamic structures. Functional imaging studies have shown overactivity in the SCC and amygdala, and underactivity in the DLPFC, NAC, and ventral striatum—abnormalities reversed with antidepressant treatment. DBS for depression has been guided by these neuroimaging findings, as well as by an understanding of CSTC and reward system anatomy and function from anatomic and animal behaviour studies and from earlier experience with neurosurgical interventions for depression and OCD.

Subcallosal cingulate cortex

The first brain target for DBS for depression, and the one with the most evidence to date, is the SCC. The rationale for targeting the SCC neurosurgically was functional neuroimaging evidence of pathological hyperactivity of this area in depressed subjects and subsequent normalization of activity with antidepressant treatment. With prevailing theories of the mechanism of DBS being a functional inhibition of the target region, it was hypothesized that inhibition of a hyperactive SCC would enable release from a pathologically negative mood state. Further, connections between the SCC and the insula, hypothalamus, and brainstem would enable changes in neurovegetative symptoms, while connections between the SCC and the medial prefrontal, orbitofrontal, cingulate, and subcortical structures would allow for changes in cognitive, hedonic, and motivational symptoms of depression.

A total of 77 depressed patients (70 MDD, 7 bipolar type 2) from eight clinical sites have been reported to date, most in the context of open-label stimulation experiments, with follow-up of at least 6 months and most for 1 year [16–22]. Clinical response across all studies has been defined as a 50% decrease in the Hamilton Depression Rating Scale (HDRS-17), with a score of <8 defining clinical remission. Combined results of all open-label studies demonstrate a response rate of 53% at 6 months, 47% at 12 months, 69% at 24 months, and 60% at 36 months. Remission rates are 27% at 6 months, 30% at 12 months, 39% at 24 months, and 40% at 36 months. Thus, response/remission is maintained over time and appears to continue to improve over years.

Retrospective analyses of response outcomes, compared to final target placement within the SCC grey matter, were unable to

attribute better outcomes to a more specific location within the SCC [23]. More recently, visualization and targeting of specific white matter tracts passing through, and adjacent to, the SCC have been associated with SCC DBS treatment response [24].

Across research groups, it has repeatedly been observed that even sustained antidepressant effects are lost in response to device failure or naturalistic depletion of the battery, evidence that ongoing stimulation is required, even years after implantation. There has been one attempt to study this as a double-blind trial in five SCC DBS patients who were in stable remission over ≥ 3 months [25]. They were randomized to 3-month blocks of active or sham stimulation in a crossover design. During active stimulation, four patients remained in remission, while one patient lost remission but maintained antidepressant response. During sham stimulation (discontinuation), 2 of 5 patients maintained remission, one patient lost remission but maintained response, and two patients relapsed into a major depressive episode. One subject withdrew from the study during the sham phase due to relapse severity. These results support observations that discontinuation of SCC stimulation typically results in a gradual return of depression symptoms over a period of weeks; a pattern distinct from the rapid change in negative mood described with discontinuation of stimulation at other targets.

Stimulation-related side effects are uncommon, and no mania or hypomania has been reported. On the other hand, there are reports of acute effects of intraoperative stimulation, including an increased sense of calm, increased interest, and ‘lightness’. Recent studies suggest that these effects are actually predictable with careful intraoperative testing, and their presence identifies the site for long-term stimulation. Refined analyses of the link between white matter tract location, stimulation-induced acute effects, and long-term efficacy are now emerging [24, 26]. Of the 77 patients described in these reports, there were six suicide attempts (8%) and three completed suicides (4%).

Ventral capsule/ventral striatum

Stimulation of the VC/VS for treatment of depression extended from earlier studies of VC/VS DBS for OCD and from observations that depressive symptoms decreased in these patients. This region of the internal capsule contains fibre tracts connecting the SCC to the thalamus, and the ventral striatum is linked to motivation and reward. Thus, this target is positioned to affect the neurocircuitry underlying some of the key symptoms of depression.

The initial open-label series described outcomes in 15 depressed patients (14 MDD, 1 bipolar type 1) from three clinical sites [27]. Response rates (decrease in HDRS-24 $>50\%$) were 50% at 3 months and 47% at 6 months; remission rates (HDRS-24 <10) were 20% at 3 and 6 months. Response and remission at the last follow-up (mean 23.5 months) were 53% and 33%, respectively. In five subjects with at least 36 months of follow-up, three had responded and two had remitted, suggesting that, as with the SCC target, response is maintained over time. Subsequently, a double-blind, sham-controlled study randomized 30 patients to either active ($n = 16$) or sham ($n = 14$) stimulation for 16 weeks, followed by an open-label stimulation continuation phase [28]. After the 16-week blinded treatment phase, three subjects in the active stimulation group vs two subjects from the sham stimulation group met response criteria, failing to demonstrate efficacy of VC/VS stimulation. After 8 months of open-label stimulation, 20% of subjects met response criteria and 13% were in remission. This

increased to 23.3% response and 20% remission at 24 months. No subject who met responder criteria maintained response for the duration of the follow-up period. In an effort to address study design weaknesses brought to light by the double-blind trial, another group performed a double-blind crossover trial following an open-label optimization phase [29]. Twenty-five subjects at two sites underwent VC/VS DBS. Sixteen subjects participated in a blinded crossover phase. The open-label response rate was 40% (similar to the initial open-label reports), and there was a significant difference in depression rating scores between the active and sham arms of the crossover phase, strengthening the evidence that the antidepressant effect was, in fact, due to stimulation. However, the optimization period was prolonged (52 weeks) and the crossover phase was foreshortened, because 75% of subjects had to be prematurely crossed over due to increased depressive symptoms, often within 1 day of stimulation discontinuation, highlighting the relatively rapid return of depressive symptoms with discontinuation of stimulation at this target.

Intraoperative stimulation in some cases produced improved mood, decreased anxiety, and increased awareness, but also increased anxiety, sweating, speech perseveration, and facial motor effects. Outside of the operating room, two episodes of hypomania were reported in a patient with bipolar disorder, while one unipolar depression patient experienced mania, which resolved with a change in medication and stimulation parameters. During the blinded phase of the later study, irritability, suicidal ideation, hypomania, and mania were described in 1–3 active stimulation subjects but were not observed in any of the sham stimulation subjects. In the 70 subjects described in the VC/VS reports, there were nine suicide attempts (13%) and one completed suicide (1%).

Nucleus accumbens

The NAC's central role in mediating motivation in reward is key to its appeal as a DBS target for both OCD and depression. If anhedonia is a defining symptom of depression, modulating hedonic centres makes theoretical sense. The NAC is known to be involved in reward processing and reward-seeking behaviours, as well as in drive and motivation. Dysfunctional reward processing has been described in patients with depression, as has abnormal activity of the ventral striatum. Further, the NAC connects with motor, memory, and emotion processing centres, which provides a mechanism by which NAC stimulation may produce antidepressant effects beyond the modulation of anhedonia.

A single study of 11 patients reported a 46% response rate and 30% remission rate at 1 year, with response maintained for up to 4 years [30]. Although patients reported being unable to detect when the stimulation was turned on, initial stimulation induced prompt positive behavioural changes and decreased depression scores. Side effects included erythema, anxiety, sweating, paraesthesiae, hypomania, and, in one case, psychotic symptoms. All such side effects resolved with parameter changes. At times, stimulation parameter changes were associated with acute (2 weeks), but not long-term, mood improvement. Discontinuation of stimulation produced a rapid return of depressive symptoms. One suicide attempt and one completed suicide were reported.

Medial forebrain bundle

From the experience with NAC DBS and the anhedonia/reward modulation rationale, attention turned to the MFB. The superolateral

branch of the MFB (slMFB) connects the ventral tegmental area and the NAC. It crosses under the thalamus and joins the ALIC, projecting to the OFC and DLPFC. Animal and imaging studies have supported the MFB as a DBS target. In addition, hypomania that has been seen with STN stimulation for Parkinson's disease has been linked to current spread to the MFB, and electric field modelling has suggested that current spread from the SCC, VC/VS, or NAC may reach the slMFB.

In the first pilot study of seven patients given MFB DBS for TRD, six patients experienced an improvement in depressive symptoms within the first 2 days of stimulation [31]. After 1 week, four patients experienced $\geq 50\%$ improvement in depression rating scores. After 12 weeks, six patients met this response criteria, four of whom additionally met criteria for remission. In most patients, response was maintained once achieved. The longest follow-up reported for these patients to date is 33 weeks. All patients had acute intraoperative effects suggestive of improved mood and engagement. At higher stimulation amplitudes, all patients experienced blurred vision and strabismus, which limited stimulation parameters. No hypomania was reported in this sample. Notably, the only non-responder in this cohort had suffered an intraoperative haemorrhage, essentially lesioning the slMFB bundle.

An early report on replicability of these findings demonstrated that 3 of 4 subjects implanted with MFB DBS showed acute intraoperative effects, as well as a 50% reduction in depression scores at 1 week [32]. At 6 months, two subjects continued to be responders. Acute intraoperative effects and visual adverse events were as described in the initial study. Long-term follow-up and randomized controlled studies are not yet reported.

Other targets

In addition to these targets for DBS for depression, two additional regions have been targeted, each with a single case report. As described in the OCD section, one patient was successfully treated with DBS targeting the ITP. The other area targeted is the lateral habenula (LHb). The habenula is a small, midline glutamatergic structure that is well positioned to influence the brain regions implicated in depression symptoms and the neurotransmitter systems modulated by current pharmacotherapies. Convergent lines of evidence support a role for the LHb in negative reward prediction signalling, a possible role in risk-avoidant behaviours, and link LHb hyperactivity with depressed mood states [33]. The single patient implanted at this target had a complicated, but ultimately successful, treatment course.

Across targets, open-label stimulation has been shown to improve symptoms in severe and refractory depression. Failure of large-scale, double-blind trials to replicate these effects warrants consideration of alternate clinical trial designs to better account for the nature and time course of DBS treatment effect. There is clear evidence of target-specific differences in the time course of treatment and discontinuation effects. Suicide is always a concern in the treatment of TRD, but this risk is not exacerbated by DBS.

Eating disorders

Anorexia nervosa

Anorexia nervosa (AN) consists of persistent food restriction, an intense fear of gaining weight or behaviour that interferes with weight gain, and a disturbance in self-perceived weight or shape. Lifetime

prevalence for women is estimated to be 1–4%, with a ten times greater prevalence in women than in men. It has the highest fatality rate of any psychiatric disorder, with 5.1 deaths per 1000 person-years. One in five AN deaths is from suicide [34]. It also has a high rate of comorbidity with mood and anxiety disorders—68% for MDD and 26% for OCD according to one estimate.

The first reports of DBS for AN were in patients treated for MDD or OCD. One woman treated with SCC DBS for MDD, who had comorbid AN, maintained a relatively stable body mass index (BMI) after DBS surgery, even despite depressive relapses. An increase in disordered eating was successfully treated behaviourally, and no further interventions related to weight in the 3 years of follow-up were needed. A woman with AN who received ALIC DBS for OCD reported feeling differently about food after DBS. She ate more and was less distressed about weight, caloric intake, and sweets. Her BMI after surgery and through 3 years of follow-up was in a healthy range. The authors did not report on OCD symptom improvement.

In the first case series of DBS specifically to treat AN, the SCC DBS target was chosen, based on imaging studies showing similarities in SCC activity in AN and MDD. In addition, treating mood and anxiety comorbidities in patients with AN improves outcomes over treating weight alone. Six adult women with 3–37 years of AN were treated with SCC DBS [35]. All women completed a behavioural treatment programme preoperatively to improve their weight and to be healthy enough for surgery. After 9 months of stimulation, three of six women had maintained their weight at or above their preoperative baseline. In the other half, weight had decreased to near their historical baseline. The three patients who had maintained healthier weights all had comorbid MDD, and all experienced significant improvement in MDD symptoms. These three women also had comorbid OCD, and two were OCD responders as well. Of the four total women who had a depression rating scores in the severe range, all were MDD responders. Five of the six women met criteria for OCD at baseline, of whom three were OCD responders. After 6 months of stimulation, PET imaging demonstrated decreased SCC and medial frontal activity, decreased insula activity, and increased parietal activity, similar to findings in SCC DBS for MDD.

In two Chinese samples, NAC lesions ($n = 6$) and NAC DBS ($n = 2$) were performed in adult women with a BMI of <14.5 , and NAC DBS in an additional four women aged 16–17 with a BMI of <13.3 . In all cases, BMI improved to 18–22, and comorbid depression, anxiety, and obsessive-compulsive symptoms improved. Weight changes tended to stabilize after 6–12 months of stimulation. No serious adverse events were reported.

Obesity

While DBS for AN would seem a logical clinical extension of the use of DBS, given the rates of comorbid depression and OCD and the similarities in imaging findings between these illnesses, the rationale for the use of DBS for disorders of overeating comes primarily from animal models of appetite, homeostasis, and self-regulation. Lesions and high-frequency stimulation of the lateral hypothalamus (LHA) decrease food intake in animal models. Given rising obesity rates worldwide, including an estimated 6.6% of persons in the United States having a BMI of >40 , it is perhaps no surprise that innovative solutions are being sought to address this epidemic.

The first individual to undergo DBS implantation specifically for obesity was reported by Hamani and colleagues in 2008 [36]. In the course of their intraoperative exploration of the hypothalamic target, they serendipitously elicited remarkable memory effects. Six months of high-frequency stimulation (130 Hz) did not result in any weight change. With low-frequency stimulation (50 Hz) over 5 months, the patient lost 12 kg, without intentional changes to diet or exercise. However, after this weight loss, the patient began to turn the stimulation off in the evenings due to a desire to eat, and he regained the weight. Following this, three patients were implanted with DBS in the LHA, with outcomes reported for up to 39 months [37]. Stimulation raised the resting metabolic rate in two patients. Chronic stimulation on optimized settings for 9–11 months resulted in a modest weight loss of 12.3% and 16.4%. The third patient did not demonstrate an altered resting metabolic rate and experienced negligible weight loss over 16 months. Experientially, patients reported that the best contact settings resulted in a decreased urge to eat, which returned when stimulation was discontinued. Acute stimulation effects included nausea, feeling hot or flushed, anxiety or panic, and increased arousal or activity. Chronic stimulation did not result in any changes in nutritional, hormonal, or neuroendocrine/neuropeptide changes. Psychological testing showed no worsening of binge eating, cognitive restraint, increased hunger, or worsening of body image or quality of life. No significant adverse events were reported over an average follow-up period of 35 months.

Addiction

Substance use disorders (SUDs) have high prevalence and high relapse rates, despite several proven and effective treatments. In animal models of addiction, behavioural changes have been reported after stimulation of the NAC, LHb, medial prefrontal cortex, and STN. Anecdotally, STN DBS for Parkinson's disease has been described to alleviate impulsivity and behavioural manifestations of dopamine dysregulation syndrome (hypomania, gambling, hypersexuality, punding), as well as drug use [38]. Retrospective observations in patients receiving NAC DBS for Tourette syndrome describe decreased use of nicotine [39].

Despite highly developed animal models to explain the neurobiology of addictive behaviours and behaviour changes in response to stimulation in these animals, the results in human case series are less compelling. Patients selected for DBS, to date, include the most chronic and treatment-resistant patients, all of whom had prior treatment, including multiple admissions to rehabilitation programmes, agonist therapies (such as methadone), and negative reinforcement treatments such as disulfiram. In NAC DBS for opiate dependence in two patients, levomethadone dose and opiate cravings were reduced over a period of 1 year; however, concurrent use of other drugs continued, and one patient relapsed on heroin [40]. In five patients who received NAC DBS for alcohol dependence, all reported decreased craving; however, only two patients remained abstinent [41]. In a single-case report on NAC DBS for cocaine dependence [42], after 2.5 years of chronic stimulation, the patient markedly decreased cocaine use but was not abstinent. As expected, given NAC DBS effects in other disorders, in the cases described, decreased depressive symptoms and possible parameter-dependent hypomania were reported.

Persistent use of substances despite reduced cravings highlights the biggest challenge for trying to treat addiction with

neuromodulation of a discrete brain target. While NAC DBS may reduce cravings, SUDs involve more complex behaviours than just reward system dysfunction, with long-standing habits and psychosocial factors that make abstinence difficult and which cannot be captured in animal models.

Alzheimer's disease

AD is a progressive dementia marked by a gradual, but progressive, decline in memory and cognition, associated with accumulation of beta amyloid plaques and neurofibrillary tangles in the brain. The prevalence of dementia is roughly 24 million cases worldwide and rising, with approximately 70% of cases attributed to AD. The highest rates are in North America and Western Europe. Current treatments do not significantly alter disease progress.

The first series of six patients with mild AD to undergo DBS followed an unexpected intraoperative finding that stimulation near the fornix evoked vivid memories and improvement in verbal recall and spatial associative learning [36]. Based on this incidental finding in an individual without cognitive impairment, the same group performed DBS at the same fornix/hypothalamic target in six individuals with mild AD [43]. The fornix is a large white matter tract connecting the hippocampus and the medial temporal lobe. Lesions here disrupting the Papez circuit are known to produce memory deficits, underscoring its importance in memory function. Of the six patients implanted, only two had the intraoperative stimulation-related recall events demonstrated by the index case. The primary outcome measure was the cognitive subscale of the Alzheimer's Disease Assessment Scale (ADAS-cog). On average, the ADAS-cog score increased by 4.2 points after 1 year of stimulation, an indication of worsened cognition and disease progression. However, as the expected rate of decline may be closer to 6–7 points per year, this outcome may represent a slowing of expected disease progression. The absence of symptoms of hypothalamic dysfunction or serious adverse events prompted the undertaking of a larger double-blind, sham-controlled trial of 42 patients [44]. While there was comparable worsening of cognition after 1 year of active or sham stimulation, subanalysis revealed that AD patients aged <65 years receiving active stimulation had *worse* cognitive scores, compared with those receiving sham stimulation. Patients aged >65 years did appear to have some benefit from active vs sham stimulation.

A second group of six patients with mild to moderate AD underwent DBS targeting the nucleus basalis of Meynert [45]. It should be noted that the specific subregion being targeted—the Ch4 subdivision—was sometimes not able to be stimulated directly due to regional anatomy, thus demonstrating one of the challenges of DBS, that is maximizing benefit while minimizing side effects, a particular challenge in small brain areas where undesirable stimulation in nearby regions is unavoidable. Stimulation settings chosen by this group included low-frequency stimulation (20 Hz), in an effort to exert a potentially excitatory effect on target neurons and stimulate acetylcholine release. No acute stimulation effects were reported. After 11 months of stimulation, the patient group experienced an average increase of 3 points on ADAS-cog. This again indicates worsening of cognition but may represent slowing of expected disease progression. No serious adverse events were reported.

Summary

There are unique challenges to pursuing DBS within psychiatry. Psychiatric illnesses are complex syndromes with biological and psychological drivers, currently defined categorically, without biologically informed criteria. The complexity of human behaviour cannot be reduced to a single circuit, any more than it can be reduced to a single neurotransmitter. Our current understanding of focal neuromodulation is better suited to treat specific symptoms, rather than broad diagnostic syndromes.

Unlike in DBS for Parkinson's disease, where treatment effect on motor symptoms can be fully realized almost immediately, clinical effects of stimulation on psychiatric symptoms appear to generally take weeks to months, with benefits continuing to accumulate over months to years. This time course does seem to be target-specific, with MFB DBS producing more rapid symptom improvement, but not disease-specific or procedure-specific, with similar response trajectories reported for OCD and MDD following DBS and surgical lesions. Understanding the time course of treatment response has implications for understanding the mechanism of action of DBS, as well as for timing supportive interventions such as psychotherapy.

As reviewed here, much of the experience with DBS for psychiatric disorders to date comes from individual case studies and series. Long-term studies suggest that there is good reason to be optimistic about DBS as a treatment for severe, treatment-refractory psychiatric illness; however, traditional double-blind, sham-controlled clinical trials have been disappointing. Small sample size and suboptimal control for placebo effects are frequent criticisms of DBS trials in psychiatry. Small samples exacerbate the difficulty of designing optimal dose-finding trials, as not only are there many parameters to adjust (pulse width, current, frequency), but the target itself may also have considerable inter-individual variability, precluding the use of standard co-ordinates to guide surgical targeting. One strategy to mitigate concerns about placebo effects is the use of a blinded, staggered-onset of chronic stimulation. The advantage of this approach is the ability to evaluate for a response to sham stimulation without losing statistical power by withholding the intervention entirely from a portion of the subjects. Blinded discontinuation designs similarly preserve statistical power. The other advantage of a blinded discontinuation design is that it allows for optimization of stimulation parameters to occur at the beginning of stimulation. Discontinuing stimulation only after a period of stability has been achieved strengthens the argument that a decline in response is due to the loss of stimulation. The drawbacks to this approach, however, include difficulty in disambiguating whether symptom emergence is truly a return of the illness state vs a stimulation withdrawal syndrome, and also the inability of many subjects to tolerate abrupt discontinuation in some, but not all, of the proposed targets. Reports from multiple targets, most notably the NAC and VC/VS, describe dramatic worsening of symptoms in a short time after discontinuation, including accidental discontinuation. Such symptoms can include suicidal ideation. These challenges highlight the need for thoughtful trial design that takes into account the circumstances particular to DBS as a procedure, as well as the typical patterns of response to stimulation and discontinuation at specific targets. DBS remains a promising intervention for treatment-resistant psychiatric disorders, not only due to its clinical application potential, but

also because the discrete modulation of neural circuits sheds light on the underlying neurobiology of these complex illnesses.

Adherence to treatment in psychiatry

Amy Chan and Rob Horne

Adherence: a missing link in psychiatric care?

The scale of non-adherence

Adherence to treatment is crucial for achieving optimal outcomes [1–3]. Non-adherence to medicines prescribed for mental health conditions is thought to be a common reason for poor treatment outcomes. Reviews of the prevalence of non-adherence in mental health disorders estimate that 25–60% of medicines prescribed for these conditions are not taken as advised [4–6]. Non-adherence is not, of course, unique to psychiatry. It is ubiquitous in medicine, with the WHO estimating that about half of all medicines prescribed for long-term conditions are not taken as prescribed [6]. The consequences of non-adherence are great, both for the individual, society, and the health system [7]. In psychotic disorders, such as schizophrenia, poor adherence is associated with a 3.7 times higher risk of relapse, compared to those who are adherent [8], a greater risk of hospitalization and suicide [7], and an almost three times increase in external service costs [9]. In mood disorders such as depression or bipolar disorder, the statistics are similar. Patients who discontinue their medication early have a higher risk of relapse, hospitalization, and suicide [10]—in a 1-year period, those who were non-adherent to mood stabilizers had an almost four times higher risk of hospitalization than those who were adherent [11], with associated costs being four times or more in non-adherent vs adherent individuals [12, 13].

These figures are, however, reported from published clinical studies, and we should be cautious how we interpret or extrapolate these results, as non-adherence rates and associated consequences vary widely between individuals, across different mental health conditions, and according to how adherence is defined and measured. Nevertheless, non-adherence is an issue which needs to be addressed by those providing, receiving, or funding health care. It not only entails a waste of resources, but also a missed opportunity for health gain [3]. It is the missing link between effective treatment and outcomes in psychiatric care [1, 2]. In a world where resources are limited, it is imperative that we address non-adherence if we are to bridge the gap between treatment efficacy and clinical outcome [3, 6].

Yet despite the vast amount of adherence research published in the last few decades, non-adherence remains a key challenge in

clinical practice. Adherence and non-adherence have been defined in various ways, with multiple terms used to describe a similar concept [14], ranging from the traditional paternalistic view of ‘compliance’ with orders from health care providers to ‘adherence’ with an agreed plan between the patient and the health care team [6]. Currently, adherence is defined by the WHO as ‘the extent to which a person’s behaviour (such as taking medication) corresponds with the agreed recommendations from a healthcare provider’. More recently, this overarching concept has been refined by considering three stages of adherence: initiation, implementation, and persistence [14]. Non-adherence can occur at each of these stages. The patient may not initiate treatment (termed primary non-adherence), or they may fail to take the prescribed regimen correctly—where the medication is not taken at the right time, dose, or frequency, or the treatment may be discontinued prematurely (non-persistence). Non-adherence may be used as an umbrella term for each of these specific behaviours [15]. Recent research in schizophrenia seems to suggest that not only is adherence important per se, but the *pattern* of non-adherence may also be significant—different patterns of medication-taking have been associated with different outcomes [2, 16].

Achieving true adherence, where the patient and the provider agree to a particular treatment plan, is challenging in psychiatry, as there are unique mitigating factors such as mental health legislation, stigma, discrimination, social isolation, lack of insight, comorbid substance abuse, and cognitive impairment to consider [7, 17].

Challenges in psychiatry

Although non-adherence is common to all health conditions where long-term adherence is key to outcomes, there are unique challenges in psychiatry. Firstly, patients commonly do not perceive themselves to be ill. The WHO International Pilot Study on Schizophrenia found that lack of insight occurred in 98% of patients and was the most common symptom of schizophrenia [18]. This is similar in patients with bipolar disorder [19]. This lack of illness insight affects not only adherence, but also engagement with health services in general [20, 21]. People who do not perceive themselves to be unwell fail to recognize the need for treatment and care, and as such, poor insight has frequently been associated with non-adherence [8, 20]. Many treatment benefits in psychiatry are silent and long-term, which further reinforces the lack of insight. The ‘no symptoms, no

problem' view of health is intuitive; thus, adherence is particularly challenging when there is minimal insight and understanding of the illness [20, 21]. Moreover, non-adherence may not lead to an immediate deterioration—relapses may not occur for months, or even years, after stopping medication [21]. Likewise, treatment benefits are often delayed—drugs for depression or psychosis usually take 4–6 weeks before a perceivable benefit is attained. Together, these factors reinforce the perception that medication may not be necessary. As such, early discontinuation of medication is a common manifestation of non-adherence in psychiatry [21], as treatment is stopped when patients judge that the condition has improved.

Secondly, even when patients do gain illness insight, they may not have the capacity to adhere to treatment [2]. This may be due to cognitive impairment that can accompany mental health disorders, the illness itself, or their psychosocial circumstances, which make establishing a regular medication-taking routine or affording long-term medication difficult [2, 22]. Comorbid intellectual disability or substance misuse are other important factors to consider in psychiatry which can influence treatment adherence [20].

Shared decision-making and therapeutic alliance between the clinician and the patient have been shown to be important mediators of adherence—adherence is likely to be higher when there is a positive, trusting clinician–patient relationship [20, 23]. However, this can be difficult to achieve in psychiatry when treatment is started in a compulsory treatment setting and when there is mental health legislation governing this process [24]. In a survey of 104 individuals with schizophrenia, over one-third reported fear of coerced treatment as a barrier to seeking treatment; the use of reminders or warnings about the consequences of non-adherence were perceived negatively as pressures to adhere and were reported as increasing barriers to treatment [25]. Lastly, stigma associated with mental health conditions has consistently been shown to be an adherence barrier [22]. This is common across all mental health conditions, with patient perceptions of stigma influencing treatment behaviours and adherence negatively [26]. These unique challenges need to be considered if we are to promote adherence in psychiatry.

Interventions to improve adherence in psychiatry: what lessons can be learnt from trials of adherence support?

What interventions are effective? A review of 20 years of adherence research

Although the problem of non-adherence is well recognized globally, there continues to be no effective solution [27]. A vast amount of research have examined the reasons for non-adherence, and many adherence interventions have been tested in RCTs; yet a sustainable and effective solution remains elusive. In the most recent Cochrane review of adherence interventions, 182 published RCTs were included [27], of which 29 were on psychiatric disorders—primarily in schizophrenia and related psychotic disorders, followed by depression. The quality of these RCTs were low; of these 29 RCTs, only one [28] was considered to have a low risk of bias. Even when all studies are taken into account, the effects of these interventions on adherence are mixed and non-consistent.

There is a general lack of convincing evidence to support one particular intervention over another; where one type of intervention demonstrates positive effects on adherence, the same intervention in a similar population will report negative results. For example, compliance or adherence therapy—a cognitive behavioural intervention using techniques from motivational interviewing to discuss adherence—was reported to improve adherence in patients with psychosis in two studies [29, 30] but failed to demonstrate any effect in two other studies [31, 32]. The wide variability of studies, in terms of study populations, conditions, setting, intervention design, and adherence and outcome measurement, make it difficult to draw comparisons between the different types of interventions. Even when effects are seen on adherence, the benefits are relatively small and effects on clinical outcomes frequently not assessed. Questions on the sustainability and feasibility of implementation into practice also remain. Many of the psychiatric adherence interventions tested are typically very complex—involving multiple resources and intensive follow-up—something that may not be able to be delivered in a real-world clinical setting. Furthermore, details on the actual content and delivery of the interventions are commonly not described in sufficient detail to replicate in practice. These limitations that currently exist with adherence intervention literature make it difficult to design effective interventions in practice; there is a need for more innovative approaches to adherence.

Lessons learnt from research—there is no 'one size fits all' for adherence interventions

Adherence interventions which have been tested in psychiatry include adherence therapy, education, telemedicine, shared decision-making, family therapy, and pharmacist-led education or medicines management [27]. As the literature highlights, interventions and outcomes are varied and many different approaches have been tried to address non-adherence. There are learnings that can be gained from these 20 years of adherence intervention research. Although there is no evidence to support one particular intervention over another, interventions which have been successful in improving adherence usually consist of: (1) multiple components; (2) ongoing support tailored to address barriers to adherence; and (3) delivery by health care professionals, with additional support from the family or peers [33–36]. Clues can also be provided from adherence studies that investigate relationships between particular patient or illness factors and adherence; although such findings provide little information on how to design effective interventions, they can be useful to help identify groups at risk of non-adherence. For example, patients who lack a support system or have comorbid substance abuse are at a higher risk of non-adherence [20, 21]. This can help target and prioritize adherence interventions to people who need it the most, particularly in limited-resource settings.

However, to design effective interventions on an individual level in practice, one must look beyond population studies and focus on the individual. Study findings may not be easily extrapolated to daily practice. An intervention that may be successful within a particular study population may not be effective for a particular patient. Although some interventions have been able to improve medication adherence, the exact components of the interventions which contributed to its effectiveness are often not known [27]. The lack of detailed, consistent reporting and measurement makes it difficult to draw definitive conclusions to apply in practice. Previous reviews

of interventions to improve adherence to psychotropic medicines echo these findings [33–35]. As Kane *et al.* describes—the idea of a ‘standardized, universally valid and reliable’ approach to promoting adherence is a myth—individualized interventions tailored to the individual are likely needed to improve adherence [21].

Non-adherence: towards behaviourally intelligent solutions

Adherence is a behaviour, not a trait

With the vast amount of adherence research, it might seem a wonder why non-adherence still exists. Yet the problem might lie in the approach that has been taken in the past when investigating non-adherence—the limitations of this approach have been discussed previously in Section 2. Prior to the 1970s, much of the research focused on the notion of the ‘non-adherent patient’—where attempts to explain non-adherence used ‘easily identified and quantifiable dimensions’ such as patient, regimen, or illness characteristics [37]. Yet the ‘non-adherent patient’ is a myth, as most of us are non-adherent some of the time [15]. Associations observed between sociodemographic variables, such as gender and age, and adherence are neither clear nor consistent [15].

Non-adherence is therefore best understood as a variable behaviour, rather than a trait characteristic. For example, studies have reported ethnicity to be a significant predictor of antipsychotic medication non-adherence [38, 39]; yet other literature reports that ethnicity is not a consistent predictor [20]. Likewise, various personality traits have been linked with non-adherence. Extraversion was significantly associated with non-adherence in one study [40], but not another [41]. While understanding some of these factors is important, focusing on sociodemographic factors alone will not fix non-adherence. This is because non-adherence is a feature of the way the individual interacts with their treatment, rather than any particular characteristic of the patient themselves. Non-adherence varies not only between individuals, but even within the same individual over time. Non-adherence does not arise from irrational or misguided behaviour—more often than not, the patient goes through a knowledge process and the way they act come from the attitudes they develop about their condition and medicines, and their personal health experiences [21].

Indeed, patient attitudes, illness perceptions, and health beliefs have been demonstrated to be one of the strongest predictors of adherence [42–44]. Beck *et al.* investigated factors influencing adherence in patients with schizophrenia or schizoaffective disorder and found that patients who viewed antipsychotics as necessary for their treatment had higher adherence; conversely, those who had negative attitudes about medicines in general and were concerned about antipsychotics had poor adherence [43]. The authors called for adherence interventions to focus on treatment attitudes, rather than general education about the illness. These findings make sense when adherence is viewed as a health behaviour—attitudes and beliefs are more likely to be important mediators of behaviour. Adherence interventions should therefore focus on behaviour change principles and techniques. New strategies need to build on this concept of adherence as a health behaviour to allow effective interventions to be developed. Learnings from years of research show that there is no

‘adherent personality type’ and a ‘one size fits all’ adherence intervention. There is a need to develop more effective ways of tailoring support to meet the needs of individuals if we are to improve adherence in a sustainable fashion.

Adherence is a product of motivation and ability

In order to tackle this large-scale problem of non-adherence, it is important to understand why non-adherence occurs from an individual patient perspective. Firstly, non-adherence may be intentional (for example, when we decide not to take the treatment or to take it in a way which differs from the recommendations) and/or unintentional (for example, when we want to follow the recommendations but lack the capability or opportunity to do so). The easiest way to think of this is to consider adherence behaviour as being two-pronged—patients do not adhere to treatment because: either (1) they *do not want to* or (2) they *are not able to*. How non-adherence arises therefore relates to two components which drive the behaviour, respectively—*motivation* and *ability* [15]. This ability, in turn, is affected by the individual’s *environment*—both internal factors (for example, knowledge and physical capability to take the medication on time) and external factors (for example, aspects of our environment affecting access to treatment such as not having easy access to a pharmacy) [15, 45].

This forms the basis of the Perceptions and Practicalities Approach (PaPA) to supporting optimal adherence [15], which has been applied to designing interventions in psychiatric disorders [2] and in the National Institute for Health and Care Excellence (NICE) medicines adherence guidelines [46].

Perceptual or practical barriers to adherence: a Perceptions and Practicalities Approach to designing patient-centred adherence interventions

The PaPA approach to adherence support derives from an analysis of the types of reasons why people do not take their medicines (Fig. 20.1). Recognizing that adherence is a product of motivation and ability, PaPA stipulates that adherence interventions should address both perceptual factors (for example, beliefs about the illness and treatment) as well as practical factors (for example, the ability to remember the medicine, establish a daily routine, and organize or pay for medication supply) [46]. Adherence support should be tailored to the needs of the individual using a menu-based approach where specific intervention components are selected to address specific perceptual and/or practical barriers. The approach also takes account of the social and environmental factors that provide the context around the interaction of the patient with the treatment [15] (Fig. 20.1). The importance of external factors (for example, social and environmental factors) is described in Michie *et al.*’s COM-B conceptual framework for key determinants of behaviour [47]. COM-B describes three components—Capability, Opportunity, and Motivation—which act together to influence behaviour. Capability and opportunity reflect a person’s ability; opportunity can also comprise the external factors that make the behaviour possible or prompt it, and thus relates to how environmental and social factors might influence adherence. Together, these relate similarly to the motivation–ability paradigm described previously.

Based on PaPA, adherence support targeted at the level of the individual should be tailored to address the specific perceptions (for

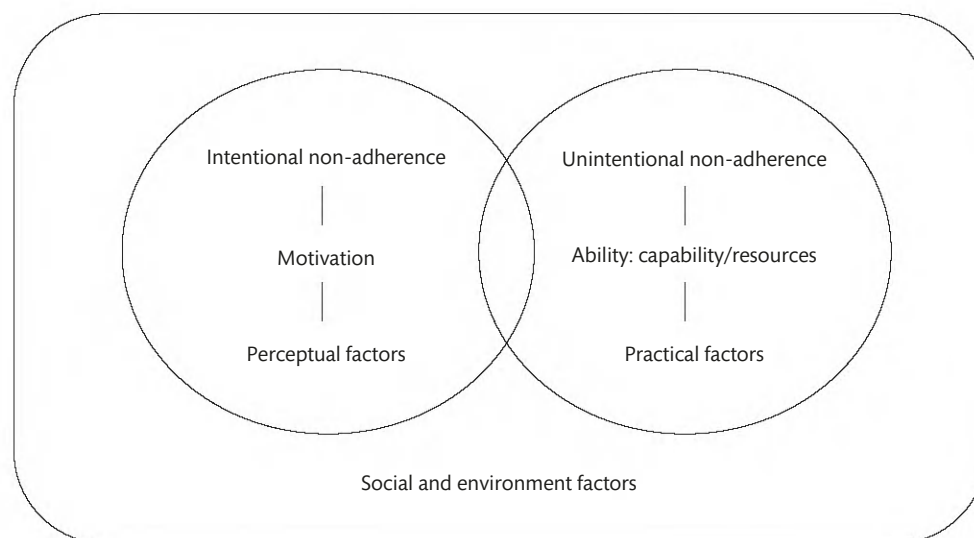

Fig. 20.1 Figure depicting the interaction between perceptual and practical factors on adherence behaviour.

Reproduced from Horne R, Weinman J, Barber N, et al., *Concordance, adherence and compliance in medicine taking: Report for the National Co-ordinating Centre for NHS Service Delivery and Organisation R & D (NCCSDO)*, Copyright (2005), with permission from National Institute of Health Research.

example, beliefs and emotions) and practicalities (for example, capability and resources) influencing a person's motivation and ability to adhere, respectively [15, 46]. As shown in Fig. 20.1, perceptions and practicalities can overlap. For example, motivation may help the individual overcome limitations in capability and opportunity, which might, in turn, influence motivation—hence, the model is depicted as a Venn diagram, rather than two discrete circles (Fig. 20.1).

Adherence is a complex behaviour with multiple determinants—both internal and external (see Fig. 20.2 for a summary). The 'internal' factors influencing motivation and ability may be moderated by 'external' variables, such as the quality of communication between the patient and the health care provider [23], and by the wider societal contexts such as access to treatment and mental health legislation [24].

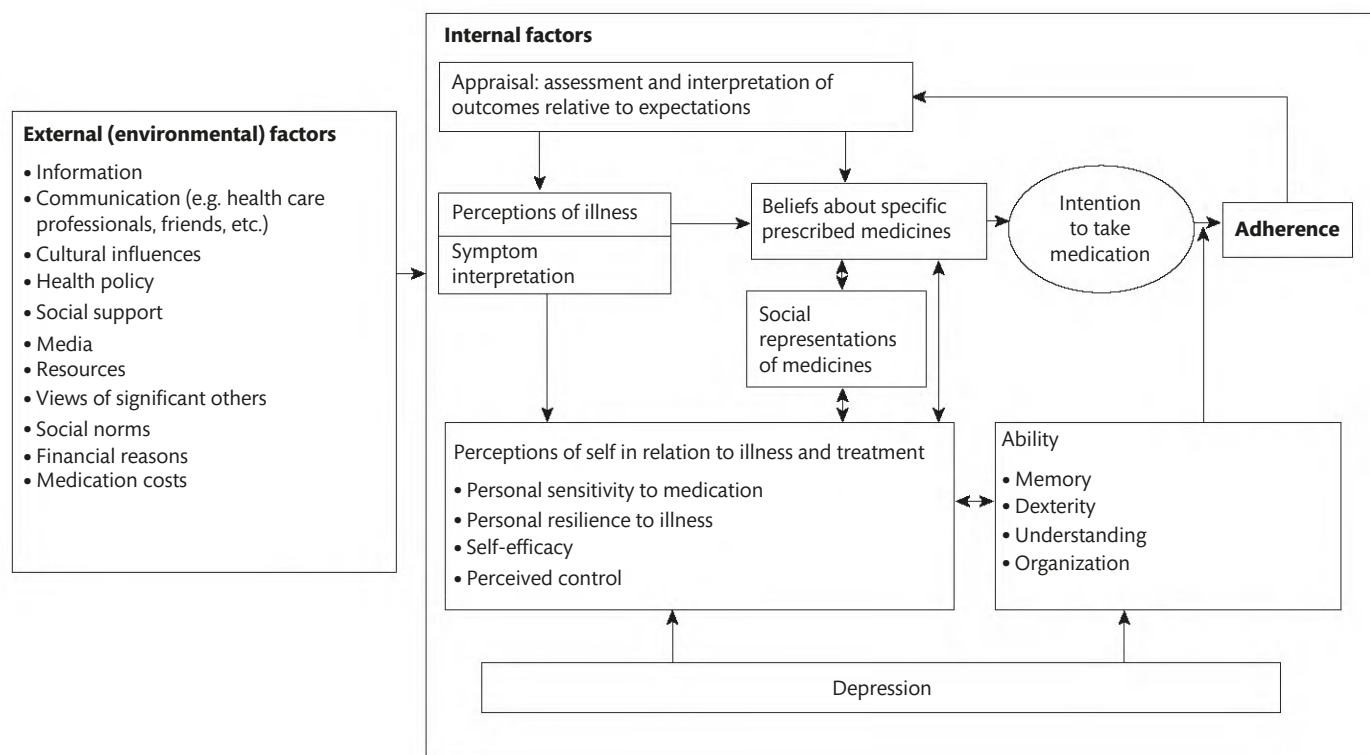

Fig. 20.2 Conceptual map of determinants of adherence.

Reproduced from Horne R, Weinman J, Barber N, et al., *Concordance, adherence and compliance in medicine taking: Report for the National Co-ordinating Centre for NHS Service Delivery and Organisation R & D (NCCSDO)*, Copyright (2005), with permission from National Institute of Health Research.

When considering adherence interventions, various aspects of this adherence behaviour can be targeted. Motivation and ability can be considered separately to help design adherence interventions, based on what factor or factors are driving the behaviour. For example, interventions to improve a patient's *ability* to adhere (such as improving access to treatment) will fail if the patient does not *want* to take the medication (such as when the patient has already decided against the treatment). Understanding what drives a patient's decision to adhere or not to adhere is key to addressing non-adherence.

The following sections explore these two drivers of non-adherence—perceptions and practicalities—in greater detail.

Perceptions: the role of general and specific beliefs about medication in influencing decisions about treatment

Beliefs about medicines can have a significant impact on adherence—simply providing information is often insufficient to achieve adherence to psychotropic medication [21, 35]. The literature on the effects of education and information provision on adherence shows that giving information about treatment benefits and harms may not impact on decisions to start and continue medication, even though knowledge is increased [48]. One study investigating adherence to tricyclic drugs found that giving treatment leaflets to patients alone, with no counselling, had no effect on adherence [49]; this is supported by a later systematic review which found education interventions demonstrated no clear benefit on adherence and depression outcomes [33]—an association also seen in other psychiatric conditions [43, 50]. Although the quality of the studies do not allow definitive conclusions, together these suggest that information provision and increasing knowledge alone do not overcome non-adherence [15].

Qualitative studies show that many people seem to hold prototypic beliefs about medicines and their capacity to produce harm, as well as benefit, and beliefs about the appropriateness of doctors' prescribing of medicines [51, 52]. These beliefs exist even before a person takes the medication. A review of knowledge and beliefs held by members of the public about psychotropics found that views were generally very negative; this contrasted with positive views about medication for physical disorders [53]. Many were concerned about dependence, lethargy, and brain damage [52, 53], perceiving psychotropics as harmful, addictive substances that should not be taken for long periods of time but tend to be overprescribed by doctors [51].

These beliefs can influence how information is interpreted by patients, what their experiences are, and how they act as a result of this information [15, 53, 54]. Indeed, negative attitudes and beliefs towards medicines used in psychiatry appear to be stronger predictors of non-adherence than demographic or psychosocial factors [20, 42–44]. These attitudes are linked to wider concerns about scientific medicine, a lack of trust in doctors, and an increasing interest in alternative or complementary health care [51, 53]. People also seem to vary in their perceptions of personal sensitivity to medicines [55], with some being more concerned than others about their response to medication.

These *general* beliefs influence the way in which people evaluate a *specific* medication prescribed for a particular condition [51]. These beliefs can affect a person's initial expectations of the outcome of taking a medication, as well as how any subsequent events are interpreted—for example, whether symptoms experienced are attributed to the illness or the medication [56]. These beliefs may

even influence the clinical outcome directly via the 'placebo/nocebo' effects of active drugs—terms describing the phenomenon of having beneficial or harmful effects occur when people have positive or negative expectations about the medication, respectively [57]. Beliefs can also be *specific* for a particular medication—for example, concerns around weight gain and extra-pyramidal side effects with dopamine antagonists [21, 58] have been linked with poorer adherence.

Perceptions: the role of perceived necessity and concerns in influencing decisions about treatment

Once a person has started a new medication, they will begin to form particular beliefs and attitudes towards the treatment, based on their initial and subsequent evaluation of the medication. This evaluation process is captured by the Necessity–Concerns Framework [51]. The framework suggests that the motivation to start and persist with treatment is influenced by the way the individual judges their personal *need* for the treatment, relative to their *concerns* about potential adverse effects. For example, a 2-year prospective study of 254 patients recovering from first-episode psychosis found that the risks of non-adherence was 1.75 times higher in those whose belief in the need for treatment was less, and 2.88 times higher in those who thought medication was of low benefit [59]. Similarly, in a study of 223 individuals prescribed medication for bipolar disorder, the odds of having poor adherence was twice as high in those who had stronger concerns about the negative effects of medication than those who did not—a finding that was independent of mood state, illness, and demographic characteristics [44]. Other studies involving patients from a wide range of other conditions have consistently found similar results—that poor adherence is related to doubts about personal need for medication and concerns about potential adverse effects [60].

Perceived necessity of a treatment is, however, not related to beliefs about treatment efficacy. Although views about medication efficacy are likely to contribute to perceived need, the two are not synonymous. For example, perceived necessity can be influenced by illness beliefs—a patient might believe that a treatment is effective but may not perceive a personal *need* for the treatment. A common situation where this might occur is when the patient lacks illness insight. In this case, the patient may not believe they need any treatment, regardless of its perceived efficacy. Beck *et al.* explored the beliefs about drugs for psychosis in 150 outpatients and found that patients who were aware of their illness were more likely to adhere due to a greater perceived necessity of the treatment [43]. Conversely, a patient might perceive a strong need for a treatment, even though they believe it is only moderately effective—for example, if it is the only treatment that is available or acceptable to the patient. This may be seen with 'natural' remedies such as vitamins or herbs [53] where the patient may express a strong need to take these, instead of the prescribed medicine, despite believing these are only moderately effective.

In terms of perceived concerns, there is much overlap in the type of concerns that patients report about medicines, regardless of the medication type. The experience of symptoms as medication 'side effects' and the disruptive effects of medication on daily living and quality of life are commonly reported concerns [56, 61]. Many patients receiving regular medication who have not experienced adverse effects worry about possible problems in the future—a view

that may be related to beliefs that regular medication use can lead to dependence or accumulation within the body and corresponding long-term effects [51, 53]. Concerns also relate to the meaning that being on regular medication has for the individual and their sense of self or identity. Taking a daily treatment may be an unwelcome reminder of their illness, which may have a negative impact on how they view themselves or perceive how they are seen by others. This can be further exacerbated by the stigma associated with taking mental health medication itself [22]. In these circumstances, non-adherence might be seen as an implicit strategy to minimize the impact on their sense of self [62].

These necessity beliefs and concerns can influence adherence separately and in combination, and the effects may be through explicit and implicit processes. For example, in some situations, non-adherence could be part of a deliberate strategy to minimize harm by taking less medication. Alternatively, it might simply reflect the fact that patients who do not perceive their medication to be important are more likely to forget to take it. The impact of perceptions of treatment on adherence may also be influenced by beliefs about adherence behaviour itself such as whether or not strict adherence to medication is needed to achieve the desired outcome.

Practicalities: enhancing capability and opportunity for adherence

Beyond addressing patient perceptions is the need to address factors that determine a patient's *ability* to adhere. Forgetting is the most commonly reported practical reason for medication non-adherence [63]. This may be due to the cognitive effects associated with mental health disorders, as well as a lack of routine and an erratic lifestyle [21]. Reminder systems or medication organizers, such as pill boxes, may be useful, though reported effects are typically modest [64]. Linking medication-taking to specific environmental cues may be more effective than a repeated reminder to help reinforce habits and routine. For example, placing the medication near the toothbrush, so that taking the medication becomes linked to an existing habit, may be useful. However, this is susceptible to changes in the environment or routine such as going on holiday [65].

Linking medication-taking to specific environmental cues may also be useful [66]. This involves planning with the patient how and when they are able to take their medication. Turning a patient's intention to take medication (for example, 'I will take my medicine') into a more specific plan (for example, 'I will take my medicine immediately after I brush my teeth every morning') increases the likelihood of the behaviour being performed [66].

Simplifying the regimen and reducing unnecessary polypharmacy is also important. Complex regimens with a high dosing frequency or complicated instructions for medication-taking can lead to poor adherence [67]. Reducing the dosing frequency to once daily can improve the patient's ability to adhere by making the treatment less intrusive and more convenient. The use of long-acting injections may also promote adherence through this mechanism and reduce the chances of forgetting treatment [68], though patients may have negative perceptions of long-acting injections as these are frequently associated with coercive treatment [69]. Strategies to improve adherence by changing formulation or dosing are therefore likely to be effective only if perceptual barriers to adherence have been addressed [43]. Involving patients in treatment decisions is important to achieve ongoing adherence—patients who were prescribed at

least one medication that had been requested by the patient in a psychiatric advance directive had higher adherence at 12 months—with the odds of adhering being 7.8 times higher—than those who did not receive medications as per their advance directive [70]. To achieve adherence, the clinician must therefore aim to elicit the patient's perspective about treatment—including their beliefs and concerns—and ensure that decisions about treatment are informed by fact, rather than misperceptions [17]. Offering a medication choice can be an effective method of involving the patient in prescribing decisions—even as simple as involving the patient in the choice of dosage form can be useful [17, 70]. Medication cost and access to health services and medication may be other factors to consider when addressing practical barriers to adherence [17].

So ... you took all your medicines? Methods of assessing adherence

Measuring non-adherence is a complex issue. While self-report is the most practical and convenient method in clinical practice to assess adherence, reports are subjective and often inaccurate. Patients often overestimate adherence [71], yet objective measures have their own shortcomings (Table 20.1). There is a need to remove the negativity surrounding medication non-adherence to encourage honest, non-judgemental communication between the patient and the health care provider. In clinical practice, 'detoxifying' non-adherence and allowing sufficient time in the consultation to discuss barriers to treatment are necessary first steps to improve the assessment of adherence [17, 46]. This may be facilitated by opening up discussions about adherence in a non-judgemental way and explaining the reasons for the discussion. It is helpful to focus the discussions on a specific time period such as 'in the past week' and asking about specific medication-taking behaviours such as skipping or changing the dose or stopping medication [46]. Patients should be encouraged to discuss freely their adherence behaviours and barriers in clinical practice—objective adherence measurement will become less of an issue when this occurs. Until then, however, there remains great interest in measurement, and multiple methods to assess adherence exist (Table 20.1).

PaPA—a 3-step process towards effective adherence interventions: tailoring support to individual needs

Informed adherence in practice

Shared decision-making with the patient and informed choice should be a key facet of clinical practice and adherence. For interventions to be effective, equitable, and efficient, one must facilitate informed choice [15]. A patient can be considered to have made an informed choice if they can demonstrate knowledge of relevant information about the treatment and then act according to their beliefs. This concept of informed choice has been extended to *informed adherence* [72] where evidence-based medicine is used to guide initial treatment recommendations. The recommendations should be presented to patients in a way that takes account of their individual beliefs and preferences, and any incompatibilities between their

Table 20.1 Summary of adherence measurement methods

Direct methods			
Direct methods provide evidence that the patient has actually taken the medication and are therefore the most accurate [77].			
Method	Description	Advantages	Disadvantages
Detection of the drug or metabolite in biological fluids	Laboratory testing of drug levels in bodily fluids	Levels are easily quantifiable Can provide data on dose-response	Invasive Low patient acceptability Tests can be costly Time-consuming Difficult to interpret Can only be used if a blood level test exists for the medicine Can exhibit large inter- and intra-patient variability Sampling times need to be accurate Does not provide information on adherence patterns
Detection of adjunct biological markers	An additional readily detectable, but inert, stable, and non-toxic, substance is added to the ingested medication, either directly into the drug formulation or taken as an adjunct to therapy	Levels are easily quantifiable Can provide data on dose-response	Not relevant to medicines used in psychiatry, as no biological marker exists Similar disadvantages to detection of drug in biological fluids
Direct observation of patient ingestion of treatment	Patient is observed while they take the dose in front of another person, either a health care provider or a family member	Provides direct proof of medication ingestion Allows direct interaction with the patient, which can reveal other aspects of their lifestyle and environment which affect their adherence	Intrusive Resource-intensive as requires repeated health care provider visits Susceptible to patient manipulation (for example, patient can hide medication in the mouth and feign ingestion)
Indirect methods			
The majority of adherence measures used are indirect, which measure adherence using patient- or third-party-generated information. These methods are unable to determine whether or not actual medication-taking occurred but are generally more acceptable to patients due to their non-invasive nature.			
Method	Description	Advantages	Disadvantages
Patient self-report	Patient reports on their own adherence behaviour through patient interviews, diary cards, journals, calendars, surveys, or validated adherence questionnaires and rating scales	Simple Cost-effective Convenient Most common method used in the literature and in practice Does not require any extra planning or resources High patient acceptability Easy to use Can provide detailed information on adherence patterns and patient awareness of behaviour if obtained from diaries, journals, or interviews Encourages active patient involvement Facilitates provider-patient discussions	Lack of objectivity—high risk of inaccurate reports of adherence Often overestimates adherence due to patient's desire to be viewed positively by others Risk of recall bias, especially if data reported retrospectively Relies on accuracy of patient records/reports Dependent on patient's ability and willingness to disclose information Patient responses can be affected by how questions are asked and relationship with interviewer
Medication counts	Physical count of the number of doses that remain in a patient's medicine bottle, delivery device, or other medication management system, after a pre-determined period of monitoring, and compares this with the expected number of doses that would remain if the patient had taken the medicine exactly as prescribed	Commonly used alternative to self-report Simple, economical Enables medication use to be monitored without the patient Been shown to be more accurate than self-report and prescription refill data, being aware of the parameter being measured Allows some detection of changes in adherence, depending on frequency of counts	Lack of detailed information on the patterns of usage over time Wide variation in accuracy—patients may combine multiple refills in same container, use multiple containers, or share medication with others Difficult to determine the dates of treatment period Need for patients to return medication containers or canisters Patients may suspect adherence is being monitored
Prescription refill records	Electronic records of prescription claims made by a pharmacy or a manual process of prescription review	Objective data Easily accessible Readily available in most cases Reduces risk of patients being aware of monitoring Allows large-scale population analyses Enables ease of patient follow-up Can determine trends over prolonged periods	No standard method of data interpretation and analysis Data availability may be delayed Only a proxy measure—dispensed medicines may not be picked up or taken as prescribed Patients may use more than one pharmacy

(continued)

Table 20.1 Continued

Method	Description	Advantages	Disadvantages
Electronic adherence monitoring	Use of electronic monitoring devices to record medication use through monitoring of the opening of medication bottles, dispensing of drops, or depression of canisters for inhaled medication	Considered as the 'gold standard' of adherence measurement Objective Not reliant on patient self-interpretation Accurate—non-biased data Reliable Less prone to patient deception Provides detailed information about medication taken Allows adherence patterns to be monitored	Inaccurate data recordings or data loss can arise due to device malfunction Devices can be lost or damaged May require patient and practitioner training No confirmation of ingestion Presence of device may change patient behaviour Costly Ethical considerations with monitoring of behaviour Patients may suspect monitoring

personal beliefs and the prevailing evidence should be resolved by non-judgemental discussion [54].

One approach to achieving informed adherence is to consider the following 'PaPA-based approach to adherence support' in any consultation about treatment:

1. *Facilitate an honest and open discussion.* The discussion should aim to normalize non-adherence and allow patients to report non-adherence and express doubts and concerns. This allows assessment of adherence in a non-judgemental way. Effective communication is important. Factors such as mental state, health literacy, language barriers or visual or hearing impairment may need to be considered to ensure effective communication.
2. *Communicate the **necessity** of treatment.* In psychiatry, many patients do not believe treatment is necessary, as they do not perceive themselves to be ill. Discuss with the patient what their understanding is of the reason for treatment. Explain the condition and how the treatment will influence this, considering the aims of the treatment and what the patient themselves hope to achieve. Focus on how the patient may benefit from the treatment, taking into account the individual motivations the patient may have, which may not be directly related to the illness.
3. *Elicit and address any **concerns** raised about the treatment.* Use open-ended questions to encourage patients to discuss and ask about their condition and treatment. Find out what the patient knows, believes, and understands about their treatment before starting or changing a medicine. Often these concerns centre on dependency and side effects of weight gain and lethargy and how this will affect their daily lives. Discuss and agree a plan of action to manage these concerns with the patient.
4. *Minimize any **practical barriers** to adherence.* It is helpful to discuss how the patient will fit the medication into their daily routine and remember to take the medication. Identify any barriers, and agree a plan of action with the patient.

This approach ensures that both the perceptual barriers (necessity/concern beliefs) and practical barriers are addressed. Previous interventions have had limited effects, partly because either they have not addressed all these factors or the intervention has not been individualized to the patient. Many have focused on single causal factors, whereas adherence is best seen as a complex health behaviour with multiple determinants—both internal and external (see Fig. 20.2 for a summary). By using this approach, interventions can be tailored to the individual while achieving informed adherence.

Practical considerations in intervention design

When designing and implementing adherence interventions in practice, three dimensions of the intervention need to be optimized for success. This can be remembered as the '3 components to behaviour change' or '3CBC'—content, channel (delivery vehicle), and context.

Content

This is the basic substance of the intervention and how the specific barriers and enablers of adherence are addressed. Approaches should be tailored to address both the perceptual factors influencing motivation to initiate and persist with treatment, as well as facilitate the ability to adhere, for example by addressing any capacity and resource limitations. The PaPA model described is one method that can be used to ensure all aspects of adherence are addressed.

Channel

Adherence support should occur, not just at the start of treatment, but also during treatment review, as perceptions, abilities, and adherence can change. For psychiatric disorders, support should extend beyond the prescribing consultation to ongoing medication counselling and review. The increasing use of e-technology (such as smartphone apps) offers the prospect of additional channels to complement practitioner-delivered support [73]. However, despite the plethora of technology and digital solutions available, there is, as yet, little evidence for their efficacy. A recent systematic review found mobile and electronic interventions to be feasible and acceptable in patients with serious mental illness; however, effects on adherence and outcomes are yet to be determined [74]. Applying these principles to develop theory-based content might improve their effectiveness and utility.

Context

Context considers how appropriate prescribing and adherence support is facilitated by wider contextual factors, such as media representations of treatment and ease of access to treatment. Examples of such strategies include allocating appointments to patients with minimal delay and ensuring medicines are readily accessible and affordable [17]. Organisational and service delivery issues may also impinge on the opportunity to access treatment and support services [75]. The impact of community treatment orders is another contextual factor to consider, particularly as these are widely used in

many countries yet the benefits of these on adherence and outcomes remain controversial [76].

Conclusions

Medication non-adherence is an age-old problem that has existed since the time of Hippocrates; yet it remains a significant problem facing psychiatry today, leading to many lost years of health and livelihood. Despite decades of research, advances made have had limited effect on addressing this issue. The new approach taken in the last few decades where medication adherence is understood as a variable behaviour, rather than a trait characteristic, has shown great potential in paving the way towards an effective intervention. An individualized approach, where each person's unique beliefs, capability, and motivation are taken into account, should be the foundation of every adherence intervention undertaken today. Adherence is everybody's issue—we must endeavour to address this in our everyday practice with every patient we meet. Every small step we take towards targeting this complex behaviour is one step closer to building the missing link between psychiatric treatment and outcome. Only then can we begin to see the gains from the medical advances that our predecessors have achieved many years and decades ago.

Introduction

This chapter focuses on two main issues: (1) the core dimensions that are part of systems of classification that define what is meant when a person is said to have an intellectual (learning) disability, and how these systems have developed with time; and (2) the behavioural and mental health needs of people with intellectual disabilities (ID) and how such needs might be best conceptualized. The characterization and classification of a group of people as having ID, and including such a classification within the taxonomy of mental disorder, has not been without controversy. The reasons for this relate to the key elements of any classification system—is it valid, and is it reliable? Does it inform and clarify our understanding? To what end is it being used? Does it enhance those it so classifies, or does it demean and contribute to stigma and marginalization? When it comes to illness or disease, accurate diagnosis based on agreed diagnostic criteria is the cornerstone of epidemiological and aetiological research, enabling informed treatment development that can then be generalized to others with similar illnesses. However, an ID is not an illness, and identifying someone as having an ID is not fundamentally a diagnosis because, on its own, the term provides no information about the cause, pathophysiology, or likely prognosis. Rather ‘intellectual disability’ serves as an umbrella term for a set of ‘core dimensions’ that describe what is an extremely heterogeneous group of people. In addition to the ways we are all different, children and adults with ID also differ extensively in other ways, such as in the cause, nature, and degree of their disabilities and in the presence or absence of secondary sensory, physical, and/or psychiatric comorbidities and/or a pattern of early developmental characteristics of the autistic spectrum disorder. The assessment of children and adults with ID in clinical practice requires that these various strands are integrated into a coherent and comprehensive formulation, which, in turn, informs intervention.

Background

The initial development of modern systems of classification for ‘mental retardation’, as it was known then, was reviewed in a special edition of the *American Journal of Psychiatry* in 1972 [1]. The systems referred to used varied terms, and their use and some of

the actions that resulted from such labelling would certainly now be seen as unacceptable. However, with time, thinking has developed, and the core dimensions have been reshaped and expanded to better reflect the complexity and interactive nature of the concept of ‘intellectual disability’, together with a better understanding of the reasons for, and potential pitfalls of, any system of classification. In the 1900s, in the UK, the characterization and classification of people with ID was considered to be necessary to facilitate the segregation of people deemed to be harmful to the population as a whole, or even a major source of criminality, by virtue of their abnormal genetic endowment. The eugenics movement took these ideas to be axiomatic, and they persisted well into the twentieth century. The work of Jack Tizard and others transformed thinking about how people with ID should be supported, leading to the acceptance that people with ID should be, and could be, supported outside of institutions. The 1960s saw the emergence of the concepts of normalization and social role valorization as the principles that should guide the support of people with ID. Within Europe, North America, and other high-resource countries, these changing approaches led to developments in legislation and in policy and practice. With the development of new ways of conceptualizing ID, there was a move away from seeing the nature and extent of the disability as exclusively based in the individual, rather than seeing a person’s disability as a consequence of interactions between some innate limitations, the influence of the past and present social and family environments, and importantly educational and life opportunities. Additionally, the nature and extent to which society itself accepted and responded to people with disabilities could ameliorate the disadvantages experienced by those affected.

These social and attitudinal changes occurred during a period in which there were also major advances in areas such as genetics and neurosciences, and in understanding the major environmental causes of ID. The work, for example, of Lionel Penrose and the publication in 1938 of his book *Biology of Mental Defect* identified the causes of ID [2] (Penrose 1949). The normal human chromosome complement of 23 pairs of chromosomes was identified in the 1950s, and trisomy 21, as the cause of Down’s syndrome, was identified shortly afterwards. The sequencing of the human genome was undertaken in the late 1900s and early twenty-first century, and many abnormalities of chromosome number (aneuploidies), chromosomal rearrangements, DNA copy number variations, and

single-gene mutations have been described in association with the presence of developmental delay and ID [3].

The recognition of specific environmental causes of ID, as diverse as maternal iodine deficiency, fetal alcohol syndrome, or rubella embryopathy, has all had very clear public health implications in terms of primary prevention. In LMICs, it is recognized that varied environmental and social factors impact on the early cognitive and socio-emotional development of children [4]. These different issues are primarily the province of public health, child health, and maternity services. However, in addition, as findings from studies in the 1970s onwards identified that children and adults with ID have high rates of behavioural problems and mental ill health [5, 6], so the need to address such issues became increasingly apparent. It is primarily for this reason that there is a focus on ID in a textbook of psychiatry. Given research evidence about such comorbidities and with the earlier changes in attitudes and policy, the role of psychiatrists, in particular, has altered beyond recognition from being medical superintendents of large long-stay institutions to being members of community-based interdisciplinary teams undertaking much more focused and nuanced interventions.

Classification of intellectual disabilities

Given the heterogeneity of people with ID and the potential complexity of the health and support needs of people with ID, what is clear is that no one system of classification is fully adequate and which system is employed, if any, critically depends on the context and the reason for its use. If the question is about the nature and type of support to be offered, this will be better characterized through the lens of a more interactive and dynamic model, in which barriers to that person's full participation and inclusion in society are the focus of enquiry. However, if the question is about the cause of a child's significant developmental delay, then the focus will be more on an accurate description and characterization of his/her unique features—the phenotype, in order to identify the cause. The former approach helps guide educational and service planning and support and is based on what is described as a social model of disability, and the latter is based around a biomedical model. In each of these, the 'core dimensions' will overlap, yet differ in terms of emphasis, as each system of classification has a different purpose.

Historically, there has been a tension between the social and biomedical ways of conceptualizing the needs of people with ID, and in papers advocating these different perspectives, the language and concepts used and the conclusions drawn at times appear irreconcilable. However, such debate has unnecessarily polarized each perspective, and there is a need for a more nuanced understanding [7]. While those from different professional backgrounds may emphasize a different perspective, there is necessarily a coming together of these perspectives, thereby providing the means for structuring our thinking about the needs of people with ID and, in turn, how we might respond to these needs. Diagnostic and classifications systems, such as the *Diagnostic and Statistical Manuals (DSM)* of the APA, first published in 1952, and now as DSM-V [8], and the WHO's *International Classification of Diseases* (soon to be ICD-11), have been developed and modified over time, and newer systems have been developed, which seek to better reflect the nuances required of systems of classification. These aim to both characterize the nature and

extent of a person's impairment and disability on the one hand, and on the other, to be structured enough to be used reliably to compare findings across countries and over time. These include the American Association on Intellectual and Developmental Disabilities' manual *Intellectual Disability: Definition, Classification, and Systems of Support* [9] and the WHO's *Classification of Impairments, Disabilities and Handicaps* [10] and its successor the WHO's *International Classification of Functioning, Disability and Health* [11].

Although, in some areas, the use of systems for classification may be subject to criticism, there are at best very positive benefits to an individual being assessed as having an ID. These include: the prospect of going on to identify the exact cause of a person's ID; awareness of the potential for, and the identification and treatment of, associated health problems; and access to specialized educational support and additional financial support through the benefits system. It is against this background that the defining of what it means to have an ID and the core dimensions that are part of such a definition need to be considered. For the paediatrician, the question may be why this child is developmentally delayed. For the geneticist advising the parents, the questions are: is there a genetic cause, and what is the implication in terms of recurrence risk? For teachers and educational psychologists: what is the nature of the child's intellectual impairment, and how and in what way can education enhance the child's development and acquisition of skills? For public health practitioners: what is the extent and nature of need at a population level, and are there causes that are potentially preventable? For the psychiatrist, clinical psychologists, and community nurses: what is the relationship between the nature and extent of any impairments and disabilities and the emotional and behavioural difficulties that may have brought them in contact with specialist child, adolescent, or adult mental health services? Classification should have a defined purpose, and because the reasons may differ, so then the assessments and classification systems used will vary.

The diagnostic criteria are set out in DSM-V [8], Chapter V of ICD-10 [12], and the American Association of Intellectual Disabilities' *Intellectual Disability: Definition, Classification and Systems of Support* (AAIDD-11) [9]. There are three essential components to all these definitions: (1) evidence of significant intellectual impairment assessed using an established and valid assessment and normally considered to be present when there is a score of less than two standard deviations below the mean; (2) evidence of significant impairment in adaptive functioning, given the age and cultural background of the person concerned; and (3) these features having their origins in childhood, with delays in, or an inability to reach, specific well-recognized developmental milestones and educational attainments, usually with evidence of delay in the first 5 years of life. The exact nature, extent, and severity of the delay will vary across people considered to have an ID but may involve delay in one or more of the following areas: gross motor, sensorimotor, language, and adaptive behaviours. Revisions of the standard classification systems have led to a change in terminology, and 'intellectual developmental disorder' (IDD) is the term now used.

Intellectual developmental disorder (DSM and ICD systems) (American Psychiatric Association, 2013)

The structure of the classification within DSM-V has been shaped around developmental and lifespan considerations and within a

cultural context that recognizes the dimensional nature of psychiatric disorder. It encompasses how factors within an individual's environment in which a person lives influence whether a particular symptom has functional significance or not, thereby moving beyond a simply diagnosis. In DSM-V, IDD is included in a section headed 'Neurodevelopmental disorders', which also includes communication disorders, autism spectrum disorders (without distinguishing between Asperger's syndrome and autism), attention-deficit/hyperactivity disorder (ADHD), specific learning disorders, motor disorders, and other neurodevelopmental disorders. The focus is not primarily one of aetiology, but rather of quantifying the extent of disability by defining the level of intellectual impairment and listing the range of possible adaptive functions that might be impaired. The definition makes it explicit that the onset is within the developmental period and that IDD is the final common pathway of a number of potential aetiologies. Significant sub-average intellectual function is defined as an intelligence quotient (IQ) of 70 or below (using standard IQ tests). IQ is also used to help determine the level of ID (mild, moderate, severe, or profound). Adaptive functioning has to be measured against what would be expected for a person of that age, and the social and cultural experience of the person has to be taken into account. The Wechsler Scales for IQ and the Vineland Adaptive Behaviour Scales or the revised Adaptive Behaviour Scales of the American Association for Mental Retardation for characterizing functioning are established instruments for the measurement of these abilities for which there are normative data for comparison.

Bertelli *et al.* (2016) [13] have reported on development work undertaken to inform ICD-11, specifically whether or not ID should be classified as a health condition. They also proposed the use of the term 'intellectual developmental disorder', defined as 'a group of developmental conditions characterized by a significant impairment of cognitive functions, which are associated with limitations of learning, adaptive behaviour and skills'. They also suggested that the primary category, replacing that of 'Mental retardation', would be 'Neurodevelopmental disorders'. IDD would be a subset of this primary category and encompass 'a broad grouping of heterogeneous developmental conditions which result from significant interference with the growth and maturation of the brain during its early developmental phases including the prenatal and perinatal periods, infancy, childhood, and extending into adolescence'.

These developments in classification systems still use frameworks developed for the classification of illness and are thus unsatisfactory when it comes to ID. However, they do have value in bringing consistency and a degree of rigour to the classification process. Thus, it can be reasonably assumed when the classifications are properly used that there is a degree of reliability to the conclusion that an individual has an ID, and it will not have been based simply on appearance or educational abilities, but rather will have taken into account evidence for a delayed and atypical pattern of development and the continuing presence of intellectual and functional impairments. Depending on circumstances, the next question might well be whether there is a single major cause for such developmental delay (genetic or environmental) or whether that is unlikely and a combination of factors has contributed to a person's atypical developmental history. Given that these approaches have their limitations in terms of characterizing the possible multiple factors that may result in disability, other means of classification with more extensive core dimensions have been proposed.

Impairments, disabilities, and handicaps (World Health Organization, 1980)

In 1980, the WHO proposed a system of classification that attempted to overcome the limitations of other earlier methods of classification and, most importantly, aimed to guide intervention. **Box 21.1** summarizes the terms. In this system, ID can be conceptualized at different levels. At the level of 'impairment', in the case of ID, the organ system involved is the CNS. It is the impairment of this system for genetic, chromosomal, or environmental reasons that primarily affect the acquisition of developmentally related skills and the ability to learn. For the paediatrician or geneticist, a key task is to identify the reasons for any abnormality of brain development, and therefore intellectual impairment. This may have treatment implications, may guide prognosis, and most importantly may help to make sense of the disability for the parents of those affected. It may also have important implications for genetic counselling.

Box 21.1 World Health Organization's definitions of impairments, disabilities, and handicaps

Impairment

- Is any loss or abnormality of psychological, physiological, or anatomical structure or function.
- Represents deviation from some norm in the individual's biomedical status.
- Is characterized by losses or abnormalities that may be temporary or permanent.
- Includes the existence or occurrence of an anomaly, defect, or loss in a limb, organ, tissue, or other structure of the body, or a defect in a functional system or mechanism of the body, including the systems of mental functioning.
- Is not contingent upon aetiology.

Disability

- Is any restriction or lack (resulting from impairment) of ability to perform an activity in the manner or within the range considered normal for a human being.
- Is concerned with compound or integrated activities expected of the person or of the body as a whole such as represented by tasks, skills, and behaviours.
- Is the excesses or deficiencies of customarily expected activities and behaviour, which may be temporary or permanent, reversible or irreversible, and progressive or regressive.
- Is the process through which a functional limitation expresses itself as a reality in everyday life.

Handicap

- Is a disadvantage for a given individual, resulting from an impairment or a disability that limits or prevents the fulfilment of a role that is normal for that individual.
- Places some value upon this departure from a structural, functional, or performance norm by the individual or his or her peers in the context of their culture.
- Is relative to other people and represents discordance between the individual's performance or status and the expectations of his or her social/cultural group.
- Is a social phenomenon, representing the social and environmental consequences for the individual stemming from his or her impairment and disability.

The associated disability is the effect of the impairment on a person's ability to learn and acquire the new skills that come with development. These, in turn, enable the acquisition of increasingly advanced skills necessary for an independent life. The exact nature and extent of the disability may not only include ID, but also physical and sensory disabilities. The extent to which a given impairment results in a loss of function (disability) may well be influenced by the extent and nature of interventions such as special education or, for example, the correction of hearing loss through treatment and/or the use of a hearing aid.

The final level—that of 'handicap'—is a result of an interaction between the disability and the extent to which support is available or environmental adjustments made at a societal level. It is a measure of disadvantage. The extent of disadvantage can be ameliorated through, for example, the presence of support to enable individuals to go out, or environmental modifications (for example, wheelchair ramps) that diminish the impact of physical disabilities. Such interventions or environmental modifications maximize independence and thereby reduce disadvantage by ensuring that the impact of any given disability on an individual's independence and quality of life is minimized. Shakespeare (2006) [14] has argued that such a structure as this model helps to bring together the biomedical and social models of disability.

Functioning, disability, and health (ICF) (World Health Organization, 2001)

This new system of classification to replace the 1980 version was published by the WHO in 2001. The focus switched from a system

that was seen as just characterizing the negative to a system of classification that also emphasized the positive—what someone is able to do, rather than just what he/she could not do. While the context in this chapter is about people with ID, this system of health classification was developed by the WHO to enable the characterization of 'health domains' across the whole population and therefore should be seen to have universal application. Part 1 is the means whereby body functions, structures, and activities and participation can be characterized. Part 2 relates to 'contextual factors', whether in the environment or the individual. Fig. 21.1 illustrates the relationship between the different components of this classification system. The authors emphasize that it enables a multi-perspective approach and that it can be used by different disciplines as 'building blocks for users who wish to create models and study different aspects of this process'. Part 1 is divided into organ systems. With respect to people with ID, the sections on mental functions and structures of the nervous system may be of particular relevance, but these may be compounded by secondary disabilities, consequent upon abnormalities in structure and function of other organ systems such as those associated with sensory impairments. All of these categories are extensively subdivided. In Part 2, the focus is very much on the specific personal circumstances and the characteristics of the individual environment, including the health system and support available.

This system seeks to do two things. Firstly, it aims to provide a reliable structure for the description of the complex effects of ill health and those factors that might moderate its impact, thereby enabling accurate comparisons across countries, between cultures, and throughout the lifespan. Secondly, it aims to provide a more comprehensive framework to aid intervention, one that moves beyond

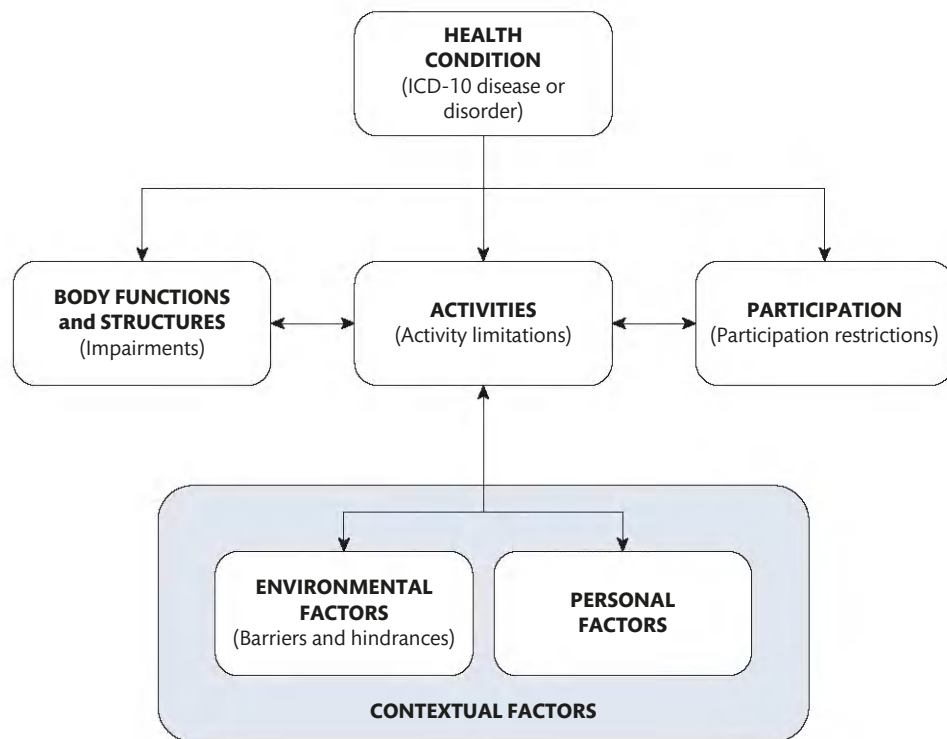

Fig. 21.1 The World Health Organization's International Classification of Functioning, Disability, and Health model of intellectual disability (WHO ICF model).

the single word or brief phrase of classification systems, such as in the ICD and DSM, to a more structured and meaningful description of an individual's strengths and difficulties. In this respect, it seeks to incorporate aspects of the biomedical and social models of disability and an understanding of the person within the context of his or her support network and culture.

This more dynamic and interactive concept of what it means to have an ID and what might contribute to the extent of social inclusions and well-being of that individual is illustrated in the American Association on Intellectual and Developmental Disabilities model of disability (or the AAIDD-11 model). The emphasis is on the moderating effects of individual past and present circumstances and the wider national policy that seeks to ensure that the 'mismatch between competency and environmental demands' is minimized and people with ID are fully included in society. The way in which these formulations influence the approach to treatment is described at greater length in Chapter 35.

Prevalence and aetiology of intellectual disabilities

As argued, the classification systems described in this chapter are not diagnostic. In addition, these different ways of conceptualizing ID emphasize that the paths to functional impairments are not simply to do with biology; there are interactions with respect to the extent and nature of the statutory provision of education, opportunities in adult life, and societal attitudes, all of which impact on ability and quality of life. Particularly in early life, the biomedical perspective is fundamentally about understanding the reasons for identified problems at birth or in childhood, and in this regard, there have been significant advances. Furthermore, the cause of a person's ID may also inform understanding of behaviour problems and mental ill health, as they affect people with ID and it has become increasingly recognized that this may be an important aspect to psychiatric assessment.

Two broadly distinct groups were identified through population-based studies such as the Aberdeen children's cohort study of the 1950s [15]. Firstly, there are children who have a definite or likely genetic abnormality or specific environmental causes with major effects on subsequent development. Secondly, there are those for whom there is no obvious single major cause for an early developmental delay and subsequent ID. Here, the small effects of many genes combined with social disadvantage may be crucial. The broad difference between these two groups are summarized in **Box 21.2**. This 'two group' perspective also illustrates the difficulty in arriving at a true prevalence of ID in any given community, given the fact that more than an IQ of below 70 is required when determining if someone should be considered to have an ID. The distribution of IQ in the general population is near normal, with a skew to the left, given the presence of specific neurodevelopmental disorders that are generally associated with a downward shift in IQ. Given this, a figure of 2–2.5% is estimated as the proportion of the population with an IQ of below 70. The problem then is to know how many of this group truly should be considered to have an ID. To address this issue, there have been studies of the administrative prevalence of people with ID, that is the percentage of any given geographic population known to ID services. Figures of between 0.4% to just under 1% are arrived at, depending on a number of factors, including whether

Box 21.2 Differences between biologically determined and subcultural ID

Biological

- Moderate/severe impairment.
- Significant impairment in adaptive functioning.
- Equal distribution across families of different socio-economic status.
- Parents and siblings usually of normal intelligence.
- Dysmorphic characteristics common.
- Other impairments and disabilities common.
- Neglect unusual.

Subcultural

- Mild or borderline impairment.
- Minor or no impairment in adaptive functioning.
- More common in families of lower socio-economic status.
- Intellectual ability impaired in family members.
- Dysmorphic characteristics unlikely.
- Other impairments and disabilities unusual.
- Neglect more common.

active screening for people with ID in the population was attempted, whether it was the number of people already known to ID services, whether children and adults were included, and specific geographic factors such as levels of deprivation. Studies indicate that there is a peak in prevalence in childhood and that there may be significant regional variations in any given country. Examples of studies from different countries include that of Sondenaa *et al.* (2010) [16] in Norway; McConkey *et al.* (2006) [17] in the island of Ireland; Larson *et al.* (2001) [18] in the United States; and Wen (1997) [19] in Australia. In an important study in the United States, Fujiura (2003) [20] estimated that there were a further 1.27% of people with mild ID who had very substantial needs and were effectively falling through the net of ID services. A detailed consideration of the epidemiology of ID is presented in Chapter 22.

The striking feature about the ID population is its heterogeneity, both in terms of the nature and severity of disability and also in the presence, or not, of individuals whose ID is due to one of many possible single major causes. Making up this population of people, there are those with specific environmental effects, such as fetal alcohol syndrome, very low birthweight, congenital infections, and maternal iodine deficiency (worldwide, of major significance—see [21]), and those with chromosomal and single-gene disorders which either arise *de novo* or are inherited. Down's syndrome due to trisomy 21 and fragile X syndrome due to X-linked *FMR-1* mutations are two examples that are relatively common. Other neurodevelopmental syndromes due to copy number variations have been identified [22], and advances in genetics using microarray technologies (sometimes referred to as molecular karyotyping) readily enable the identification of copy number variants of various sizes, including chromosomal rearrangements, deletions, and duplications [23]. Some of these are indicative of well-recognized chromosomal deletion neurodevelopmental syndromes (for example, Williams syndrome, cri-du-chat, etc.). Others with previously unrecognized chromosomal abnormalities are still to be properly characterized by phenotypy. Whether such copy number variants should be considered to be pathogenic or a normal polymorphic variation needs to be judged using established databases such as DECIPHER [24].

With improvements in DNA sequencing technology, identification of specific gene mutations is now more readily available, for example, detecting *de novo* or inherited gene mutations such as in the *TSC 1* and *TSC 2* genes that result in the tuberous sclerosis complex. These technologies make possible the characterization and subsequent identification of an increasing number of neurodevelopmental syndromes of genetic origin associated with ID. The specific causes of ID will be considered in more detail in Chapter 23.

The assessment of a child or an adult with ID referred to child and adolescent mental health services or to adult mental health or specialist services because of problem behaviour, and the subsequent formulation, will include any identified major cause of a person's ID such as Down's syndrome. As identification of genetic and environmental causes of ID develops and, with it, our understanding of their specific impact on brain development and functioning, so interventions for mental health and behaviour problems across the lifespan will only become more nuanced and hopefully more effective.

Core dimensions of disorders of behaviour and mental ill health in children and adults with intellectual disabilities

For health professionals working in mental health or specialist services for children, adolescents, or adults with ID, the primary focus of their work will be on prevention and treatment of secondary disabilities that may arise in the form of challenging behaviours or mental ill health. In people with ID, the development of challenging behaviour may be for a number of reasons, including: being an indication of the development of a comorbid physical or mental disorder, for example, mania presenting with irritability and aggression; changes in the environment and/or in the support provided; or the onset of a physical illness. In contrast, behaviours, such as self-injury or aggression, if long-standing, may be best understood from a developmental or behavioural perspective. In addition, the cause of a person's ID may also inform our understanding of the reasons for particular behavioural or mental health problems that occur. Well-known examples include the excessive eating behaviour and risk of psychopathology associated with Prader–Willi syndrome [25], the high rates of Alzheimer's disease affecting people with Down's syndrome [26], anxiety disorders affecting people with Williams syndrome [27], and severe self-injurious behaviour in people with Lesch–Nyhan and Smith–Magenis syndromes [28]. This observation of an association between specific neurodevelopmental syndromes and a characteristic behaviour was described by Nyhan as 'the behavioural phenotype of organic genetic disease' [29]. Such observations have very significantly altered our understanding of the aetiology and pathophysiology of such behaviours and psychiatric disorders.

Conceptually, comparative studies across different neurodevelopmental syndromes have challenged the orthodoxy of applied behavioural analysis and have required the development of more complex models, which recognize the role of the syndrome-specific developmental profiles and brain mechanisms in the aetiology of syndrome-specific behaviours (see, for example, [30] and [31] on Williams and fragile X syndromes, respectively; and [32]). Oliver and colleagues, for example, have reported very different behavioural and developmental profiles across different

neurodevelopmental syndromes, and they have gone on to propose specific models to account for their occurrence and maintenance [33]. Similarly, studies on Prader–Willi syndrome have proposed specific mechanisms to account for the different components of the behavioural phenotype [25] and the high rates of psychotic illness reported. The latter develops in early adult life but primarily affect those with the chromosome 15 maternal uniparental disomy (UPD) subtype [34]. These observations indicate the importance not only of developmental and bio-psychosocial perspectives, but also of having an understanding of the impact of particular patterns of brain development on behaviour and the risk of comorbid mental disorders. This diverse information informs intervention.

The task of assessment under such circumstances is the bringing together of what is known about the person and his/her behaviour with models of understanding that have been informed by research. This process of assessment and formulation is illustrated in Fig. 21.2 (see also [35] for discussion).

Core dimensions to the understanding of challenging behaviours therefore include establishing how best to conceptualize the problem that has led to the referral (for example, aggressive behaviour, self-injury, apparent loss of skills, etc.). The conceptual models include: (1) that of applied behavioural analysis, with behaviours being identified as having a cause and a function (such as demand avoidant or attention maintained) and being shaped by various contingencies and occurring in the context of certain internal or external setting conditions (for an overview, see [36] O'Reilly et al, 2016); (2) the developmental model, whereby such behaviours (for example, repetitive behaviours) are seen as normally a self-limiting characteristic of typical development and their continuation into later life as a consequence of delayed or an atypical developmental trajectory and/or such behaviours may be syndrome-specific (a

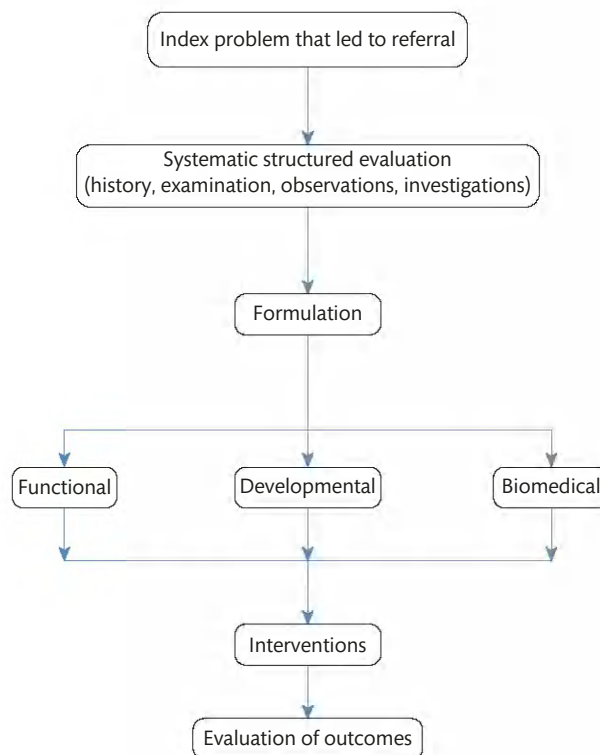

Fig. 21.2 Developing single or mixed models of understanding that inform intervention.

Table 21.1 Assessment of behavioural and comorbid psychiatric disorders in people with ID

Model	Key features	Interventions
Applied Behavioural Analysis (ABA) —also referred to as ‘functional analysis’, explains the presence of adaptive and challenging behaviours in terms of learning theory and the presence of specific contingencies that increase the probability of such behaviours	Through history and observation, the identification of specific ‘functions’ for behaviours and the predisposing, precipitating, and maintaining factors and internal and external setting conditions	The development of alternate strategies of support seeking to reinforce positive behaviours and develop adaptive responses to triggering events, and modifying predisposing and maintaining factors and setting conditions
Developmental —specific patterns of behaviour are explained as a manifestation of atypical and/or delayed development or as a direct consequence of the specific cause of that person’s ID (the presence of a ‘behavioural phenotype’)	Through history-taking and observations, the index behaviours are identified as similar to those that are usually self-limiting and occur as part of normal development or have been shown to occur in excess in those with a specific neurodevelopmental disorder	The development of specific interventions informed by other models that seek to reduce the severity and frequency of such behaviours and/or interventions that are syndrome-specific and informed by knowledge of that syndrome
Biomedical —a diagnostic approach that seeks to account for challenging behaviour or cognitive abnormalities or abnormalities of mental state on the basis of the co-occurrence of an additional developmental (for example, autism spectrum disorder, ADHD) or acquired comorbidity (for example, affective disorder, dementia, or physical illness)	Through history-taking and additional assessments and investigations, the identification of established signs and symptoms of comorbid psychiatric or physical disorders that the history indicates are likely to account for the development of the index problem that led to referral	The treatment of the specific developmental or acquired comorbid disorder using interventions known to be effective, including, for example, established psychological or pharmacological interventions

behavioural phenotype); and (3) the possibility that such problems may be integral to, or a consequence of, the development of comorbid physical or psychiatric illness. These different perspectives and their implications are summarized in [Table 21.1](#). They are not necessarily distinct. One example may be a person who has a history of a particular pattern of development characteristic of an autistic spectrum disorder and who finds change difficult to tolerate and anxiety-provoking, who also develops a comorbid illness that additionally impacts on behaviour.

In this context, the assessment of a person with an ID who has exhibited particular problematic behaviours (often referred to as challenging behaviour) is to provide an understanding of such behaviours in order to inform intervention. The core components of any assessment will include history-taking from the patient and/or an informant, a mental state examination and, where appropriate, a physical examination, investigations, and often structured observation over time. The core dimensions will include not only information on the nature, extent, and causation of the person’s ID, as described earlier, but also information on the onset and course of the index problem, a diagnostic assessment for the presence, or not, of comorbid mental or physical illness, and observations to indicate whether or not specific factors might precipitate, predispose to, or maintain such behaviours.

The history is crucial—whether some particular behaviour (for example, aggression) is long-standing or new and of recent onset is likely to lead to very different explanations. If long-standing, it may relate more directly to the nature of the person’s developmental disability, including emotional dysregulation [37] and environmental triggers. If the behaviour is new and of recent origin, then the possibility that it is a manifestation of the development of a secondary comorbid physical or psychiatric disorder is more likely. The diagnosis of comorbid psychiatric disorders, such as ADHD, severe anxiety, psychotic illness, affective disorder, or dementia, can be problematic where there is limited language development, and information from informants may be crucial. Specific modified diagnostic criteria have been developed, such as the DC-LD [38] and DM-ID [39] (Fletcher et al 2016), to inform the diagnostic process. These modified diagnostic criteria seek to balance

the tension between making them more applicable to the assessment of a population of people with impaired language development on the one hand, and on the other, ensuring that such modified criteria are still valid in terms of the condition they define. While for affective disorders, it may be possible to infer a depressed or manic state on the basis of observation or informant reports (tearfulness, agitation, over-activity, etc.), this is more problematic when it comes to the presence, or not, of thought disorder, hallucinations, or delusions. Illnesses such as schizophrenia are manifestations of disorders of brain mechanisms that underpin thought and perception, and if these have not fully developed, it remains uncertain whether they can be further impaired.

Based on the earlier work of Sovner, Hurley *et al.* (2016) [35] have summarized the specific problems that may lead to diagnostic uncertainty when assessing a person with an ID. These include: the baseline exaggeration of symptoms (such as self-injury) in times of stress; intellectual distortion in terms of the person’s understanding of the questions being asked about his/her mental state and an inability to appreciate the implications of the question; psychosocial masking whereby the symptomatology that occurs may be best understood within a developmental framework but is misconstrued as a manifestation of mental illness; and cognitive disintegration whereby a person with an ID may become grossly disorganized and apparently psychotic due to a lack of cognitive reserve, resulting in a more severe response to the development of a mental illness.

Being aware of these problems and taking a detailed developmental and longitudinal history in order to establish firstly a developmental diagnosis (ID, autistic spectrum disorder, ADHD) and secondly the presence, or not, of a comorbid diagnosis (mood disorder, dementia, etc.) is essential. However, a wider diagnostic approach also draws upon other conceptual models of understanding such as those of applied behavioural analysis.

The purpose of assessment in the context of concerns about a person’s behaviour is therefore to arrive at an understanding and to develop a formulation that sets out how the behaviour or problem in question is best understood in terms of these models. This then guides the interventions that follow. These may be as varied as

reducing anxiety by improving understanding and reducing the unpredictability of the social environment through the use of visual support, the development of strategies for defusing and best managing challenging behaviour, and the treatment of comorbid physical illness or mental ill health. Formulations should acknowledge the uncertainties that exist and ensure appropriate observations enable a systematic evaluation of the outcomes of a specific approach. Documentation of the assessment and the thinking that led to a particular intervention is essential and of great value, as it allows others now or in the future to better understand how a person's problems at that time were conceptualized.

Conclusions: the integration of perspectives

The core dimensions that make up the diagnostic criteria that define what is meant by the term 'intellectual disability' have been set out at the beginning of this chapter. The diagnostic criteria do not do justice to the complexity of the issues and have been supplemented by different ways of thinking that have emphasized the multi-dimensional and interactive nature of how we understand the link between impairments in brain development, the impact on function, and, in turn, the effect on quality of life and well-being. It is rarely sufficient simply to state that someone meets the criteria for having an ID. There is the need to consider the barriers that are limiting choice and opportunity. In recent years, there has been a bringing together of social and biomedical models of ID, appreciating that each has its place. Health and social support needs cannot be separated readily, as each depends on the other. With advances in our understanding of the causes of ID, it has also become clear that genetically determined neurodevelopmental syndromes have their own specific atypical developmental trajectories that may also include the emergence of particular patterns of maladaptive behaviours or an increased risk for developing comorbid mental and physical disorders that require treatment in their own right.

While ID falls within the group of disorders known as 'mental disorders', the health and social care needs of the majority of people with ID will not be met through child or adult mental health services, but instead in childhood by paediatric, child development, and family support services, and in adult life, by social services and primary care. However, for those whose mental state or behaviour causes concern and brings them in contact with specialist services for people with ID or with mental health services, there is an additional layer of assessment. The core dimensions of any assessment includes, but is not limited to, only a biomedical diagnostic approach. The application of different theoretical perspectives leading to a wider diagnostic perspective is required that seeks to understand why this problem has affected an individual in a specific way at this time. It is this process of assessment, often requiring expertise from different disciplines and information not only from the person him-/herself, but also his/her family and paid support providers and observations over time, which inform intervention. These interventions are often directly with the family or at the interface with social care and, as has been illustrated, may well take many forms.

Epidemiology and course of intellectual disabilities

Sally-Ann Cooper

Prevalence of intellectual disabilities

Intellectual disabilities are not uncommon. A meta-analysis of 52 studies reported the prevalence of intellectual disabilities to be 10.37/1000 population [1]. Prevalence varied according to age, income group of the country of origin (with higher rates from low-income countries), and study design. In high-income countries, rates for all ages combined were 9.2/1000, with the highest rates in child/young person populations only at 18.3/1000, and the lowest rates in adult-only populations at 4.9/1000. Careful understanding of the nuances is needed though to interpret these findings. Twenty-five of the studies included in the meta-analysis did not provide their age range; a further two did not report their observation period, and some studies were outliers in their findings.

An earlier review of studies between 1960 and 1987 is of lesser relevance to today's population, given cohort effects, almost all were studies in childhood/youth, and some provided very limited methodological information [2].

Studies of prevalence are, of course, challenging to conduct, as they ideally require intelligence to be tested on whole populations and therefore would incur considerable resources and costs. Other approaches can provide useful information, for example:

- Studies of administrative samples, such as people known to local authorities, which account for the majority of studies. These are the people who are making demands upon services, so the information is useful, but there are likely to be some people with intellectual disabilities not included in these samples and some people who do not have intellectual disabilities within the sample. For example, a rate of 4.3/1,000 aged 16+ was reported from Welsh local authorities as being in receipt or in need of intellectual disabilities services [3].
- Studies of people with a record of intellectual disabilities in their general practitioner medical records. In high-income countries, people are likely to have been assessed once their developmental delay was reported, so a record is likely to exist. However, this is complicated by the multiple and changing terminology in use over time. For example, a rate of 5.4/1000 patients aged 18+ was reported from an English database of 451 practices [4].

- Other secondary analysis of data routinely collected for other purposes. These have the attraction that large and whole-country samples can be analysed at relatively little costs, but findings reflect the original definitions used and the ways the data were collected. For example, a rate of 4.9/1000 aged 16+ (self-/proxy report) was reported from an analysis of Scotland's 2011 census [5], and a rate of 23/1000 school-aged children/young persons (teacher report) was reported from Scotland's 2015 pupil census [6].

Population intelligence approximates to a normal distribution, with a mean intelligence quotient of 100 and a standard deviation of 15 points. A statistical definition of intellectual impairments is an intelligence quotient less than two standard deviations from the mean, that is, <70. Simplistically, this would suggest that 2.3% of the population have intellectual impairments. However:

- The greatest deviation from the normal distribution of intelligence is at the extreme ends.
- A test error of 5 points is recognized—and a normal distribution would place 2.5% *within* the range of 70–75, so this can greatly influence identified prevalence.
- There is the Flynn effect (overly high scores due to out-of-date test norms).
- Intellectual disabilities is a social construct, not simply a statistical measure of impairments; the definitions of intellectual disabilities in the standard classificatory manuals ICD-10 [7] and DSM-5 [8] also include the functional requirement of the need for additional support. People learn throughout their lives, and so a child with an intelligence quotient of 69 will need additional educational support at school but, as an adult, may gradually acquire life skills to live independently, maintain relationships, hold employment, raise children, and not identify with intellectual disabilities nor be identified by others as having intellectual disabilities or put demand on services designed for people with intellectual disabilities.
- In countries that provide additional educational support for children with intellectual disabilities, there is a clear advantage to having the label, and flexibility in its use is beneficial for children with abilities that are a little above an intelligence quotient of 70 ('borderline' intellectual disabilities).

- People with intellectual disabilities experience premature death; hence, the proportion of the population with intellectual disabilities progressively falls within older age groups.
- Some children are not identified as having mild intellectual disabilities until they attend school, so rates are lower in pre-schoolers than in school-aged children.
- Cohort effects can influence rates over time, for example, the Zika virus epidemic in South America in 2015–2016 causing microcephaly, immunization, iodine, maternal smoking, and alcohol use, changes in termination rates of children with Down syndrome (currently falling, but could possibly increase with the introduction of first-trimester diagnosis) [9], improved antenatal, perinatal, and neonatal health care, increased survival of very low-birthweight infants, identification and treatment of metabolic causes of intellectual disabilities like phenylketonuria, better childhood education, access to cardiac surgery for children with Down syndrome, improved lifestyles, and access to health care.
- Migration and clustering (for example, congregate care and colonies) can influence spatial patterning at local levels and can be influenced by economic factors and local policy.
- Prevalence of mild intellectual disabilities is influenced by many cultural and societal factors that determine whether a mild learning impairment is likely to result in a functional disability, contributing to geographic differences.
- Clearly, there is an intellectual gradient across the population, and the ‘cut-off’ of 70 is purely arbitrary. Indeed, the accepted ‘cut-off’ was changed in 1973, substantially affecting rates.

Despite these complexities, there are some reasonably consistent findings across studies:

- In high-income countries, about 5/1000 adults have intellectual disabilities, falling to about 2/1000 over the age of 65 years.
- Prevalence is higher in children and young people than in adults.
- Prevalence is higher in boys/men than girls/women; across the whole of Scotland, 58% of people with intellectual disabilities are male [5].
- Prevalence is higher in low-income countries than in high- and middle-income countries for multiple reasons, including lifestyle and health care, although in areas that are less driven by technology, having mild intellectual impairments may be less disabling.
- The great majority of people with intellectual impairments have mild intellectual impairments (6 mild impairment: 1 moderate to profound impairments), and the majority with intellectual impairments in whom this is disabling have mild, rather than severe, intellectual disabilities.

Causes of intellectual disabilities

People with intellectual disabilities have some characteristics in common such as needing additional educational support at school, finding it hard to manage money and bills without help as an adult, and having difficulties remembering the temporal sequencing of events. Every person with intellectual disabilities is also unique. Each child inherits a range of genetic information from both their parents which is not shared with other children with intellectual

disabilities, and their environment and experiences shape their development, interests, likes, and ambitions. So even people with a clear genetic cause for their intellectual disabilities, such as Down syndrome, are unique from all other persons with Down syndrome, while sharing some characteristics.

Identifying the cause of intellectual disabilities is undertaken by paediatricians and clinical geneticists.

Genetic factors

Genetic studies indicate intelligence is highly heritable and can itself be conceptualized as a spectrum of syndromes [10]. Additionally, there are many genetic causes of intellectual disabilities, and recent and ongoing studies have found numerous copy number variants associated with developmental disorders, with the challenge of identifying which are clinically relevant. As described in Chapter 23, genetic conditions include:

- Chromosomal anomalies. Examples are trisomies—Down syndrome (trisomy 21), Patau’s syndrome (trisomy 13), Edwards’ syndrome (trisomy 18); autosomal deletions, for example, cri-du-chat syndrome (terminal deletion of chromosome 15), Williams syndrome (deletion on chromosome 7), and Prader–Willi syndrome and Angelman’s syndrome (deletion on chromosome 15 or uniparental disomy); and sex-linked conditions, for example, fragile X syndrome.
- Autosomal and sex-linked recessive conditions (particularly in communities with high rates of consanguinity). Examples are phenylketonuria; homocystinuria; galactosaemia; lipid disorders—Tay–Sachs disease, Gaucher disease, Niemann–Pick disease; and mucopolysaccharidoses—Hunter’s disease and Hurler’s disease.
- Autosomal and sex-linked dominant conditions. Examples include tuberous sclerosis and neurofibromatosis.

Regarding the prevalence of individual conditions in childhood:

- 1/800 has Down syndrome.
- 1/3600 boys and 1/4000–6000 girls have fragile-X syndrome.
- 1/7500 has Williams syndrome.
- 1/10,000 has Cornelia de Lange.
- 1/10,000–25,000 has Prader–Willi syndrome.
- 1/15,000 has Angelman syndrome.
- 1/20,000 has Smith–Magenis syndrome.
- 1/50,000 has cri-du-chat syndrome.

In addition to causing intellectual disabilities, physical conditions, and influencing trajectories, these genetic conditions can cause a range of other cognitive, behavioural, and mental health problems, for which the term ‘behavioural phenotype’ is used. Behavioural phenotypes have attracted particular research attention and can inform clinical assessments. Examples include high rates of dementia in middle-aged and older adults with Down syndrome [11, 12]; affective psychosis in Prader–Willi syndrome [13, 14]; self-injurious behaviour in Smith–Magenis syndrome [15]; and depression in phenylketonuria [16]. While these behaviours/mental ill health are genetically driven, it is important to avoid therapeutic nihilism, as interventions may help the individual. Additionally, some genetic syndromes effect physiological differences, which influence treatment choices, for example, the low rates of heart disease and low

blood pressure in Down syndrome, differing immunology causing high rates of thyroid disorders and other immunological disorders, and different mechanisms in dementia aetiology (an amyloid model), compared to typical Alzheimer disease. The length of this chapter precludes a detailed consideration of behavioural phenotypes, other than highlighting that clinicians do need to identify if their patient/client has a recognized genetic condition, and its associated physiological patterns.

Antenatal factors

Antenatal factors include:

- Teratogenic drugs and toxins. Examples include alcohol.
- Infections. Examples include toxoplasmosis, rubella, cytomegalovirus, herpes simplex, syphilis, Zika virus, and other infections.
- Fetal growth retardation. Examples include placental dysfunction and hypoxia.
- Endocrine. Examples include iodine deficiency.

Perinatal factors

Perinatal factors include:

- Birth injury, especially in premature and low-birthweight infants.
- Kernicterus.
- Infections.

Postnatal factors

Postnatal factors include:

- Infections, encephalitis.
- Toxins.
- Brain tumours.
- Head injury.
- Starvation.

Extreme prematurity has been shown to account for 17% of cases of intellectual disabilities; together, gestational age and birthweight centile have been reported to account for 26.6% of intellectual disabilities [17]. The month of conception (January–March conception, compared with summer conception) has been reported to account for 15% of intellectual disabilities, postulated to be related to vitamin D or infections at the critical first trimester stage of development [18]. Fetal alcohol syndrome is underdiagnosed.

Mental ill health

Two recent systematic reviews reported that mental ill health is more common in children, young people, and adults with intellectual disabilities than in the general population [19, 20]. Problem behaviours, such as aggressive, self-injurious, and destructive behaviour, are very common in people with intellectual disabilities and do not have an obvious comparator in the general population. Widely reported prevalence rates have been given in view of differences in populations studied (some from mental health services and so their rates are biased and inflated), methods used to identify mental ill health, the types of conditions included within the reported mental ill health (particularly whether or not problem behaviours and/or autism are included), the diagnostic criteria used

(ICD-10 and DSM-5 under-report mental ill health in this population if strictly applied, especially for problem behaviours), and whether studies are reporting point or lifetime prevalences or fail to indicate which [21].

It is not surprising that mental ill health is more common in people with intellectual disabilities, compared with the general population, in view of complex biological factors, psychological and social disadvantages, and additional developmental factors [22].

Population-based studies in children and young people with intellectual disabilities reported the prevalence of mental ill health, including problem behaviours, ranging from 30% [23, 24] to 50% [25]. A robust UK study reported a rate of 36% in 641 children and young people (aged 5–16 years) with intellectual disabilities, compared with 8% of 17,774 children without intellectual disabilities in the same surveys: the children and young people with intellectual disabilities accounted for 14% of all children with mental ill health [26].

Population-based studies in adults with intellectual disabilities reported the prevalence of mental ill health, *excluding* problem behaviours, ranging from 14.5% (when also excluding ADHD, autism, dementia, and personality disorder, people aged 65 and over, and people with severe intellectual disabilities [27]) to 43.8% (adults with moderate to profound intellectual disabilities only [28]). The largest adult population-based prevalence study, in which each person was individually assessed, included 1023 adults with intellectual disabilities [29]. It reported a point prevalence of mental ill health of 40.9%, or 28.3% excluding problem behaviours, and used more robust methods than previous smaller studies [30, 31].

Some types of mental ill health are more common in people with intellectual disabilities, including schizophrenia [32, 33], bipolar disorder [34], dementia (particularly in adults with Down syndrome), but also in adults with intellectual disabilities of other or unknown causes [35, 36], autism [26, 37, 38], ADHD [26], and pica. Prevalence rates of mental ill health in children and young people with intellectual disabilities are reported to be higher than for other children and young people for 27 out of 28 ICD-10 categories [26]. Depression and anxiety are common in people with intellectual disabilities, but probably not more so than in the general population [34, 39].

Problem behaviours are very common in the population with intellectual disabilities. In a large-scale, population-based study of adults aged 16+ years, 22.5% were reported to have problem behaviours [29], and of those, 10% had aggressive behaviour [40] and 5% had self-injurious behaviour [41].

The incidence of mental ill health in adults, excluding problem behaviours, has been reported to be 12.6% over a 2-year period—8.3% for affective disorders, 1.7% for anxiety disorders, and 1.4% for psychotic disorders [42, 33]. The incidence of dementia has also been reported for older adults with intellectual disabilities NOT due to Down syndrome and found to be considerably higher than for the age-matched general population. At the age of 65 years or older, the standardized incidence ratio for dementia was 4.98 [43]. Regarding problem behaviours, the 2-year incidence of aggression was reported as 1.8%, and of self-injury 0.6% [40, 41]. Full remission of psychosis after 2 years was only 14.3% [33], aggression 27.7%, and self-injury 38.2% [40, 41]. These findings suggest that while incidences are higher than those found in the general population, much of the current high prevalence of mental ill health is due to

enduring disorders, rather than new episodes, though research on this is limited in quantity.

Studies on common types of mental ill health using general population longitudinal cohorts show high and enduring rates of depression and anxiety in adults with intellectual disabilities, compared with the general population [44–46]. These studies have the attraction of drawing direct comparisons with the general population but included few people with intellectual disabilities, and of those, most had mild learning disabilities and very few severe intellectual disabilities, in view of their design and also with differential loss to follow-up of people with intellectual disabilities, so findings may be biased.

Longitudinal studies have also reported on the mental ill health of children and young people with intellectual disabilities. In an Australian cohort study, children and young people aged 4–19.5 years were followed over four waves of data collection over 14 years. High rates of psychopathology levels were reported, with hyperactivity more prominent at younger ages and persisting for longer in children/young people with more severe degrees of intellectual disabilities. Emotional disorders emerged later in childhood [47–49]. Similar findings have been reported from longitudinal studies in children with intellectual disabilities/borderline intellectual disabilities (excluding those with more severe intellectual disabilities or with additional sensory or physical disabilities) in the Netherlands [50, 51].

Neurodevelopmental disorders cluster

Gillberg coined the term ‘ESSENCE’ (Early Symptomatic Syndromes Eliciting Neurodevelopmental Clinical Examination) to describe this [52]. He defined ESSENCE as major problems in: motor skills; general development; speech and language; social interaction and communication; behaviour; hyperactivity or impulsivity; hypoactivity; inattention; and sleep or feeding difficulties. Genetic data also increasingly support clustering of neurodevelopmental (including epilepsy) and mental health problems [53].

Physical ill health, disabilities, and multi-morbidity

Additional physical ill health and disabilities are common in people with intellectual disabilities. Indeed multi-morbidity is typical for people with intellectual disabilities [4, 54], and hence too is polypharmacy. This has implications, as it adds complexity to mental and physical health assessments (for example, distinguishing between complex partial seizures, depression, and anti-epileptic drug side effects), in assessments that are also challenging due to communication needs, impairment of understanding, and visual and hearing impairments, all of which are common in people with intellectual disabilities. This probably contributes to the under-recognition of mental ill health that occurs in this population. It also means that there are more disease–disease, drug–disease, and drug–drug interactions to take account of when managing conditions. For example, postural problems and deformities (common in people with cerebral palsy and people with profound intellectual disabilities) impact upon gastro-oesophageal reflux disease (GORD), which is extremely common in people with intellectual disabilities, more so the more severe their intellectual disabilities, and can cause anxiety. GORD

occurs in about 50% of adults with intellectual disabilities; a consequence is that drugs to manage osteoporosis cannot be tolerated, and osteoporosis is common in this population. Many psychotropic drugs, commonly prescribed for people with intellectual disabilities, lower the seizure threshold, and epilepsy is common. People with intellectual disabilities may not be able to self-report drug side effects and are reliant on others observing these; hence, pharmacovigilance is essential. Anticholinergic burden due to polypharmacy of drugs with these side effects is an issue for people with intellectual disabilities, with potential negative side effects such as further impairment of cognition [55].

Long-term conditions are more common for adults with intellectual disabilities, compared to the general population. Children, young people, and adults with intellectual disabilities have higher rates of epilepsy (25% [56]), visual impairment (50%), hearing impairment (40%), impacted cerumen, GORD (50% [57]), dysphagia [58], constipation, diabetes, thyroid dysfunction, osteoporosis, contractures, mobility and balance impairments, injuries, eczema, xerosis, obesity, and heart failure, compared with the general population [4, 54, 59, 60]. Asthma is also reported to be more common in people with intellectual disabilities and may be due to obesity, but it is possible that some of this is a misdiagnosis of reflux pneumonitis or aspiration pneumonia. In some cases, the excess physical ill health burden relates to the person’s underlying cause of intellectual disabilities (for example, thyroid dysfunction and Down syndrome), but lifestyle and environmental factors and suboptimal support and health care are also important contributors. Some problems predispose to others. For example, psychotropic drugs (prescribed to about 20% of the adult population with intellectual disabilities) [61] can increase diabetes risk, as can obesity which is common [62], and sedentary lifestyles, also common [63]).

In view of the shorter life expectancy of people with more severe intellectual disabilities and those with syndromal causes for their intellectual disabilities, older adults with intellectual disabilities have different characteristics, compared with younger adults. Older adults as a group have milder levels of intellectual disabilities and lesser quantities of additional physical ill health. The profile of their health needs changes, as they have lower rates of the physical ill health and disabilities associated with severe intellectual disabilities but start to acquire physical ill health associated with ageing. In extreme old age, the health characteristics of people with intellectual disabilities becomes more like those of the general population.

Lifespan

People with intellectual disabilities do not live as long as other people; and life expectancy is shorter, the more severe the person’s intellectual disabilities. A recent systematic review included 27 studies and found that although life expectancy has improved in recent decades, it is lower, compared with the general population, by about 20 years, with no evidence of any closure of the inequality gap [64]. More severe intellectual disabilities and/or additional comorbidities were associated with the shortest life expectancy. Standardized mortality rates showed a greater inequality for women than for men, for reasons that are unknown. The main causes of death differed from the general population, with respiratory disease the most common, then circulatory diseases (with

greater congenital, and lesser ischaemic, disease compared with the general population). Cancer was less common, compared with the general population, and the cancer profile differed from that in the general population.

Specific syndromes can also shorten life expectancy, including death *in utero* and in infancy and childhood. Life expectancy for people with Down syndrome has improved markedly over the last 50 years, with access to treatments for congenital heart disorders and improved surgical techniques and post-operative care accounting for much of this [65], but is still reported to be 30 years less than in the general population. Down syndrome has been reported to occur in 1.2/1000 pregnancies, of which 78.1% are live births. Survival at 1 year for live births in 1995–1999 was 91.6% [66], and 85% are estimated to survive to 10 years [67]. The proportion of people with Down syndrome reduces in older cohorts; 75% survive to 50 years, 50% to 58.6 years, and 25% to 62.9 years [68].

The shorter life expectancy of people with intellectual disabilities does not just relate to syndromal causes of death and multimorbidity. Some deaths are potentially avoidable, being amenable to good-quality care. A confidential inquiry reviewed 247 deaths of people with intellectual disabilities, finding that 22% were aged less than 50 years [69]. Avoidable deaths from causes that could have been amenable to good-quality health care occurred in 37%, compared with only 13% of the general population [69]. A further large-scale study (16,666 people with intellectual disabilities—656 deaths, compared with age-, gender-, and practice-matched controls, $n = 113,562$ —1358 deaths) also found high rates of deaths amenable to good-quality health care at 37.0%, compared with 22.5% in the general population [70]. The authors also pointed out the standard definition of amenable deaths they used did not include some types of death that could be considered amenable to health care and which they found occurred more commonly in people with intellectual disabilities, including deaths from urinary tract infections and aspiration pneumonitis [70]. Hence, these disturbing figures are actually an undercount of the deaths amenable to good care that people with intellectual disabilities experience.

Improving health care for people with intellectual disabilities needs to become a priority for clinicians, service commissioners, and policymakers.

Aetiology of intellectual disability and its clinical features

Judith L. Rapoport, Dale Zhou, and Kwangmi Ahn

Causation

The complexity of causes

Intellectual disability (ID) can follow many biological, environmental, and psychological events. Most do not directly, or inevitably, lead to ID. Genetic causes may be hereditary or non-hereditary and may or may not produce specific syndromes. It is no longer easy to separate genetic from non-genetic causes; for example, some environmental causes, such as lead, contribute to ID and can produce heritable epigenetic changes. In other disorders, environmental factors are more prominent or perhaps more easily measured. This is a rapidly changing area, as advances in genetic methodology and the ability to share large samples have greatly increased the identification of genetic determinants of severe ID [1].

It is presumed that abnormality in prenatal brain development accounts for many, if not most, cases of ID. Neurological symptoms during the neonatal period are strongly associated with prenatal developmental disturbances. Placental insufficiency may lead to malnutrition, intrauterine growth retardation, and prematurity. One of the most important examples of impaired prenatal brain development is that of fetal alcohol spectrum disorders (FASD). Research on this very common cause of ID has focused on several neurotransmitters, insulin resistance, alterations of the hypothalamic–pituitary–adrenal (HPA) axis, oxidative stress, and epigenetic factors [2]. Other toxic substances, such as lead, not only contribute to intellectual impairment, but may also produce heritable epigenetic changes [3–5].

As discussed elsewhere, ID frequently coexists with other medical, neurological, and psychiatric disorders, which may further restrict interactions with the environment and further delay the development of the individual.

Classifying causes

It is difficult to establish the prevalence of ID, as perhaps 70% of those so classified have relatively mild disturbance. Rates are higher among very low-birthweight infants, with substantial variations in rates of mild ID by socio-economic status, but similar rates for

severe ID [6]. There are many possible bases for classifying causes. Here too, the issue is complex with respect to underlying brain abnormalities. Both genetic and non-genetic forms of ID share cellular and cortical neurophysiological pathogenetic signatures that result in anomalous function of pyramidal neurons [7].

Classification by timing may be more successful, although here too pre-existing risk factors, such as low iodine in certain geographic regions, complicate recommendations for screening for thyroid dysfunction [8, 9]. Thus, screening of environmental, maternal prenatal, and neonatal measures may all be indicated (for example, folic acid deficiency). Separating a group with known genetic syndromes has been useful to date, but because these syndromes are proliferating and often overlap substantially, it may be unclear in the future how helpful these will be as primary classifiers as the number of syndromes continue to *increase*.

This chapter is divided into four sections:

1. ID in which there are well-documented external prenatal environmental factors.
2. ID with salient genetic causes.
3. ID treatment and prevention.
4. ID-associated syndromes in which multiple clinical manifestations are apparent, in addition to ID (see Chapter 22).

The section on treatment and prevention focus on the nature and timing of treatment and preventive efforts.

Prominent environmental causes

External prenatal factors

Fetal alcohol exposure

Fetal alcohol spectrum disorder (as it is commonly called in the literature) is one of the main causes of ID worldwide and the leading non-hereditary cause of ID in Western geographic regions, with 1% of children in the United States affected. It is now identified in DSM-V through a specifier and is no longer a separate entity in ICD-11. Part of the reason for this diagnostic change is the variability

in, and non-specificity of, neurological and physiognomic features. Research has focused on a broad array of physiological abnormalities, as well as epigenetic pathways [2]. Current treatment involves support to the families with symptom-focused cognitive and psychiatric remediation [10]. Future efforts must prepare for better strategies for the prevention of this major societal problem.

Congenital hypothyroidism

The essential role of thyroid hormone in CNS maturation has been clearly demonstrated, and the critical period for this CNS dependency extends from fetal life to 24–36 months of age [9]. The benefit of early treatment was apparent, and with the availability of congenital hypothyroidism (CH) screening through assays for thyroxine and thyroid-stimulating hormone and an adaptation of these methods to the filter paper blood spots used for phenylketonuria (PKU) screening, CH screening is now a standard of care. The majority of children who were treated early experience normal growth and normal-range IQ values [11]. Widespread micronutrient deficiencies exist with pregnant women and their children under 5 years at highest risk. Iron, iodine, foliate, and zinc deficiencies are the most widespread and all contribute to poor growth and intellectual impairments [12].

External postnatal factors

Brain injury

Traffic accidents are a major source of brain trauma. Here too, multiple factors are involved in recovery [13, 14].

Meningitis

Meningitis after the neonatal period can result in ID, particularly in severe cases. Lead is a potent neurotoxicant, with demonstrated effects on the brain of children and adults. There is a documented association between early life exposure to lead and impaired cognitive function in children. These impairments are influenced by the degree of exposure, indicated by childhood blood lead levels and sociodemographic factors, with impairment generally falling in the milder range [15, 16]. Early treatment is of great importance, alongside environmental monitoring.

Salient genetic causes

Twin and family studies in various populations and patient cohorts revealed a strong genetic basis, with 30–90% heritability, depending on the diagnostic category and study design [17, 18]. Similar to IQ, mild ID ($50 < \text{IQ} < 70$) is heritable and caused by many genes of small effect [17, 19–22]. However, a major cause of severe ID could be rare, non-inheritable *de novo* point mutations [23–25], along with environmental factors [26, 27].

Genetic causes of ID are thought to account for 25–50% of ID cases and are more frequently observed in the group of severe ID, accounting for up to 65% [28–33]. Genetic causes of severe ID include chromosome aneusomies (aneuploidy and translocation), chromosome structural abnormalities, and monogenic disease. Unfortunately, ID displays extreme genetic locus heterogeneity, and about 50% of ID still remain without any molecular diagnosis [34]. ID shares some genetic mechanisms with the broader group of

neurodevelopmental disorders [30]. The combination of novel technology, such as next-generation sequencing (NGS), and increased biological understanding is rapidly increasing the diagnostic yield of genetic tests in ID and improving the usefulness of genetic test results for patients and families involved [35–37]. In addition, it is providing possibilities for carrier testing and prenatal screening, as well as new targets for treatment [25].

Chromosome aneusomies

As chromosome aneusomies are the most common known causes of ID, several new methods, based on high-density microarray techniques or NGS followed by karyotype analysis, have been developed and widely used over recent years to increase detection rate of subtle aneusomies [21, 38–40]. These causes explain up to 15% of severe cases [41, 42]. Trisomy 21, or Down's syndrome, is the most common chromosomal aneuploidy associated with ID, with an estimated frequency of 1.5 in 1000 pregnancies and accounting for 6–8% of all ID. Other common chromosomal abnormalities include X chromosome aneusomies and a variety of cytogenetically balanced and unbalanced translocations. The most frequent X chromosomal aneusomies are XXY (Klinefelter's syndrome), XO (Turner's syndrome), and XYY syndrome, accounting for 1% of severe ID. There is also a wide range of recurrent sub-chromosomal deletions or duplications such as Prader–Willi and Angelman syndromes (15q11.2–q13 deletion), Williams–Beuren syndrome (7q11.23 deletion), Smith–Magenis syndrome (17p11.2 deletion), and di George syndrome (22q11.2 deletion). The wide application of high-density microarrays increases the identification of copy number variants (CNVs) associated with ID. Approximately 15–20% of patients with ID had microdeletions and duplications revealed by array-based CNV analyses [39, 43–45]. These CNVs include both rare *de novo*, as well as rare inherited, mutations. It is anticipated that clinical overlap will make their syndromal phenotypic distances less useful, as more genetic events are identified.

Single-gene causes

It has been estimated that mutations in more than 700 different genes may cause ID [25]. These mutations include X-linked, autosomal dominant, and autosomal recessive ID and can be inherited or arise through *de novo* events. Until NGS methods came into use, only a handful of autosomal ID-associated recessive genes were discovered, possibly due to limitations of cytogenetic and sequencing technology and the absence of large families with autosomal forms of ID [25]. Most metabolic disorders belong to autosomal recessive forms of ID (ARID), caused by single mutated genes that disturb metabolism by deficient enzyme activity. These diseases include PKU and homocystinuria. For the last decade, over 300 genes have been identified for ARID, mostly by homozygosity mapping using single-nucleotide polymorphism (SNP) microarrays in large consanguineous families and subsequent follow-up of candidate genes by Sanger sequencing [46, 47]. In outbred populations, ARID may account for about 10–20% of the cases, while autosomal recessive disorders were found to be up to 3-fold more frequent among inbred, compared to non-inbred, cases [48, 49].

Autosomal dominant genes cause tuberous sclerosis, myotonic dystrophy, Gorlin syndrome, neurofibromatosis type 1, Apert syndrome, Menes syndrome, and Huntington's disease. The trio-based exome sequencing design allowed the identification of dominant

de novo mutations (heterozygous) or small indels associated with severe, sporadic non-syndromic ID, accounting for 13–55% of patients with high locus heterogeneity [17, 35, 50]. Exome sequencing also rapidly identified autosomal dominant sporadic syndromes associated with ID such as Schinzel–Giedion syndrome [51], Kabuki syndrome [52], and Bohring–Opitz syndrome [53].

For many years, research into the molecular causes of ID has focused on the X chromosome because males are affected more often than females [54–56]. Mutations in more than 100 X-linked genes are now known to cause ID, accounting for 10–12% of males with ID, with none of these genes individually explaining more than 0.1% of ID [57–59]. The most well-known example is fragile X syndrome, which is caused by expansion of a CGG repeat in the *FMR1* gene (fragile X mental retardation 1) and is the second most common genetic cause of intellectual disability, accounting for about 0.5% of ID, after Down syndrome [60].

The genetic causes of ID are rapidly being uncovered and will be essential for genetic counselling, diagnostics, and treatment in the future. Microarrays for mutation screening of known disease genes, as well as exome and whole-genome sequencing, will likely become essential tools, both for clinical diagnostic purposes and research.

Treatment and prevention

Screening/prevention/preatment

Newborn screening—tests that can be done within the first hours or days of life and have a potential for preventing severe health problems—has evolved from simple blood or urine tests to a comprehensive and complex system, detecting over 50 different conditions, including those relevant to ID such as CH and several amino acid deficiencies. The newborn blood spot taken from a heel stick is mandated in most of North America and Europe [61].

Table 23.1 shows the timing and nature of screening for genetic disorders and those with prominent environmental factors. Box 23.1 lists the diagnostic examinations for presumed or established intellectual disabilities.

Environmental/social assessment

FASD—prenatal counselling of the mother and family, family counselling, and prenatal care.

Table 23.1 Aetiology of intellectual disability based on time and mechanism of the injury to the central nervous system and history for timing of diagnosis and treatment

Aetiology	History
Genetic causes: chromosomal, CNV, single gene, single base pair Mitochondrial disorders	Family history: recurrent miscarriages, consanguinity
External prenatal factors: infections, maternal illness, for example, hypothyroidism, micronutrient deficiency	Gestational history: maternal infection, trauma, drugs, alcohol, exposure
Postnatally acquired disorders Infection Brain trauma Psychosocial, for example, environmental stimuli	Social history History of meningitis, rubella Trauma, toxicity, for example, lead

Box 23.1 Diagnostic examination of presumed or established intellectual disability

- General examination for dysmorphic features.
- Neurological, ophthalmological, audiological, cardiological, and neuropsychological assessments.
- Full blood count, thyroid function.
- Genetic screening (Table 23.1).
- Blood/urine.
- Neuroimaging.
- Neurophysiological EEG.

Prenatal screening/maternal assessment

There have been potentially revolutionary changes to prenatal diagnosis and screening and include both imaging and tissue diagnoses. The discovery of cell-free fetal DNA in maternal plasma opened up a new frontier in the quest for a non-invasive prenatal screening strategy [62], since validated in several studies [63, 64]. Future population studies will be essential to evaluate these data, as the overall cumulative prevalence of many genetic risk markers is not established.

Newborn/infant tests and treatments (for example, thyroid)

Newborn screening for CH—awareness of an iodine-poor environment and CH screening at birth now permit levothyroxine therapy by 4–6 weeks of life, which represents the standard of care.

Syndromes causing intellectual disability

Classic syndromes are usually associated with chromosomal abnormalities and large structural variations, since this type of alteration is more likely to lead to additional phenotypic presentations other than ID alone. This section deals with some of the syndromes that increase to have ID. In syndromic ID, patients present with one or multiple clinical features or comorbidities, in addition to ID. However, symptoms of some syndromes may be so subtle that they are extremely difficult to diagnose, unless the features are looked for specifically in the context of a known genetic defect previously associated with these features. Thus, the distinction between syndromic ID and non-syndromic ID is often blurred [30].

Table 23.2 describes the most well-known syndromes causing ID.

Tuberous sclerosis occurs in 1 in 7000 people, with a majority arising from spontaneous mutations to 9q34 and 16p13. This syndrome is characterized by a triad of epilepsy, intellectual deficiency, and a characteristic facial skin lesion.

Turner's syndrome occurs in 1 in 10,000 female births and is caused by a loss or an abnormality of one X chromosome in women. Ninety-nine per cent of affected fetuses miscarry. Affected women exhibit normal intelligence and verbal abilities, with significant variation. They show deficits in spatial perception, visual motor integration, affect recognition, visual memory, and attention. Furthermore, they tend to display hyperactivity and distractibility during childhood, poor social skills, immature social relationships, and low self-esteem in adolescence. Dysmorphic features include: a webbed neck, a low hairline at the rear of the head, widely spaced nipples, and multiple pigmented naevi. Some have cardiovascular abnormalities.

Table 23.2 Most prevalent syndromes associated with intellectual disability

Classification	Prevalence	Genetic abnormality	Behavioural and cognitive features	Physical features
Klinefelter's syndrome	1 in 660 live births (possibly increasing)	Additional X chromosome(s) in phenotypic males	IQ score ranges from 60 to 130, with greater impairment to verbal IQ. High rate of learning disability, speech and motor delays, and impairment in language processing. Adults may have increased impulsiveness and rate of antisocial behaviour	Small testes; hypergonadotropic hypogonadism; azoospermia; infertility; increased luteinizing hormone and follicle-stimulating hormone; hypogonadism; gynaecomastia Below-average height, weight, and head circumference at birth; accelerated growth and increased height from 3 years onwards Increased risk of diabetes and metabolic syndrome, abdominal obesity, autoimmune diseases, osteopenia, cryptorchidism, decreased penile size (children), congenital malformations (for example, clinodactyly), cardiovascular abnormalities, breast cancer, osteoporosis, mediastinal cancers
XXX syndrome	1 in 1000 female births	47,XXX resulting from primary non-disjunction of a maternal or paternal X chromosome during meiosis. Only 40 cases of 48,XXXX reported Risk increases with advanced maternal age	Affected women have IQs of between 80 and 90, with increasing severity of IQ deficits corresponding to additional X aneuploidies. Women with XXXX syndrome have IQs of 55–75 Developmental delay; motor and speech delays; higher risk of cognitive deficits and learning disabilities in school-age years. Some experience relatively poor short-term auditory memory Under-activity and withdrawal have been reported; slowed emotional development	Hypotonia, low birthweight, and small head circumference in newborns. Increased height in adulthood, with a low body mass index, epicanthal folds, hypotonia, and clinodactyly Unimpaired fertility, but possible premature ovarian failure and recurrent spontaneous abortions Seizures, renal, and genitourinary abnormalities
XXY syndrome	1 in 1000 live male births	Primary non-disjunction of the Y chromosome; 10% have mosaic 46,XY/47,XXY chromosome complement. Offspring with two Y chromosomes are rare	Affected men have lower mean intelligence scores, but with large overlap with the normal distribution Poor social adaptation, distractibility, hyperactivity, temper tantrums, and speech and language problems are relatively common in childhood Increased frequency of XYY men among inmates in special prisons Balance and co-ordination minimally compromised	Increase in body and leg length between years 4 and 9. As adults, most are over 10 cm taller than their fathers Sexual development and fertility are unaffected
Down's syndrome	1 in 2000 at maternal age of 30 1 in 100 at maternal age of 40	Additional chromosome 21. Rarer cases caused by chromosomal translocation or mosaicism	Adults have moderate ID Affected children have some degree of specific speech and language delay Stubbornness and obsessional features over-represented	Muscular hypotonia that typically improves with development, short stature in adulthood, with characteristic facial appearance, eyes sloping upwards and outwards, wide nose bridge and unusually shaped head, transverse crease on the arm, large cleft between first and second toes, relatively short upper arms Thyroid abnormalities, heart abnormality, gastrointestinal abnormality, changes in blood cells
Velo-cardio-facial syndrome	1 in 2000 people	Microdeletions at 22q11 (90% of cases arise <i>de novo</i> ; 10% inherited)	Learning disability, as well as speech and language problems are common Difficulties with social interaction. Anxiety, social withdrawal, and other disorders have also been reported	Physical features include cardiac abnormalities, including ventriculoseptal defects, pulmonary stenosis, and cardiac outlet abnormalities Prominent nose with broad bridge and squared tip, small head, or small lower jaw; ocular abnormalities; cleft palate; short stature and long, thin, hyperextensible fingers

Table 23.2 Continued

Classification	Prevalence	Genetic abnormality	Behavioural and cognitive features	Physical features
Neurofibromatosis type 1	1 in 3000 births	Associated with 17q11.2, which produces neurofibromin and is involved in regulating cell division and tumour suppression; 50% of all new cases arise in unaffected families due to high spontaneous mutation	Speech or language abnormalities, learning disability, specific developmental disorders involving reading writing, or numeracy Distractibility, impulsiveness; visuospatial abnormalities, lack of co-ordination	Diagnosis usually requires two or more of the following symptoms: six or more light brown skin lesions of >5 mm in diameter before puberty or 15 mm after puberty; two or more neurofibromas or one plexiform neurofibroma; freckling of the inguinal or axillary regions; two or more Lisch nodules; optic nerve glioma; bony lesions; a first-degree relative with the disorder Non-enhancing hyperintensities on MRI located at the cerebellum, basal ganglia, brainstem, and thalamus Tumours from connective tissue of nerve sheaths
Fetal alcohol syndrome ²	0.33 per 1000 births	Exposure to alcohol at any stage of fetal development inhibits <i>N</i> -methyl- <i>D</i> -aspartate receptors, which mediate post-synaptic excitatory effects of glutamate, and affects cell proliferation and causes cognitive impairment	Usually mild to moderate ID, but may be severe Reduction in attention span, over-activity, irritability in infancy, and co-ordination problems	Facial dysmorphism: thin upper lip and smooth philtrum, small jaw, low-set abnormal ears, and palate abnormalities. Growth retardation, skeletal abnormalities, for example, deformed ribs and sternum, spinal curvature, dislocated hips, fused or webbed or missing fingers or toes, limited joint movement, small head Heart abnormalities and urinary tract anomalies Small brain with abnormally arranged cells
Fragile X syndrome	0.3 in 1000	X-linked trinucleotide repeats eventually halt function of the <i>FMR1</i> gene Healthy individuals have around 50 repeats; carriers with 50–100 repeats are considered to have the pre-mutation, and carriers with over 230 repeats are considered to have the full mutation	Mild to moderate ID. Severity of ID in women depends on the random proportion of cells with X inactivation. Pre-mutation carriers are intellectually unimpaired Problems with attention and concentration may be disproportionate to the severity of ID Speech and language delay; disorganized speech Some degree of social impairment. Men with fragile X syndrome are usually affectionate, without the aloof quality typical of autism Self-injury; stereotyped behaviour, for example, hand flapping	Large testes apparent after puberty; long face; high-arched palate; large forehead, ears, and lower jaw; hyper-extensible joints, flat feet; cardiovascular abnormalities; ear infections; cataracts
Congenital hypothyroidism	1 in 4000. Occurs more commonly in females	Majority of cases caused by deficiency of iodine in mother or infant. Some cases due to mutations in genes involved in thyroid development and hormonogenesis such as <i>PAX8</i> , <i>TSHR</i> , <i>TSHB</i> , <i>DUOX2</i> , <i>TG</i> , <i>TPO</i> , and <i>SLC45</i>	If untreated, even mild cases may lead to failure of cognitive development, resulting in ID Sleep disorder	Severely affected children have a characteristic appearance, with a puffy face, large and protruding tongue, dry and brittle hair, low hairline, and low muscle tone Constipation and jaundice
Duchenne muscular dystrophy	1 in 4000 male births	X-linked recessive, with 30% of cases due to new mutations Deletions, duplications, and mutations at Xp21 result in failure to produce dystrophin, a protein component of muscle tissue	Some affected people have IQs within normal range Specific reading disorder and learning disability Low mood, anxiety, and social abnormalities	Typical onset is from 2 to 6 years. Progressive muscle weakness, affecting the pelvis, upper leg, and upper arm first Respiratory muscles and cardiovascular muscle abnormalities may occur later Severity is initially greater in the legs and torso, eventually moving up to the arms and respiratory muscles

² No longer separate in DSM-V.

Angelman syndrome occurs in 1 in 10,000 births and is associated with deletions at the 15q11–q13 region of maternal origin (see Prader–Willi syndrome). Affected patients exhibit severe ID, markedly delayed motor milestones, little speech development, and over-activity associated with short attention span. Physical features include hypopigmentation, a small head, characteristic face with wide mouth,

‘hooked’ nose, prominent lower jaw, widely spaced teeth, and tongue protrusion. Voluntary movements are jerky, and gait is ataxic with stiff legs. Affected patients tend to enjoy social and physical contact, mouthing objects, and display a fascination with water.

PKU occurs in 1 in 10,000 live births and is caused by a mutation at 12q22–24.1, which results in deficiency of the enzyme phenylalanine

hydroxylase. Affected patients exhibit moderate to severe learning disability, displaying deficits in mathematical, visuospatial, and language skills. Physical features include a small head, blond hair, blue eyes, and eczema. Behavioural features include over-activity, self-injury, irritability, and marked social impairments. They are often affected by tremor and movement disorders.

Rett's syndrome occurs in 1 in 10,000 women and is associated with a mutation at Xq28, which is usually lethal in males but may persist in a small number of surviving males. Affected patients exhibit severe learning disability. Physical features include cessation of development, lack of muscle tone, scoliosis, spasticity, reduction in brain size with reduced cortical thickness, reduced neuronal branching, and depigmentation of the basal ganglia. Behavioural features include immobility at infancy, loss of skills from around 18 months onwards, stereotyped movements, over-breathing or cessation of breathing, sleep disturbances, and withdrawal.

Williams syndrome occurs in 1 in 15,000 infants and is associated with a deletion at 7q11.3. Affected children have moderate or severe learning disability. Behavioural features include difficulty feeding, irritability, constipation, and failure to thrive at infancy. Affected children display social disinhibition, over-activity, poor concentration, eating and sleeping abnormalities, abnormal anxiety, poor peer relationships, and abnormal hearing sensitivity. Physical features include prominent cheeks, wide mouth, flat nasal bridge, growth retardation, high serum calcium concentrations, and kidney and heart lesions.

Smith–Lemli–Opitz syndrome mostly affects males, occurring in 1 in 30,000 live births, and is due to abnormalities at 11q12–13. Affected patients have moderate to severe learning disability. Physical features include growth retardation of the fetus during pregnancy, small head, drooping eyelids, squint, forward-facing nostrils, small lower jaw, abnormalities of external genitalia, hypospadias, undescended testes, cleft palate, finger abnormalities, and abnormalities of almost all major organ systems. Behavioural features include aggressive and self-injurious behaviour.

Cri-du-chat syndrome occurs in 1 in 35,000 births and is associated with deletions at the 5p terminal. Affected patients have mild to severe intellectual deficiency, with markedly delayed language development. Behavioural features include hyperactivity, feeding difficulties, and an abnormally high-pitched cry at infancy. Physical features include ear abnormalities, round face with widely spaced slanting eyes, small head, flat broad nose, small lower jaw, and premature greying of hair. They sometimes have an asymmetrical face, cleft lip or palate, curved fingers, hernias, and orthopaedic abnormalities.

Prader–Willi syndrome occurs in 1 in 40,000 live births and is associated with a deletion at 15q11–q13 of paternal origin. Physical features include hypotonia, short stature, small hands and feet, a characteristic pattern of facial appearance, and lack of sexual development at adulthood. Behavioural features include feeding problems in infancy, overeating in early childhood, insatiety, sleep abnormalities, lower threshold for loss of temper, scratching or picking at skin, insistence on routines, and compulsive behaviours. Obesity may result due to overeating.

Smith–Magenis syndrome, occurring 1 in 50,000 births, is associated with deletions at 17p11.2 and commonly results in moderate ID. Behavioural and cognitive features include placid newborns, difficulty with feeding, hyperactivity, self-injury, self-hugging, mid-line handclapping, sleep disorder, absence of rapid eye movement

(REM) sleep, and insensitivity to pain. Physical features include flattened mid face, abnormally shaped upper lip, short hands and feet, single transverse palmar crease, abnormally shaped or placed ears, and sometimes a high-arched palate or protruding tongue. Otitis media and squint are common.

De Lange syndrome occurs in 1 in 60,000 live births and is associated with mutations in chromosome 5 at the *NIPBL* gene. It results in severe learning disability, with very limited speech. Physical features include hearing impairments, gut malformations, congenital heart defects, gastrointestinal pain, growth retardation, well-defined arched eyebrows meeting in the middle, long and curled eyelashes, small nose with forward-facing nostrils, down-turned mouth with thin lips, and small or shortened limbs. Behavioural features include self-injury, autistic features, and pleasurable responses to vestibular stimulation.

Mucopolysaccharidoses are autosomal recessive (except for Hunter's syndrome, which is X-linked) that occur in around 1 in 100,000 to 1 in 500,000 births. ID ranges from absent to severe. Physical features include gargoyism, hepatosplenomegaly, joint stiffness, eye abnormalities, and short statures. Behavioural and cognitive features include sleep problems, aggression, over-activity, restlessness, and anxiety.

Rubinstein–Taybi syndrome occurs in 1 in 125,000 live births and is associated with microdeletions at 16p13.3. Patients have moderate learning disability. Physical features include congenital heart defects, urinary tract abnormalities, decreased height, inadequate weight at infancy, small head, beaked or straight nose, downward-slanting eyes, stiff gait, and thumbs or first toes with broad terminal phalanges, sometimes with an angulation deformity. Behavioural cognitive features include constipation, friendly disposition, propensity to self-stimulatory activities, and reduced attention span.

Lesch–Nyhan syndrome occurs in 1 in 380,000 births and is an X-linked recessive trait which results in hyperuricaemia. It can also be caused by complete and partial deletions, insertions, and duplications of Xp26q27. Patients with this syndrome have mild to severe ID. Physical features include hypotonia, hyperreflexia, and clonus during the first year, growth retardation, and gout. Behavioural features include compulsive behaviours, self-injury, spasticity and choreo-athetoid movements at 9 months, dystonic movements, dysarthria, and athetoid and movement abnormalities.

Management and treatment of intellectual disability

José L. Ayuso-Mateos and Cary S. Kogan

Introduction

The advent of a model of disorders of intellectual development/intellectual disability that emphasizes inclusiveness and participation in society for affected individuals brought with it a greater emphasis on considerations of the influence of contextual factors that facilitate or impede functioning within society (see also Chapter 21). The WHO revision of the International Classification of Diseases (ICD), the most widely used health classification worldwide, was approved by the World Health Assembly in May 2019. The focus of the revision of the ICD Mental and Behavioural Disorders chapter led by the WHO Department of Mental Health and Substance Abuse is the incorporation of current scientific evidence in a set of diagnostic guidelines that will maximize clinical utility and global applicability [1, 2]. Consistent with the overarching goal of the classification revision to enhance clinical utility, the ICD guidelines for disorders of intellectual development were written to facilitate more pervasive, efficient, and accurate identification of affected individuals, with the ultimate goal of enhancing access to appropriate services in varied settings globally [3].

Disorders of intellectual development is a term proposed for the first time in ICD to replace the label of mental retardation that appeared in ICD-10. Although intellectual disability is frequently used and indeed appears in DSM-5 [4], inclusion of the word ‘disability’ in the label would be at odds with the approach promoted by the WHO Family of International Classifications that distinguishes between health conditions classified in the ICD from the consequences of those conditions (that is, disabilities) classified in the ICF. The ‘Disorders of intellectual development’ title also reflects that the onset of the condition is during the developmental period and focuses on the broad construct of ‘intellect’ that is well understood in policy circles, as well as among researchers and clinicians [3]. Disorders of intellectual development is classified among other neurodevelopmental disorders, and its guidelines are used in concert with the guidelines for autism spectrum disorder to characterize the degree of impairments in intellectual functioning in individuals affected by that disorder.

Disorders of intellectual development are defined by three essential features in ICD: (1) significant limitations in intellectual

functioning generalized to various domains (for example, perceptual reasoning, working memory, etc.); (2) significant limitations in adaptive behaviour, which is the set of conceptual, social, and practical skills; and (3) onset of both of these limitations during the developmental period. ICD-11 preserves the existing four levels of severity that appear in ICD-10 (that is, mild, moderate, severe, and profound), largely due to evidence that increasing severity is associated with a number of important support needs, including choice of living arrangements [5]. ICD-11 will propose an approach that requires consideration of both intellectual and adaptive behaviour functioning to determine the level of severity. Each level of severity is defined by the expected range of performance on measures of intellectual and adaptive behaviour functioning, with a caveat stipulating that differentiation between severe and profound levels on the basis of intellectual functioning is unreliable and therefore should be guided by findings on measures of adaptive behaviour skills. There is also a qualifier to indicate a provisional diagnosis that is used when a comprehensive assessment has not been, or cannot be, performed (for example, sensory limitations) or if a child is 4 years or younger. Poor reliability of the assessment of intellectual and adaptive behaviour functioning in young children preclude a definitive assignment of severity.

In recognition of the fact that, in many settings worldwide, particularly in low- and middle-income countries, patients are unlikely to be assessed by mental health or developmental specialists, the ICD-11 guidelines also include a set of tables that outline concrete behavioural indicators of intellectual and adaptive behaviour functioning at each severity level expected of individuals falling into one of three age ranges (early childhood, childhood/adolescence, and adulthood) [6]. These tables were developed primarily to assist non-specialists to determine the level of severity of a disorder of intellectual development. Although the use of standardized, normed measures of intellectual and adaptive behaviour functioning is preferable for determining the level of severity, the WHO recognizes that availability of such measures in local languages in many global settings is limited. Thus, the behavioural indicator tables provide an alternative means of establishing severity on the basis of observed or informant-reported behaviours. This system represents a considerable improvement over the idiosyncratic determination of

severity or overreliance on the use of a provisional diagnosis, practices that limit patients' access to appropriate services. Clinicians are instructed to assign the level of severity on the basis of the level at which the majority of the individual's intellectual ability and adaptive behaviour across all three domains fall, using various sources of data and clinical judgement.

Co-occurring disorders in ICD-11

Chapter 24 has outlined the common comorbidities seen between intellectual disability and other psychiatric disorders. The ICD-11 proposals for the disorders of intellectual development guidelines provide users with comprehensive guidance on the detection of commonly co-occurring disorders in affected individuals. Identification of these co-occurring conditions is of vital importance in understanding the needs for, and developing, an appropriate treatment plan for affected individuals. Therefore, ICD-11 proposals outline guidance on the more commonly comorbid conditions, including autism spectrum disorder (ASD), attention-deficit/hyperactivity disorder (ADHD), and various other mental and behavioural disorders.

ASD frequently presents with limitations in intellectual and adaptive behaviour functioning, and when both are found to be two or more standard deviations below the mean, a diagnosis of ASD with intellectual impairment is assigned co-concurrently with a disorder of intellectual development qualified according to the determined level of severity. However, in these circumstances, the ICD-11 guidance indicates that determination of the level of severity of the intellectual disability should be more reliant on the conceptual and practical domains of adaptive behaviour functioning, giving less weight to social skill abilities, because social communication deficits are a hallmark feature of ASD and better accounted for by that diagnosis.

Rates of co-occurring ADHD in individuals with a disorder of intellectual development diagnosis are significantly higher than in the general population (for example, [7]). When inattention and/or hyperactivity-impulsivity are significantly affected in an individual with a disorder of intellectual development beyond what is expected, based on age and the level of intellectual functioning, a co-occurring diagnosis of ADHD can be assigned.

A variety of other mental and behavioural disorders are known to occur at the same, or perhaps higher, rates among individuals affected by disorders of intellectual development, as compared to the general population (for example, mood disorder, anxiety and fear-related disorders, impulse-control disorders, and psychotic disorders) [8]. ICD-11 guidelines caution clinicians to ensure that assessments are conducted with methods that are appropriate to individuals' level of intellectual functioning and to be aware that self-report is less reliable among affected individuals and may lead to underreporting of co-occurring psychopathology. Therefore, observable signs or reports by caregivers or individuals close to the person being assessed may provide a more accurate understanding of the presence of co-occurring ICD-11 mental and behavioural disorders.

Management

The general approach to management of persons with an intellectual disability is educational and psychosocial, with use of

specific appropriate management interventions for mental health and behavioural problems when needed. Psychiatric comorbidities in persons with an intellectual disability are often under-detected. Comorbidities are typically suspected when patients exhibit changes in behaviour, particularly disruptive behaviour. The Royal College of Psychiatrists (2016) [9] has recently summarized three broad situations in which people with an intellectual disability and mental health or behavioural problems might come into contact with primary or secondary care: (1) the presence of challenging behaviour that is not associated with a mental disorder; (2) the presence of challenging behaviour that is associated with symptoms that meet the diagnostic criteria for a mental disorder; and (3) the presence of challenging behaviour that is associated with some psychiatric symptoms that do not quite fulfil the diagnostic criteria for a mental disorder. In many circumstances, changes in behaviour can be attributed to physical illness, difficulties in communication, or environmental changes, or can be a reaction to stressful circumstances or frustration. The clinical assessment should consider all the aforementioned factors, and the diagnostic formulation that serves as the basis for a management plan should reflect not only the severity and known aetiology of the intellectual disability, but also any co-occurring mental and physical disorders, as well as information gathered about psychosocial stressors and behavioural problems. If the clinician considers the presence of a physical health problem as the main factor explaining the behavioural symptoms, appropriate intervention for the physical conditions should follow promptly.

Proper identification of co-occurring disorders is essential in addressing the needs of affected individuals. When assessing for co-occurrence, clinicians should be familiar with the concept of diagnostic 'overshadowing', whereby emotional and behavioural symptoms or frank psychopathology are misattributed to the features of the disorder of intellectual development, rather than a separable disorder. Overlooking co-occurring disorders deprives affected individuals of potentially helpful interventions. A mitigating strategy is to use modified diagnostic criteria sets to differentiate symptoms of disorders of intellectual development from those better attributable to co-occurring conditions [for example, Diagnostic Manual-Intellectual Disabilities (DM-ID) [10]]. A general guiding principle in the assessment of mental and behavioural disorders in individuals with a disorder of intellectual development is that clinicians employ methods that are appropriate to the individual's level of development and intellectual functioning, which may require a greater reliance on signs in combination with collateral reports. Reporting of internal states is more difficult for affected individuals, particularly those with more severe forms of disorders of intellectual development.

Psychosocial interventions

Psychosocial interventions that target behavioural and emotional difficulties, as well as diagnosable co-occurring mental and behavioural disorders, can be effective tools in the overall management plan for individuals with intellectual disability. Formulation and implementation of a treatment plan, even when it is meant to reduce or eliminate disruptive behaviours (for example, self-injurious or aggressive behaviours) should be undertaken, with the goal of improving affected individuals' quality of life and, in doing so, respect the principles of equality, non-discrimination, and self-determination. Intervention selection that promotes the acquisition

of academic skills, beneficial habits, and general development should be based on the results of a functional behaviour analysis and often include psychoeducation, skills training, positive behavioural support (for example, differential and non-contingent reinforcement, altering triggers for undesirable behaviour, minimal use of aversive strategies, and reactive strategies such as the use of distraction [11]), carer involvement and training, and, in children, token economies [12]. Furthermore, when appropriate, cognitive behavioural therapy may be indicated. Many of the same psychosocial interventions that apply to redressing adaptive skill deficits among affected individuals are relevant to the management and modification of challenging behaviours and co-occurring mental and behavioural disorders. This approach views all systems of supports as ultimately serving to improve human functioning outcomes such as socio-economic status, health status, and subjective well-being of the individual [13, 14].

Challenging behaviours refer to those that interfere with the affected individual's quality of life, including their ability to function in social, academic, and employment contexts. They typically refer to self- and other oriented aggression, destruction of property, and behavioural stereotypes [15]. In a large population-based study conducted in Sweden, behaviour problems, which are considered to be less severe forms of challenging behaviours not necessarily requiring intervention, were observed in 62% of affected individuals [16]. Typically, co-occurring challenging behaviours vary according to the level of severity of the disorder of intellectual development and with age [17–19]. Although prevention strategies that anticipate the need for establishing effective communication strategies, modifications to environmental stimuli, and awareness of consequences that might reinforce challenging behaviour are preferable [20], usually consultation requests focus on existing behaviours that significantly interfere with the patient's functioning or are affecting the ability of the individual to function within specific contexts.

Optimal management strategies often require the co-ordination of services across multiple disciplines that include, but are not limited to, psychiatry, psychology, occupational therapy, speech and language therapy, genetic counselling, and nursing. In addition to these professionals, parents, teachers, supervisors, and other caregivers should be consulted to provide their perspectives on the individual's functioning within the various contexts that they frequent. Although some challenging behaviours may generalize across contexts, some may not. Furthermore, modification of contextual factors (for example, specific stimuli in the environment) independent of other management strategies may reduce or eliminate challenging behaviours.

A comprehensive diagnostic assessment typically involves integration of data from genetic testing, physical assessment, interviews of the patient and his or her caregivers, and consultation with multi-disciplinary team members. Furthermore, challenging behaviours are most effectively addressed after a functional behaviour assessment has been conducted. The rationale for functional behaviour assessments emerges from research demonstrating that challenging behaviours serve a functional role for the individual and become established through operant principles of contingent reinforcement. Therefore, an explanation of the relationship between antecedent factors, challenging behaviours, and consequences provides a rational basis for intervention. Indeed, meta-analyses consistently support the effectiveness of functional behaviour assessments in improving treatment outcomes across all severity levels over those that do not

include such evaluations (for example, [21]). Challenging behaviours may be found to function as social positive reinforcers (for example, to obtain attention), social negative reinforcers (for example, to avoid having to complete a task), or sensory reinforcers (for example, repetitive self-stimulatory behaviours) [22]. Thus, interventions to reduce the frequency of challenging behaviours can centre on removing antecedent factors, altering identified reinforcers, or modifying reinforcement schedules. Early intervention to address challenging behaviours is beneficial in preventing these from becoming entrenched in the individual's repertoire.

Addressing comorbid psychopathology

Behavioural management strategies predicated on the results of a thorough functional behaviour assessments are also helpful in addressing co-occurring externalizing disorders (for example, oppositional defiant disorder). Supplementing clinician-administered behavioural management with parent/caregiver skills training is often more effective than direct intervention with the affected individual (for example, Stepping Stones Triple-P, [23, 24]). With respect to emotional disorders, there is emerging evidence that psychological treatments, in particular cognitive behavioural therapy, may be as efficacious in addressing mood, anxiety, stress-related disorders (that is, PTSD) in people with disorders of intellectual development as in the general population [25, 26]. The ability to engage in cognitive behavioural interventions depends, in part, on the capacity of the individual to understand the relationship between internal states, behaviours, and cognitions, a task that is more likely achievable for those with mild to moderate forms of disorders of intellectual development.

Pharmacological interventions

In general, the indications for the use of psychotropic drugs in this population are the same as in populations with normal intellectual functioning. In clinical practice, the administration of psychotropic agents in patients with intellectual disability is very common. A recent population-based cohort study of adults with intellectual disabilities in the UK showed that almost half were taking some form of psychotropic drug and that the proportion of participants with intellectual disability being prescribed psychotropic drugs exceeded the proportion with recorded mental illness [27]. Rather, many were prescribed these drugs to address challenging behaviours.

Psychiatric drug treatments are generally effective at the same doses and for the same indications than in the general population without this condition. Once a medication is selected on the basis of being properly indicated, the prescriber is confronted with a series of additional challenges. The most salient of these are: the coexistence of medical comorbidities, the concomitant use of other therapeutic substances, issues related to adherence to the medications, and the need to carefully monitor the impact of the pharmacological interventions in terms of efficacy and side effects in patients who may have communications problems.

There is no clear evidence that those with intellectual disability have more side effects when prescribed psychiatric treatments [28]. However, affected individuals have higher rates of physical health comorbidities and premature mortality [29]. Major health risk factors, such as obesity, metabolic syndrome, and diabetes, are highly prevalent in this population [30]. The monitoring of patients with intellectual disability receiving psychotropic drugs should consider

not only the elevated risk of specific drugs, such as dopamine serotonin antagonists that increase the risk of metabolic syndrome and extra-pyramidal symptoms, but also assess medical status, dietary regimen, changes in the environment, and polypharmacy. Furthermore, with greater severity of intellectual impairment, sensory deficits and neurological comorbidities (for example, epilepsy) are very frequent, increasing the risk of severe side effects at lower doses, as well as special sensitivities to the neurological side effects of these drugs.

Involvement of the caregiver should be incorporated in any management plan, because adherence, as well as reporting of response to treatment and side effects, often relies on their co-operation. Their prejudices against medication may be a contributing factor in cases of non-adherence to the prescription. The likely effects of the intervention on the patient's and carer's quality of life should also be considered. During the required monitoring period after the prescription of psychotropic drugs, efforts should be made to solicit and incorporate objective information from the carers, as well as the patients. As a general rule, the lowest possible dose should be prescribed, with the physician assessing the need for treatment continuation once the target symptoms have improved or when there is non-response and/or side effects that have an impact on the patient's functioning and quality of life.

Use of dopamine antagonists/partial agonists

Dopamine antagonists/partial agonists (meaning the so-called typical and atypical antipsychotics) are used frequently in the management of a variety of presenting symptoms, even when the evidence for efficacy is not available. Concerns about inadequate prescribing of these agents have been raised, in particular, in relation to the management of challenging behaviours [31]. While there is limited evidence that suggests that dopamine antagonists may be effective in treating behavioural disturbances in adults with intellectual disability with comorbid autism [32], evidence supporting the use of such medication outside this clinical situation is lacking [33]. The NICE guidelines (2015) [34] recommend that clinicians consider dopamine antagonists to manage challenging behaviour only if 'psychological or other interventions alone do not produce change within an agreed time; or treatment for any coexisting mental or physical health problem has not led to a reduction in the behaviour or the risk to the person or others is very severe (for example, because of violence, aggression or self-injury)' (National Institute for Health and Care Excellence, 2015).

Use of dopamine antagonists for the pharmacological treatment of aggression specifically is controversial. Once properly indicated, the follow-up of the patient should take into account that adverse effects may be more likely due to the higher incidence of comorbid conditions (for example, neurological disorders) and should consider that some patients may have an elevated baseline cardio-metabolic risk profile. Dopamine/serotonin antagonists have less risk of side effects like dyskinesia, but they have been associated with weight gain, metabolic syndrome, and increases in prolactin level. In practice, use in the intellectual disability population may be at lower doses than for other groups of psychiatric patients and is not necessarily associated with worse metabolic profiles. However, prolactin elevation (most marked with amisulpride and risperidone) is common and often associated with secondary hypogonadism in women [28]. Hypogonadism may, in turn, lead to

bone loss in a population already at risk for osteoporosis and fractures. Management of hypogonadism is indicated, although there is currently too little awareness of this risk, which should be screened for more regularly. In cases with treatment-resistant psychosis, clozapine could be considered, but only when blood test monitoring can be ensured.

Use of drugs for depression

Selective serotonin reuptake inhibitors (SSRIs) are the most commonly used medication in patients with intellectual disability, both for depressive disorders and anxiety disorders. They are also frequently prescribed for the management of obsessive-compulsive symptomatology. During the first few weeks of treatment, some patients report nervousness and agitation. Changes in behaviour (for example, increased aggression, self-injury, repetitive behaviour) may indicate adverse effects or a switch to a manic phase [35]. The prescription of these drugs should start with a low dose, and increases should be slower than in the population without intellectual disability. Treatment guidelines based on evidence collected in clinical populations without intellectual disability also stress the need for monitoring emerging suicidality and suicide attempts during treatment with antidepressants in children and adolescents with depression [36, 37]. Because the potential for drug interactions with SSRIs, the clinician should be vigilant when using these agents simultaneously with other drugs that are metabolized by cytochrome P450 enzymes.

Benzodiazepines

These agents should only be used for a limited period of time, and long-term treatment with these agents should be avoided. Paradoxical reactions to benzodiazepines (disinhibition) can manifest in this clinical population in the form of impulsivity, aggression, or rage.

Mood-stabilizing drugs

In addition to their use in bipolar disorder and acute mania, lithium and anti-epileptic drugs have been shown to be effective in the management of affective instability, which can manifest in the form of irritability, rage, and outburst of aggression [38]. Many patients with intellectual disability also have seizures that may increase the behavioural problems. As in the general population, therapy must be guided by regular serum monitoring, as lithium and anti-epileptic drugs are correlated with therapeutic and toxic effects.

There are ongoing concerns among users, carers, health care providers, and researchers that psychotropic drugs are too often used inappropriately in people with intellectual disability. It is not unusual to observe overuse of psychotropic drugs to treat challenging behaviour, excessive dosages, and polypharmacy. The off-label use of psychotropics is common practice in this area of medicine, as is the fact that once psychotropic drugs are prescribed for a particular challenging behaviour, they are incorporated in the long-term management of the case, without proper consideration as to whether long-term treatment is indicated. Current evidence suggests that comprehensive and personalized functional assessment of behaviours in their context with an overarching goal of optimizing integration and normal functioning leads to better outcomes. With these assessment data, it is easier to develop a treatment plan that is amenable to psychological and environmental management of

mental illness and challenging behaviour, which, in turn, is likely to reduce or, in some cases, obviate the need for prescription of psychotropic drugs.

Conclusions

Revised diagnostic guidelines, such as those in the forthcoming ICD-11, have focused on enhancing clinical utility and international applicability. These characteristics of the classification are expected to improve early and accurate diagnosis of disorders of intellectual development, thereby permitting a greater number of persons to be eligible for treatment. Although effective psychosocial and pharmacological interventions are available for the management of challenging behaviours and comorbid psychopathology in affected individuals, these often depend on specialized behavioural interdisciplinary teams, a luxury in most settings across the world. Future research should focus on improving universal accessibility of bio-psychosocial services across the lifespan through training of non-specialist staff, as well as carers, in evidence-based approaches such as positive behavioural support.

Core dimensions of autism spectrum disorders

Fred R. Volkmar and Scott L.J. Jackson

Introduction

Autism spectrum disorder (ASD) is a neurodevelopmental disorder that manifests during the early developmental period of childhood. This disorder is behaviourally defined by impairments in social interaction and communication, in combination with restricted and stereotyped patterns of behaviour and/or interest. There is, however, a diverse range of symptom presentation and severity among diagnosed individuals, including a range of cognitive ability that spans IQ scores representative of profound intellectual disability through to average and well above-average levels of intelligence. As a result, in less severe cases, symptoms may not become fully apparent until later stages of life when social demands surpass the individual's limited abilities. ASD is a new diagnostic label, chosen by the American Psychiatric Association for the 2013 release of the fifth edition of their *Diagnostic and Statistical Manual* (DSM-5) [1]. This label was designed to provide a singular diagnosis to individuals who would have previously been categorized by one of the pervasive developmental disorders (PDDs), as defined in the fourth edition of the DSM [2, 3] and the WHO's counterpart to DSM-IV—the tenth edition of the International Classification of Diseases (ICD-10) [4]. Resultantly, the previously unique PDD diagnoses of autistic disorder (childhood autism in ICD-10), Asperger's syndrome, childhood disintegrative disorder, and PDD-not otherwise specified (PDD-NOS) (PDD-unspecified in ICD-10), are no longer present as diagnostic options for new cases based on DSM-5 criteria but can be 'grandfathered' in by those who were already holding one of these diagnoses prior to this categorical shift.

The ASD section of this textbook will examine and discuss this disorder from a variety of perspectives. This will include chapters addressing current understandings of treatment planning, prevention and epidemiology, genetics, imaging, and management of ASD. Chapter 25, however, will provide an overview of ASD, covering topics of disorder history, prevalence estimates, demographic patterns, clinical features, diagnostic criteria, and differential diagnosis, and close with a discussion on the criticisms and concerns surrounding the DSM-5 classification of ASD and expectations for how this disorder will be defined in the forthcoming eleventh edition of the ICD (ICD-11).

History of autism spectrum disorders

Leo Kanner, an Austrian-born child psychiatrist, working at Johns Hopkins University, is credited with the first clinical portrayal of ASD in his 1943 paper entitled *Autistic disturbances of affective contact* [5]. In this paper, Kanner details the behaviour of 11 children displaying a pattern of symptoms which included intense resistance to change, insistence on 'aloneness', and impairments in both communication skills and social interaction. Meanwhile, in 1944, independent of the work being conducted by Kanner, Hans Asperger (a psychiatrist working in Austria) produced his own clinical accounts of four cases of what he referred to as autistic personality disorder in his paper *Die Autistischen Psychopathie im Kindesalter* [6]. Similar to what was being described by Kanner, Asperger notes impairments in social and emotional relationships, abnormalities in speech and non-verbal communication, and restricted, but intense, focus on special interests. The primary difference between their accounts is that Asperger additionally discusses the presence of extraordinary skills in particular cognitive domains (for example, mathematics) in the children he was observing. Unfortunately, due to the fact that his work was published in German, Asperger's clinical findings did not become widely disseminated in English-speaking regions until nearly 40 years later.

The first widely utilized label for this disorder ('early infantile autism') was provided in a 1956 paper co-authored by Kanner and Leon Eisenberg [7]. In this paper, the authors proposed that two core features define early infantile autism: 'obsessive insistence on sameness' and 'extreme self-isolation'. Kanner had observed that parents of the patients visiting his clinic presented with similar social disinterest and emotionally distant characteristics to those expressed by their children. Based on these observations, Eisenberg and Kanner proposed that emotional deprivation, as a result of this distant and 'cold' parenting, could play a role in the development of early infantile autism. However, they also went on to express that emotional deprivation could not solely account for the development of early infantile autism, as it was their belief that this disorder was a state that was present at birth and, as such, was likely to be the result of a combination of biological, psychological, and social factors. Unfortunately, it was their declaration regarding the potential

role of socially detached, ‘cold’ parenting that got the most attention initially, and eventually resulted in what becomes known as the ‘refrigerator mother’ theory of autism. In the 1960s, this theory was furthered in publications by Bruno Bettelheim [8, 9], who, for many years, was considered as one of the leading experts in the field of autism, resulting in the ‘refrigerator mother’ theory becoming widely disseminated and accepted by many in the lay population, as well as in medical fields.

Beginning in the late 1960s, and more significantly in the 1970s, research in the field of autism moved away from the clinical descriptions and/or theory presentations that previously dominated the landscape of autism literature, and began applying more scientifically stringent methodologies to the study of this disorder. Works produced during this period presented serious challenges to the psychogenic theories of autism (for example, the ‘refrigerator mother’ theory), by providing empirically supported evidence for a biological and neurological basis of the disorder [10, 11]. In addition, evidence was produced against the then-held position that autism was a form of childhood schizophrenia, with comparative studies clearly distinguishing the two disorders by their associated symptoms, phenomenology, age of onset, and family history [12, 13]. Following these scientific advances, ‘infantile autism’ was introduced as a formal diagnostic category by the American Psychiatric Association in the 1980 release of DSM-III [14]. Infantile autism was classified as a PDD, a term developed specifically for DSM-III, and defined as being characterized by pervasive and severe impairment in multiple basic functions, including socialization and communication.

In 1981 [15], Lorna Wing introduces the findings of Hans Asperger to the English-speaking world and describes ‘Asperger’s syndrome’, a milder manifestation of the clinical symptoms of infantile autism, often paired with strong cognitive abilities in fields such as mathematics, and excluding the significant language development delays associated with autism. In DSM-IV [2] and DSM-IV-TR [3], the association between this Asperger’s syndrome and autism (then labelled as ‘autistic disorder’) was officially recognized by the American Psychiatric Association, with the decision to expand the diagnostic category of PDDs to include five disorders that were thought to be related to, or share, many of the same features of one another: autistic disorder, Asperger’s syndrome, Rett’s syndrome, childhood disintegrative disorder, and PDD-NOS. Following this expansion, this group of disorders (with the exception of Rett’s syndrome) began to be discussed under the umbrella term of ‘autism spectrum disorders’ in much of the autism literature.

In 2013, the fifth, and most recent, edition of the DSM (DSM-5) [1] was released and was met with a great deal of controversy regarding its alterations to the diagnostic categorizations of autism and its related disorders. In DSM-5, the previously distinct categories of autistic disorder—childhood disintegrative disorder, Asperger’s syndrome, and PDD-NOS—have been reconceptualized as a singular ‘autism spectrum disorder’ and are defined by more rigid diagnostic criteria. This change was made in an effort to provide a more unified and rigorous definition of what autism is; however, it was met with a number of concerns and criticisms from medical professionals, as well as autism advocacy groups (see Concerns and criticisms of DSM-5 classification of autism spectrum disorder, p. 242, which contains further discussion on this topic), including negative impacts on the sense of community and identity that had been gained through specific diagnostic labels and potential issues with impaired

children not meeting the more stringent diagnostic criteria and losing access to critical services as a result. To address the former of these concerns, while Asperger’s syndrome and PDD-NOS are no longer diagnostic options for clinicians within the framework of DSM-5, it was decided that a ‘grandfather’ clause would be introduced, allowing these labels to remain in individuals who received their diagnosis prior to this change. Meanwhile, to address the concerns over diagnostic sensitivity, DSM-5 introduced a new condition called social communication disorder, intended to provide a label for children without the repetitive and stereotyped behaviour components of ASD but who do express significant social/communicative impairments.

Prevalence estimates

The first study to present data regarding an estimated prevalence rate for autism was performed by Victor Lotter in 1966 [16]. To provide this estimate, Lotter screened the entire population of 8- to 10-year-old children from a county in the south east of England (78,000 children in total) for behavioural markers of early infantile autism, as then defined by Eisenberg and Kanner [6]. The findings of this screening resulted in an estimate that autism was present in 4.5 of every 10,000 children. From this point until as late as the 1990s, autism was considered to be a rare condition, with subsequent published prevalence reports suggesting rates of 2–5 per 10,000 children [17, 18]. Following the inclusion of ‘Infantile autism’ in DSM-III in 1980 [14], and the subsequent expansion of diagnostic criteria in the 1987 release of the revised DSM-III-R [19], reported epidemiological studies began documenting dramatic increases in the estimated rates of prevalence for this disorder [20–24, 29].

Beginning in the early 2000s, the Center for Disease Control and Prevention (CDC) began collecting large data samples of 8-year old children from across the United States and producing highly detailed prevalence reports for autism based on their findings every 2–4 years. The most recent of these reports was released in 2014 and documented findings from a sample of 363,749 children (roughly 9% of the total population of 8-year olds in the United States) that was collected across 11 different sites in 2010 [20]. Based on the findings of this report, the overall prevalence of ASD (based on DSM IV-TR diagnostic criteria for autistic disorder, Asperger’s syndrome, or PDD-NOS) for children aged 8 years in the United States is 147 per 10,000 (or 1 in 68). That figure was 29% higher than their previous estimate based on data from 2008 [22], 64% higher than their estimate based on data from 2006 [23], and a staggering 123% higher than their estimate based on data from 2002 [24]. In combination with earlier prevalence studies, the findings produced by the CDC suggest a continuous and exponential growth pattern in ASD prevalence over the past 4–5 decades (Fig. 25.1).

This trend of dramatic increases in the reported prevalence of ASD has led some to the conclusion that these findings are evidence of an ‘autism epidemic’ and, as a result, has encouraged increases in research focused on identifying potential environmental factors to help explain this phenomenon. However, a majority of practitioners and researchers within the ASD field have issued caution against interpreting these findings in this manner and instead suggested that the majority of these increases can be explained by a combination of alternative factors, including: broadening of diagnostic

Fig. 25.1 Time trend of estimated autism prevalence rates (number of children per 10,000). Prevalence estimates for the reported years are from the following studies: 1966 [16], 1979 [18], 1982-1989 [21], 1999 [29], 2007 [24], 2009 [23], 2012 [22], 2014 [20].

criteria, increased availability of diagnostic services, increased disorder awareness, and diagnostic transference/substitution of children who may have previously received an alternative diagnosis (for example, intellectual disability). Though the combination of these factors may be able to account for a large portion of these increases over the years, there may yet be true increases in ASD incidence as well. As such, continued work in this area, and in the identification of potential environmental factors associated with an increased ASD liability, is warranted.

Of note, there is frequently a discrepancy between the current high prevalence rates of ASD among samples of children and the generally lower observed prevalence rates in adults. For some, this discrepancy has been viewed as support to the idea that there has been, in fact, an increase in ASD incidence in recent decades. In contrast to this position, however, it is becoming more apparent that these discrepancies are likely the result of less accurate diagnostic and identification practices in the past [25, 26]. Providing support to these beliefs, and perhaps one of the more compelling findings in opposition to the 'autism epidemic' theory, a recent large community survey estimated that prevalence rates of ASD for adults in the UK should be roughly 1.1% (essentially the same as those found in samples of children), but many of these adults are currently misdiagnosed or completely unidentified [27]. Regardless of whether there has been a true increase in incidence of ASD or not, recent reports suggest that, of all mental disorders, ASD is now the leading cause of disability in children below 5 years of age, affecting somewhere between 1% and 2%, or 52 million children [28], and a roughly equivalent proportion of adults [27] across the globe.

Demographics

One thing which has remained consistent since the earliest epidemiological studies of ASD is a disproportionate gender ratio. From Kanner's first cohort in 1943 [4] to the first reported prevalence study in 1966 [17], and all the way through to the most recent CDC report released in 2014 [20], autism has been notably more prevalent among males than females, with estimated ratios of 2.5-5:1 [20, 30].

A number of different hypotheses have been proposed to account for the presence of this gender difference. This includes ascertainment bias or altered phenotypical expression in females, resulting in issues with underdiagnosis [31, 32], increased susceptibility of males due to elevated prenatal and early postnatal testosterone levels [33], or the existence of a female protective effect requiring a greater aetiological load in girls before ASD behavioural symptoms will manifest [34]. At the moment, however, no definitive explanation for why ASD is more prevalent in males than females has emerged. Based on current estimates [20], the male:female gender ratio for ASD is 4.5:1, with a slight increase in this discrepancy when specifically examining individuals without co-occurring intellectual disability (4.9:1).

Unlike gender ratios, one aspect of the demographics of individuals with ASD that has changed over the years is intellectual ability. In particular, over the last decade or so, there have been notable increases in individuals identified with ASD with average or above-average intellectual ability. Likely a result of improved awareness and detection of the often subtler behavioural manifestations of ASD in this more intellectually able cohort, recent findings suggested that 46% of children with an ASD diagnosis have IQ scores in the average to above-average range (>85), 23% in the borderline range (IQ = 71-85), and 31% considered to be in the range of intellectual disability (IQ ≤ 70). Finally, estimated prevalence rates of ASD tend to be higher among white/Caucasian children, compared to other ethnic/racial groups [20]. However, much of this variation can be accounted for by the significantly higher rates among white children of ASD diagnoses without co-occurring intellectual disability (a diagnosis that can be more difficult to recognize) and thus is likely more suggestive of the influence of socio-economic variables on the quality and quantity of diagnostic and treatment services available to families than of a true discrepancy of ASD prevalence between ethnic/racial groups [35].

Clinical features and diagnostic criteria

Although there is a general consensus that there is a strong genetic and biological basis to ASD, currently no definitive biological,

neurological, or genetic markers for this disorder have been identified. As a result, clinical definitions of ASD remain fundamentally behavioural and historical, reliant on observations (by the clinician or caregiver) of characteristic problems of social interaction, communication, and unusual behaviours which are of early onset (hence the importance of history). Complicating the task of diagnosis (and probably consistent with emerging genetic research [36]), it is clear that a broader spectrum of condition(s) are involved [37].

For the past two decades, the approach of ICD-10 [4] and DSM-IV [2, 3] have been generally concurrent, and partly as a result of this international diagnostic consistency, there has been an explosion of knowledge and research. This has recently changed with the rather different approach adopted in DSM-5 [1] which focuses on a rather narrower view of autism, in the more classic sense of Kanner's autism, resulting in many more cognitively able or less 'prototypical' cases being excluded from an ASD diagnosis [38]. Further complicating the matter are the 'grandfather' clauses (adopted, in part, as a result of criticism of the increased diagnostic stringency) that allow older cases with 'well-established' DSM-IV diagnoses to retain their diagnosis.

Current diagnostic criteria for ASD, as defined by DSM-5, necessitate the presentation of impairments in the following two areas [1]:

1. Persistent deficits in social interaction and social communication (including impaired social-emotional reciprocity, deficits in non-verbal social communicative behaviours, and impaired ability to develop, maintain, and understand age-appropriate social relationships).
2. Restricted and repetitive patterns of activities, behaviours, or interests (including repetitive or stereotyped motor movements, speech, or use of objects; inflexibility with regard to routine adherence, insistence on consistency, or ritualized patterns of behaviour; highly restricted interests that are atypical in focus or intensity; and hypo- or hyper-reactivity to sensory input or atypical interest in sensory features of their environment).

For a diagnosis to be received, the presence of these symptoms must be present during a child's 'early developmental period' and result in clinically significant impairment in some critical area of functioning (for example, occupational, social, academic). The first of these requirements, however, includes the caveat that explicit symptoms of impairment may not become fully apparent until in later stages of life when social demands surpass an individual's limited abilities [1].

The DSM-5 approach has been extensively critiqued [38], and a recent meta-analysis has confirmed the consensus that it represents a move to a more stringent diagnostic concept [39], somewhat undercutting the significance of the name change from the previous category of 'Pervasive developmental disorder' to 'Autism spectrum disorder'. Although perhaps intended to provide a diagnostic option to those individuals not captured by this more stringent diagnostic approach, the inclusion of a new communication disorder—social communication disorder—was introduced in DSM-5. However, the introduction of social communication disorder presents with its own issues, given the very small amount of work supporting such a concept and the complexities involved in its application [40, 41].

Differential diagnosis

ASD must be differentiated from other developmental disorders—most frequently from intellectual disability (which co-occurs in roughly 30% of cases of ASD [20]) and language/communication disorders. In intellectual disability without ASD, developmental skills (including social ones) are generally relatively evenly developed (or impaired), as compared to the more typical pattern of marked areas of strength (non-verbal abilities) and weakness (verbal and social abilities) seen in ASD. The tasks of differential diagnosis can be most complicated in individuals with severe or profound intellectual disabilities, as differences in relative areas of strength and weakness can be less discernible at these levels of cognitive impairment. Conversely, for more cognitively able individuals, such as those with a DSM-IV diagnosis of Asperger's syndrome, receiving a new diagnosis of ASD may become an unnecessarily complicated task due to the grandfather clause component of DSM-5 [1]. In communication disorders, social vulnerabilities are usually not particularly prominent and the desire to communicate often is clearly present. The new diagnosis of social communication disorder allows for a diagnosis when social and communication problems (but not restrictive behaviours) are present, but not as severe as in the more classic ASD [41].

Some individuals who go on, in later adolescence or young adulthood, to develop schizophrenia may exhibit social oddities earlier in life, similar to, but not typically as severe as, those seen in ASD. Occasionally, severe social anxiety problems may initially be confused with ASD; however, these cases will generally not present with the restricted and repetitive behaviours and interests found in ASD. Conversely, the unusual (often due to intensity or repetitive nature) behaviours or interests of individuals with obsessive-compulsive disorder may be taken to suggest ASD; however, in these cases, the social and language communication skills will be preserved. Sometimes, in cases of severe neglect, a range of symptoms suggestive of ASD may be present; however, in these cases, a history of neglect will often be observed and the social vulnerabilities will begin to abate once appropriate care is provided [42].

Concerns and criticisms of DSM-5 classification of autism spectrum disorders

Both Kanner's original description of early infantile autism [5, 7] and Asperger's description of autistic personality disorder [6] have been somewhat modified over time. For Kanner's autism, Rutter's 1978 synthesis of subsequent work [43] focused on both social and language/communication deficits of a specific kind (not just explained by overall developmental delay) associated with problems in dealing with change and 'insistence on sameness'. Similarly, Wing's 1981 paper [15] introduced, in large part, Asperger's clinical reports to the English-speaking world, but also modified and broadened it in important ways in her definition of Asperger's syndrome [44]. Kanner's autism was officially recognized in DSM-III [14] and, up until the release of DSM-5 [1], maintained this traditional grouping of diagnostic features/criteria. Of note was the inclusion of other disorders with autism in the PDD category in DSM-IV [2, 3], including Asperger's syndrome, and the convergence of ICD-10 [4]

and DSM-IV definitions of these categories. For autism (or autistic disorder/childhood autism, as were then the labels), the DSM-IV/ICD-10 definition proved quite flexible, with many possible combinations of criteria resulting in a diagnosis.

A number of overall changes impacted the DSM-5 review process. Several decisions were made at a programmatic level (for example, to avoid having an entire child section, to change approaches to multi-axial classifications and ‘not otherwise specified’ conditions) that impacted the process. A further consideration was the decision to primarily rely on data from commonly utilized ASD diagnostic instruments, rather than on field trial data, to provide the new definitions for disorder criteria. Early on, the decision was made to move to a new diagnostic label—autism spectrum disorder (although note the singular term)—and avoid finer-grained classifications like Asperger’s syndrome, etc. The use of modified codes and measures of severity were incorporated and were meant to provide the important detailed information otherwise lost with the unification of the previously distinct disorders under a singular label. The decision to eliminate Asperger’s syndrome was most controversial, given that despite continued disagreements about the best diagnostic approach to use, research on that condition had increased significantly and meta-analyses were just beginning to appear that showed important differences from more classic Kanner’s autism, which can have critical impacts on effective treatment options and strategies [45, 46].

Factor analysis of an extensive data set using measures of both current functioning and past history was utilized to come to the decision to adopt a ‘two-factor’ approach for the ASD diagnostic criteria in DSM-5. The two factors, determined by this analysis, included one set of monothetic criteria (that is, all four features must be present) focused on social communication problems, and a second set of polythetic criteria (that is, two of four features must be present) focused on restricted, repetitive, or atypical interests and behaviours. Post hoc analyses of the data suggested this to be a well-functioning criteria set. However, some problems have quickly become evident. In the first place, the combinations of criteria that resulted in a diagnosis of ASD were drastically reduced. Secondly, the inclusion of a new diagnostic feature associated with hypo- and hypersensitivity to sensory input did not appear well justified, as a similar feature had produced little predictive value in DSM-IV field trials [47]. In the latter, a factor analysis had shown that two-, three-, or five-factor solutions worked reasonably well (the two-factor solution paralleling the DSM-5 approach, and the five-factor solution providing additional sub-factors based on the repetitive behaviour category) [47]. It should be noted, however, that interpretations of factor analyses can be particularly susceptible to some significant issues, particularly if important data are not included and thus are unable to influence the factors being produced (see [48] for a discussion of the uses and misuses of factor analysis). Some recent studies have now questioned aspects of the factor solution proposed for DSM-5 [49, 50].

As a practical matter, it was quickly apparent that the approach adopted would disqualify many individuals from a diagnosis—particularly those who were younger or more cognitively able (see [51] for a recent meta-analysis). As a result, a decision was made to ‘grandfather’ in those cases with well-established previous diagnoses, thus resulting in both DSM-IV and DSM-5 diagnostic categories being in effect simultaneously. Some aspects of the approach adopted by DSM-5 are welcome. In fact, the current diagnostic definition is, in many ways, more consistent with Kanner’s classic

definition of autism than the broader autism spectrum adopted in DSM-IV, which has a considerable body of support from both genetic and psychological research [38]. As noted previously, the inclusion of a new communication disorder—‘social communication disorder’—was not well justified and, as a practical matter, may not succeed in its purpose of capturing those individuals who will fall outside the more stringent DSM-5 diagnostic criteria for ASD, as it was not developed to be convergent with previous diagnoses of Asperger’s syndrome or PDD-NOS.

Expectations for ICD-11

The eleventh edition of the WHO’s International Classification of Diseases (ICD-11) is currently being developed and likely will be approved in 2018. A major focus of this effort has been the desire to make the manual (or at least the clinical version) more user-friendly. There has been some attempt to encourage the use of a standard template for clinical decisions and diagnostic guidelines [52]. On balance, it likely will have areas of convergence with DSM-5, with some potential differences as well. A draft version is available, and efforts to evaluate it are now under way [53]. It seems likely that the ICD-11 diagnosis will certainly include individuals with ASD in DSM-5; at this point, the questions centre more around the approach to grouping certain conditions, for example, cases with regression or the more prototypical Asperger’s phenotype, and whether the ‘grandfathering’ rule of DSM-5 will also be adopted.

It should be noted that, in addition to official systems like ICD and DSM, adoption of the Research Domain Criteria (RDoC) approach, proposed by the National Institute of Mental Health, attempts to cut across traditional definitions and focuses on domains of neurobiology and behaviour [54]. The RDoC approaches are organized around several domains of functioning and various approaches of units of study [55]. The latter can range from genes to behaviour to self-report. This approach has been extensively critiqued [56, 57] but has stimulated new lines of enquiry in fields such as co-occurring conditions in traditional approaches. As such, it may have some utility for clinical and treatment studies in which the focus or target behaviour(s) cut across transitional diagnostic categories [54, 58, 59].

Basic mechanisms and treatment targets for autism spectrum disorders

Emily J.H. Jones

Introduction to autism spectrum disorder

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by difficulties with social communication, and the presence of restrictive interests, repetitive behaviours, and sensory symptoms [1]. Symptoms must be apparent from early childhood for a diagnosis to be made. ASD is 3–4 times more common in boys than girls, which likely represents a combination of biological differences and under-identification of girls in community settings. The name ‘autism *spectrum* disorder’ reflects the huge variability in the degree and nature of the symptoms that people with ASD experience and the likely heterogeneity in their underlying causal mechanisms. While some individuals with ASD have highly successful professional and personal lives, others may never live independently, have a job, or form strong peer relationships. Developing new treatment options for individuals with ASD requires determining the mechanisms that underlie the emergence, consolidation, and maintenance of core symptoms throughout the lifespan. This chapter will describe the approaches used to study the basic mechanisms underlying ASD, review our current understanding of the processes that contribute to symptoms, and indicate the value of this work for identifying new treatment targets.

Approaches to identifying the mechanisms that underlie symptoms of ASD

When searching for treatment targets, we need to identify the biological or neurodevelopmental pathways that cause the emergence or maintenance of clinical symptoms of ASD. Such causal mechanisms need to be distinguished from secondary or compensatory processes and be separated from differences related to co-occurring symptoms (like anxiety or ADHD), in order to target core domains of ASD symptomatology. We must understand how mechanisms relate to both strengths and weaknesses in ASD, in order to avoid unwanted effects of targeted treatments. To address these pressing goals, researchers have taken a range of approaches that I shall summarize now.

Case-control studies

The vast majority of efforts to delineate the mechanisms underlying ASD symptoms rely on comparing neurocognitive function in people with and without ASD. Any difference in the ASD group is usually interpreted as atypicality and considered to be a candidate causal mechanism. Such ‘case-control’ designs can provide a rapid assessment of whether a particular measure is likely to have value for further investigation. However, they have many limitations. Firstly, the interpretation of group differences always relies on the selection of an appropriate control group, but finding the ‘perfect’ control group is very difficult (and perhaps impossible). Groups may differ on both core and associated symptoms (for example, anxiety and depression); examining whether variables associated with case/control differences are dimensionally related to autism symptomatology can mitigate this concern but require large group sizes. Dealing with IQ is similarly problematic; uneven cognitive profiles in individuals with ASD can make matching difficult, and the considerable neurobiological heterogeneity in children with general developmental delays can limit our understanding of the differences we see in the ASD group. There is also a degree of genetic overlap between developmental disability and ASD [2], so we could be ‘controlling’ for variation in which we are interested. An alternative option is to contrast how performance on a neurocognitive task relates to variables, such as chronological age, mental age, or social communication skill, in both the ASD and comparison groups. This ‘developmental trajectories’ approach has been used to show that face-processing skills co-vary with broader social communication skills in the same way in children with and without ASD, such that children with ASD were showing patterns resembling those in younger typically developing children [3]. This approach is very promising but is yet to be widely adopted. In light of such limitations, research has moved away from traditional case-control designs and towards other approaches.

Trait-based approaches

Trait-based approaches, like the Research Domain Criteria (RDoC) framework, address some of the limitations of case-control designs [4]. Moving beyond the clinical diagnosis, the RDoC specifies a number of domains that can be described at multiple levels of

analysis (from genetics to behaviour). Focusing on particular key domains within heterogeneous participant groups may be fruitful in identifying the neural mechanisms that are associated with variation in a particular symptom cluster. Since most genetic risk for ASD lies with common variation [5] and genes carrying risk for ASD co-vary with typical variation in social communication skills in childhood [6], studying the neurocognitive underpinnings of ASD-related traits in the general population could be very fruitful. Given the developmental nature of ASD, studies in infancy are particularly important. Indeed, we recently showed that infant measures of social attention that predict later ASD also co-vary with parental ASD-related traits in a large group of typically developing infants [7] (Fig. 26.1). Such studies provide great potential for understanding the neurodevelopmental processes that mediate between genetic risk and phenotypic expression of ASD-related traits.

The RDoc framework is not without limitations. The developmental aspects of the framework need elaborating [8], which is critical to increasing its applicability to neurodevelopmental disorders

like ASD. This can be challenging, because neural functions may be less specialized or differentiated in early infancy and the mapping between brain function and cognitive process may be different [9]. A further challenge to fully implementing trait-based approaches is the relative fragility of our current neurocognitive batteries. Many lack acceptable basic psychometric properties like test-retest reliability, or context insensitivity, which may be a critical limitation to their use in indexing individual differences in a clinical context. One way to mitigate these concerns is to select tasks for investigation that produce robust replicable responses in individuals. However, will these be sensitive to ASD-related differences? A number of recent studies have linked ASD to increased intra-individual variability in responses [10, 11] or greater idiosyncrasy in functional activation patterns [12, 13]. If ASD is characterized not by stably different (trait-like) neurocognitive function, but by greater 'state' variation in activation patterns, simple tasks that achieve high test-retest reliability in individuals with ASD may actually be those that are least likely to identify deficits. In general, the field may need to

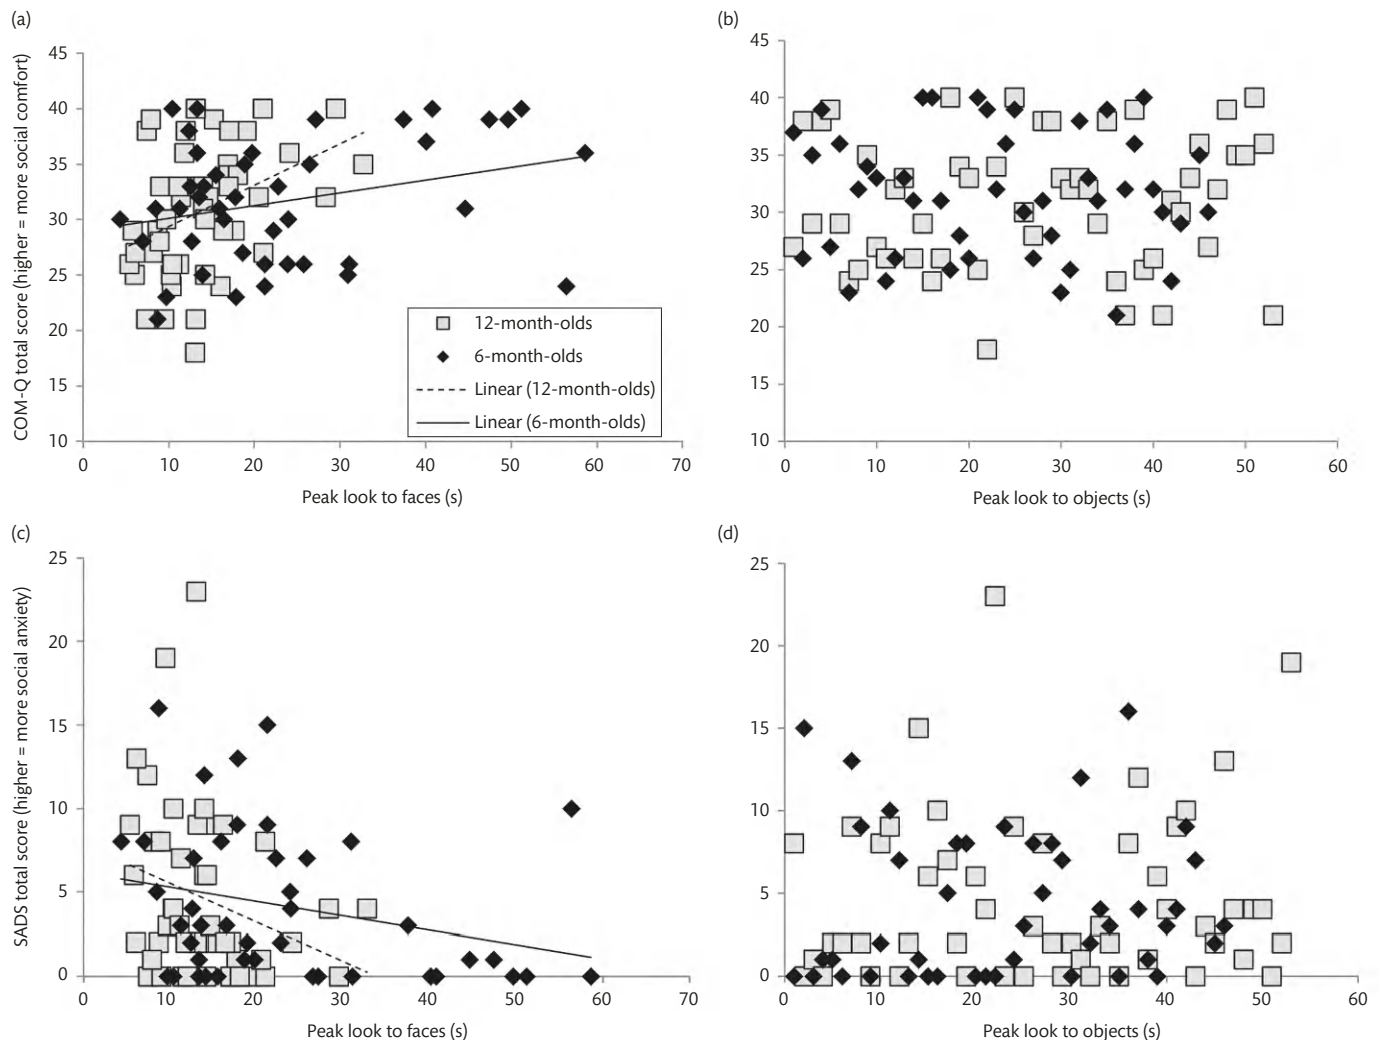

Fig. 26.1 Higher parent social anxiety (SADS, social anxiety, and distress) and lower social comfort (COMQ, Social Competence Questionnaire) relate to shorter peak look to faces (a, c), but not objects (b, d) in 6- and 12-month-old infants. Shorter peak looks to faces have been previously associated with later ASD.

develop more sophisticated neurocognitive methodologies rooted in neurobiology to find metrics that circumvent these issues. This may include a shift of approach from static cognitive traits towards identifying markers of state-related changes in brain responses.

Longitudinal prospective studies

Longitudinal studies of children with ASD allow the identification of neural mechanisms that predict later symptom variation. In a recent example, Neuhaus and colleagues showed that more normative neural responses to faces at the age of 3 years predicted greater improvement in core ASD symptoms between the age of 3 and adolescence [14] (Fig. 26.2). Although these associations do not prove causality, they provide a more powerful way of identifying good candidate mechanisms to subject to more rigorous testing. Prospective studies of infants at familial risk for ASD go one step further by allowing investigators to identify mechanisms that may underpin symptom *emergence*. Such studies follow groups of infants with older siblings with ASD, who have a 20% chance of developing ASD themselves [15]. Researchers use a battery of measures to assess early neural, cognitive, and behavioural development in these infants, which can then be examined in light of their ASD outcome status from toddlerhood (Fig. 26.3). Recent reviews of this literature highlight the accumulation of behavioural autism symptoms in the second year of life, preceded by more subtle, but apparently more

domain-general, atypicalities [16, 17]; early reports from parent-mediated interventions for high-risk infants suggest that some of these domains can be successfully targeted [18–20] (Fig. 26.4).

Genetics

Given the high heritability of ASD, genetic information is critical to building causal models of symptom emergence. Advances in technology have rapidly expanded our ability to extract and interpret information about genetic variation associated with ASD, although there is still much to discover [21]. However, turning genetic information into meaningful hypotheses about causal mechanisms remains challenging. Many genetic studies still use coarse phenotypes like the presence or absence of a clinically determined ASD diagnosis, which shares many of the limitations of case-control studies of neurocognitive measures described (including the common failure to consider co-occurring syndromes like depression, ADHD, or anxiety). Further, the path between genotype and phenotype is not static but emerges through a developmental interaction between the gene and the environment on the substrate of the developing brain (Fig. 26.5). Substantial compensatory and adaptive mechanisms exist to buffer early disruptions, and these likely include epigenetic modifications that produce significant changes in gene expression over development [22]. In order to understand how genetic variation underpins ASD symptom emergence, prospective studies are required that measure genetic variation, epigenetic

regulation, the developing brain, and emerging behavioural symptoms over time.

A complementary approach to incorporating information about genetics into models of ASD emergence is to study children with genetic syndromes associated with high rates of ASD like fragile

X, tuberous sclerosis, or Cohen's syndrome [23]. Animal models of some of these conditions are available, allowing clearer links to be drawn between human research and basic neurobiology and allowing identification of putative treatment targets. However, medications targeted at mechanisms in conditions like fragile X produce

impressive effects in rodents but have yet to show promise in human trials [24]. The significant limitations of mouse and rat models in modelling social and communication domains may play a role. Further, little is known about which of the neurodevelopmental paths underlying symptoms of ASD in genetic disorders are shared with children with idiopathic ASD. Fortunately, a number of investigators have recently begun longitudinal prospective studies of infants with conditions like tuberous sclerosis or neurofibromatosis type 1, which will go some way to addressing these questions.

Current understanding of the mechanisms underlying ASD symptoms

The rapidly expanding literature on ASD constantly produces new hypotheses about its underpinning mechanisms. I have selected three explanations in the following sections that illustrate the necessity of both theories derived from 'top-down' clinical studies of individuals with ASD and those with a strong emphasis on genetics and neurobiology. I will point to areas of interface between these levels of explanation, which hold promise for the eventual reconciliation of these frameworks. However, it is important to note that there may or may not be one 'final causal path' to autism symptoms—it is probable that autism represents the combination of several risk pathways that happen to co-occur in some individuals, and the number of possible combinations may be many and varied (the 'autisms' [25]). There is very unlikely to be one single explanation for autism, and indeed the following accounts contain many different specific routes to differences in a very broadly defined area of neurocognitive function.

Social attention, motivation, and affiliation

Social communication impairment is one of the most distinctive features of ASD. 'Social first' theories propose that children with ASD find social stimuli less engaging than they should (for a variety of

possible reasons), which may compromise learning about the social world and the ongoing development of the social brain [26–28]. Routes to diminished engagement may include a failure to assign reward value to social stimuli, altered responsivity to complex and unpredictable stimuli, or difficulties with specific aspects of social cognition. Children may experience one or more of these specific difficulties, but the common end result posited is a gradual withdrawal from the social world. Given that self-directed experience is likely very important in social communication development, children's initial difficulties are compounded by this social withdrawal.

Evidence for the role of social attention

A range of evidence exists for the early emergence of differences in social attention. While 'innate' social subcortical orienting may be intact [29], putatively 'cortical' aspects of social attention are altered early in infants with later ASD. By 6 months, infants with later ASD show altered temporal profiles of attention engagement with faces [30] (Fig. 26.6), reduced interest in speaking faces [31], reduced interest in social scenes [32], and declining interest in the eyes [33]. Differences in social behaviours like joint attention accumulate through the second year, resulting in a profile of a gradually decreasing interest in other people that matches that hypothesized in developmental accounts [34]. Taken together, data from prospective studies indicate that differences in social attention are observed from early development of infants with later ASD. One critical next step is to establish whether such differences are simply a signature of ASD unfolding [35] or whether they additionally contribute to later emerging social communication problems.

Studies of newly diagnosed toddlers confirm differences in social attention. For example, when viewing naturalistic social scenes, toddlers with ASD pay less attention to other people's activities [36] and show reduced interest in faces and people when speech and eye contact are introduced [37]. Further, toddlers with ASD show reduced attention to stimuli depicting biological motion [38, 39], a

highly conserved ability typically present from birth [40]. By the time of diagnosis, differences in social attention are accompanied by alterations in face processing. Expert face processing relies on experience with faces in early development [41], and thus, early alterations in face processing could represent downstream consequences of diminished social attention. For example, pre-schoolers with ASD show altered neural responses to familiar faces [42] and faces displaying emotional expressions [43] that predicted symptom trajectories into adolescence [14], indicating broad disruption to social brain systems. Toddlers with ASD also take longer to learn about faces [44] and show delays in neural responses to face familiarity that are in line with their broader social delays [3] (Fig. 26.7). Of note, basic face-processing components like the N290 appear typical in earlier development [30, 45]. Taken together, disruptions in social attention may be associated with downstream effects on aspects of social cognition by the time of diagnosis.

Moving forward, the potential role of social attention in the emergence of ASD makes it a suitable target for developing proxy markers of treatment outcome. This may be particularly important in developmental populations in which symptoms may not have fully emerged. However, the likelihood that there is heterogeneity in the processes that underlie alterations in social attention means that we will likely need a range of 'biomarkers' if we wish to target the underlying neural systems. Measures like eye-tracking responses to complex social scenes may be closer to the symptoms used to diagnose ASD and may thus show shared alterations across a broader range of individuals. In contrast, EEG or fMRI studies may target

systems that are only altered in a subset of individuals and may thus be more suited to identifying meaningful subgroups of participants. Whether or not these subgroups require different treatment approaches remains an open question and relates to whether or not alterations in particular neurocognitive systems can be linked to particular aspects of molecular pathophysiology. It may be EEG- or fMRI-derived subgroups can be used to define measures that are used to test the effects of treatments on the systems that appear altered in that individual, but the underpinning pathophysiological alterations may not fall into the same categories. For example, one might determine that social reward networks are underpinning social difficulties in one subgroup, while differences in social cognition are most problematic for another. The same treatment might be tested, but its effects on social reward used as the primary outcome in one group and its effects on social cognition as the primary outcome in another. Alternatively, a treatment may specifically target social cognition, in which case participants may be screened on the basis of neurocognitive measures for trial entry. New efforts to use EEG to identify participants for clinical trials are an important step in testing such ideas.

Treatment targets

Although neurodevelopmental studies with humans do not examine the primary distal causes of autism (genetic and environmental), they can identify developmental processes that serve to canalize or consolidate development down an atypical path. Targeting such processes may provide valuable ways of ameliorating later symptom

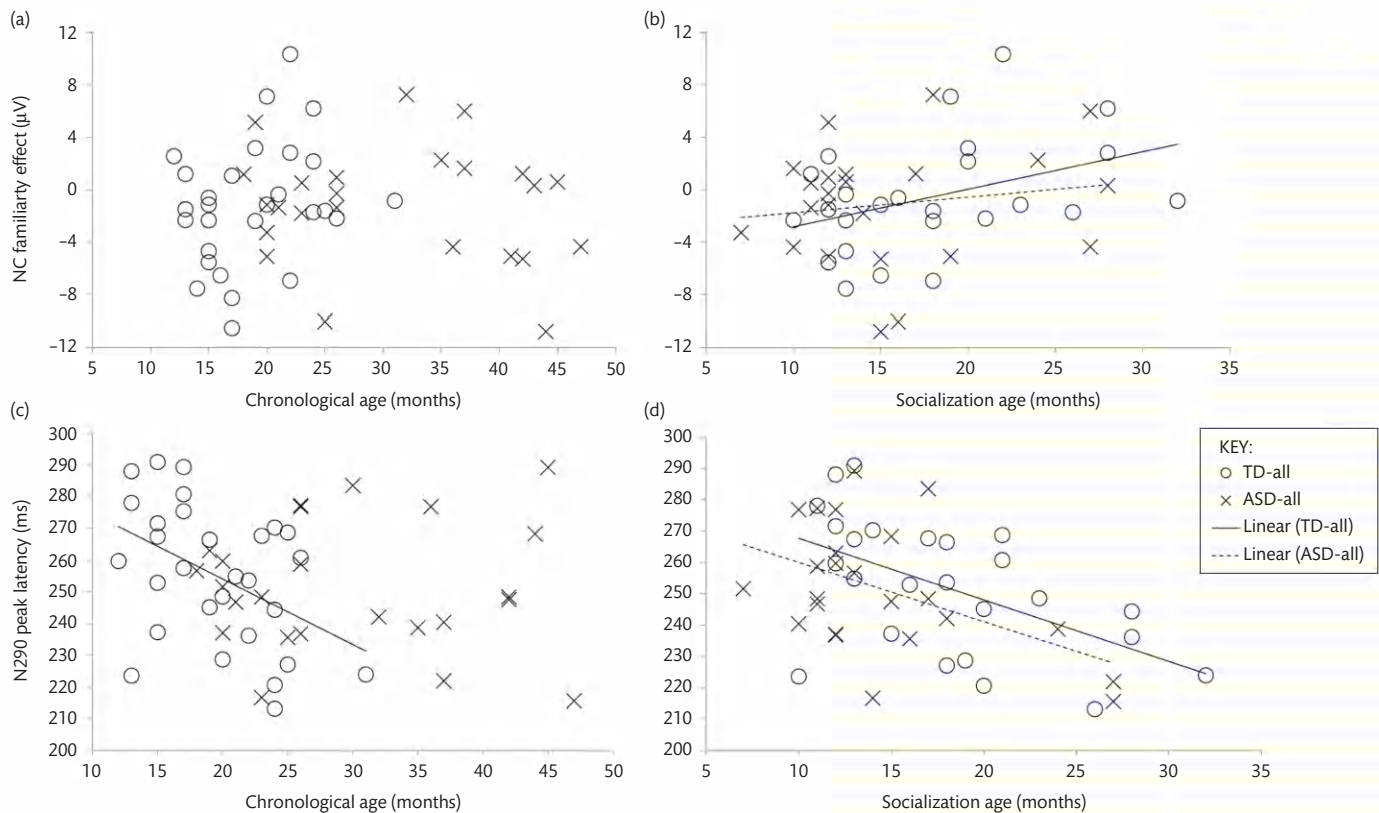

Fig. 26.7 Relationship between the Nc event-related potential familiarity effect (response to familiar minus unfamiliar face) and (a) chronological age and (b) socialization age, taken from the Vineland Adaptive Behavior Scales. Relationship between the N290 event-related potential peak latency and (c) chronological age and (d) socialization age. Findings show that in toddlers with autism, responses to faces develop in line with social, but not chronological, age.

trajectories. Joint attention is a construct that illustrates the potential for developing causal models of ASD emergence that can be used to develop new treatments. Joint attention refers to the ability to ‘coordinate attention between interactive social partners with respect to objects or events in order to share an awareness of the objects or events’ [46]. Most typically developing infants are able to share attention, follow another’s direction of attention, and direct another’s attention by pointing themselves by around 12 months. Early joint attention skills predict individual differences in later language development [47], consistent with the idea that shared attention scaffolds early language development. Toddlers with ASD show marked impairments in aspects of joint attention [46, 48] that relate both to concurrent and future language skills [49]. Building on this research, Connie Kasari and colleagues have developed programmes targeted at joint attention, in addition to other symbolic play and engagement skills [Joint Attention, Symbolic Play, Engagement and Regulation (JASPER)], and shown significant effects on social communication, emotion regulation, and language in pre-schoolers [50, 51]. Indeed, JASPER is one of two interventions recommended by NICE in the UK as evidence-based. The progress in this research field highlights the power of a developmental approach.

Social engagement (broadly defined) has been the target of other successful behavioural intervention approaches for children with ASD. For example, Dawson and Rogers have developed comprehensive and intensive programmes (the Early Start Denver Model)

that also feature inter-personal exchange and shared engagement as a core target; these have improved both communication skills [52] and neural responses to social stimuli [53] in young children with ASD. Green and colleagues have developed the less intensive Preschool Autism Communication Trial (PACT) model, which focused on increasing the engagement and reciprocity of interactions between children and their parents [54]. This intervention can produce long-term improvements in symptoms in children with ASD [55]; improvements are likely mediated through changes in parental synchrony and child initiations [56]. Plasticity in early development has the potential to be even greater, and so researchers have also developed parent-mediated programmes for infants at high familial risk for ASD. These typically focus on boosting sensitivity to early communicative cues, encouraging the child’s efforts to enter the social world. Though replication is needed, early results are promising and suggest there may be effects on emerging autism symptoms [18, 20] and the neurocognitive correlates of social attention [19]. One key limitation of psychosocial trials is that parents and caregivers are aware of treatment status, making the use of caregiver questionnaire measures (the most common outcome measures used in pharmaceutical trials) very problematic. Blinded behavioural or neurocognitive outcome assessments are thus critically important in this field. However, the relevance of many of these measures to everyday functioning for individuals has not been demonstrated. Ongoing efforts to develop new objective biomarkers for social

cognition [57] and analysis approaches for common diagnostic assessments that are more sensitive to treatment change [58] will facilitate progress in this area. Further, testing whether changes in social attention/social cognition predict longer-lasting change in social functioning will be an important test of causal frameworks and will indicate whether such measures could form proxy outcome measures for future trials.

Pharmacological treatment targets in the domain of social cognition have also been identified. One promising line of investigation is the neuropeptides oxytocin and vasopressin. These are highly conserved mediators of complex social cognition and behaviour and, with appropriate caution, could thus prove valuable translational targets [59, 60]. Several trials of the effects of oxytocin have been reported in people with autism, with some predicted effects on social cognition and behaviour [61–63]. One challenge to be addressed is the mode of oxytocin administration, since effects on the brain of intranasal administration (the most common method) may be limited to high doses and within certain time windows after administration [64]. The developmental window during which oxytocin is administered may also be critical. For example, mice with a mutation in *Cntnap2* display deficits in social behaviour and reduced oxytocin; daily application of oxytocin improved later social engagement, but this was most pronounced when treatment occurred earlier in development [65]. These results are promising, but in wildtype mice, chronic application of oxytocin developmentally can produce compensatory mechanisms that *reduce* sociability in adulthood [66]. Such results illustrate the importance of considering compensatory systems and the need for individualized treatment approaches. Vasopressin (which differs in only two amino acids from oxytocin) has been less well investigated, but in addition to core functions in regulating blood pressure, it also has an important function in mediating social behaviours [4]. Vasopressin enters the CNS after intranasal administration and can modulate brain networks involved in processing emotional information [67]. Thus, a number of clinical trials targeting vasopressin in ASD are under way (<https://clinicaltrials.gov>). Interestingly, while some investigators are testing the effects of increasing levels of vasopressin (<http://med.stanford.edu/clinicaltrials/trials/NCT01962870>), others have reasoned that suppressing vasopressin activity may be more appropriate [68]. Taken together, neuropeptides show some promise as translational targets for further work.

Inhibition/excitation balance

Evidence

Network and clustering-based approaches to genetic data have identified common functions that appear to be compromised by a range of risk variants for ASD, which include neural signalling and development, synaptic transmission, chromatin remodelling, neural-glial signalling, and transcriptional regulation [69]. Examination of expression patterns of risk genes by brain region and developmental stage has identified transcriptional regulation and synaptic development during pre- and early postnatal development as loci of alteration, with concentrations in superficial cortical layers and glutamatergic synapses [70]. Taken together, such work indicates (perhaps unsurprisingly) that ASD is related to differences in the formation and specialization of brain networks. One specific line of investigation has focused on disruptions in either glutamate or

GABA-ergic systems, which could lead to alterations in the co-ordination of inhibition/excitation in the brain [71]. The high co-occurrence of epilepsy in individuals with ASD forms one line of evidence for this hypothesis [72], in addition to the high rates of ASD in disorders that disturb glutamatergic or GABA-ergic functioning like 15q11–13, fragile X, or neurofibromatosis type 1 [73]. Alterations in GABA and glutamate levels have been identified in individuals with ASD using magnetic resonance spectroscopy, though findings are somewhat inconsistent and limited by lack of spatial precision [74, 75]. Emerging evidence from stem cell models implicate an over-production of GABA-ergic neurons [76]. Theoretical models indicate the important role of GABA in maintaining brain networks [77], and evidence from animal models suggests that GABA or glutamatergic dysfunction could contribute to maintenance of concurrent ASD symptoms [78]. Thus, a range of evidence indicates that GABA/glutamate systems may be appropriate treatment targets for targeting current symptomatology.

Developmental actions of GABA and glutamate are also critical to consider. GABA has well-defined roles in controlling processes, including cell proliferation, neuroblast migration, dendritic maturation, and synapse elimination [79, 80]. Activity-dependent GABA signalling is thought to be critical in optimizing the balance between excitation and inhibition in the developing cortex [79] and has a critical role in shaping cortical-sensitive periods [81]. Such sensitive periods are important in tuning brain responses to the faces and voices infants encounter in their environment, a process called perceptual narrowing [82]. Disruptions to GABA-ergic signalling processes could thus impact early experience-dependent specialization of the social brain, potentially resulting in ASD symptoms. Further, a wide body of research indicates that GABA initially has a depolarizing function, with a switch to a hyperpolarizing function somewhere around the end of the first postnatal week in rodents, though there has been some debate [83, 84]. Other neurotransmitter systems with significant developmental roles include serotonin, which has also been implicated in autism and is particularly involved in early development of sensory systems [85]. Understanding how key neurotransmitter systems contribute to the emergence of autism symptoms will be assisted by longitudinal prospective studies of populations of human infants with genetic syndromes associated with alterations in key neurotransmitter systems.

Treatment targets

A number of therapeutic targets have been identified that may modulate GABA or glutamatergic functioning. For example, acamprosate is a GABA_A agonist and a glutamate antagonist, which has shown some benefit in open-label trials [86]. The GABA_B agonist arbaclofen has successfully reversed symptoms in animal models of fragile X syndrome, but human trials have been disappointing [24]. Vigabatrin inhibits the breakdown of GABA and increases GABA concentration; its use for seizures in infants with tuberous sclerosis has been associated with some improvement in ASD symptoms in later development [87]. Gabapentin increases GABA concentration and is sometimes used to manage disruptive behaviours in adults with ASD [88]. Other anti-epileptic drugs like topiramate, levetiracetam, and lamotrigine have been trialled, with limited effects on core symptoms [89]. D-cycloserine is a partial glutamatergic agonist, which has had limited efficacy for core symptoms [90] but may support long-term effects of targeted social skills training in

children with ASD [91]. Bumetanide enhances GABA-ergic inhibition and again has shown some promise [92]. Targeting the serotonin system, SSRIs like fluoxetine and citalopram have been trialled in older populations, with mixed results [93]. Clearly, further work on turning promising genetic findings into drug targets is required. One key step is to develop better neurocognitive markers of targeted neurotransmitter systems that can be used as outcome measures in clinical trials.

Oxidative stress and immune activation

Evidence

Emerging evidence suggests a role for maternal immune activation/inflammation and oxidative stress in causing ASD [94–96]. Prenatal risk factors for ASD include infection, maternal gestational diabetes and medication use, exposure to significant pollution, neonatal anaemia, meconium aspiration or exposure, and respiratory distress [97–99], many of which cause some degree of hypoxia and/or a strong maternal immune response in pre- or early postnatal development. Mutations or alterations in mitochondrial functioning have also been linked to ASD [100], which may compromise energy available to neurons. With regard to inflammation, epidemiological studies indicate correlations between autism and familial history of atopic diseases like asthma, eczema, allergies, and food intolerance, all associated with inflammatory responses [96]. Prenatal immune activation may produce changes in methylation (particularly in the prefrontal cortex) that could contribute to later ASD symptoms [101]. Effects of oxidative stress or inflammation may also depend on the presence of particular risk genes in influencing outcome [102, 103]. Interestingly, gene expression studies show that individuals with ASD exhibit upregulated expression of genes associated with inflammatory responses that are correlated with downregulation of synaptic transmission genes [104]. Developmental analyses suggest that these inflammatory responses may be secondary consequences of early dysregulation associated with changes in synaptic function or brain activity across the first decades of life [22]. However, such changes may still contribute to maintenance of core and associated symptoms of autism and thus represent appropriate targets for intervention.

Treatment targets

There have been some promising signals of the antioxidant *N*-acetyl cysteine (also involved in regulation of extracellular glutamate) during adolescence in animal models of schizophrenia [105]. Early trials in ASD are not promising [106] but may have selected insufficiently sensitive outcome measures (questionnaire-based, rather than mechanistic, as in the animal model); application at a prodromal stage of the disorder may be more effective but, of course, would be associated with significant ethical hurdles. Other investigators have shown promising effects of sulforaphane (in combination with other compounds), a component of broccoli that also has significant antioxidant properties; effects were apparently reversed when the participants stopped taking the treatments [107]. Concerns have been raised about the unusually small ‘placebo’ response in the control group, although one of the key measures is not commonly used in ASD trials (the Social Responsiveness Scale). There have also been some supportive findings in animal models [108], suggesting that this kind of approach may be worthy of further investigation.

Linking top-down and bottom-up models

To date, attempts to link the literature derived from top-down dissections of the clinical difficulties experienced by children with ASD and emerging ‘bottom-up’ findings from genetic studies and animal models have been relatively exploratory. There are domain-general explanations of ASD within the cognitive literature that may map more readily onto the emerging neurobiological literature; these include ideas about neural variability [11], reduced influence of prior information on current processing [109], or alterations in weighting of errors within predictive coding frameworks [110]. However, while these explanations map relatively clearly onto some of the perceptual experiences of individuals with ASD, they generally provide relatively underspecified accounts of both core social communication symptoms of ASD. Moving forward requires rigorous experimental and theoretical and computational approaches to understanding the interfaces between these literatures. Nonetheless, there are some potential points of convergence. Firstly, effects of early widespread neuronal disruption on sensitive periods in early brain specialization may be one possibility for why the difficulties in ASD are so pronounced in the social domain. Experience-dependent learning is clearly very important in the development of social communication, since infants are not born knowing what language they will speak or what faces they will see; many ASD-associated genes converge on processes like neural signalling and development, synaptic transmission, activity-dependent chromatin remodelling, neural–glial signalling, and transcriptional regulation that would be expected to affect experience-dependent specialization. Higher-order association ‘nexus’ regions that are critical in social processing may be particularly vulnerable to altered inhibition/excitation balance, because they integrate signals from several regions [111]. Gene expression studies are also beginning to reveal degrees of anatomical specificity in observed changes that may help guide human neuroimaging studies; for example, disordered cortical patterning of gene expression has been observed in frontal and temporal cortices, critical to the social brain network. Greater refinement of genetic, neurobiological, and human phenotyping studies may converge on meaningful explanations of how apparently domain-general alterations produce the relatively specific symptoms experienced by individuals with ASD.

An alternative possibility is that the disruptions associated with highly penetrant genes or environmental risk factors may not directly cause the social symptoms associated with ASD. Some of the more penetrant genetic variants may simply cause the brain to work less effectively, which only produces symptoms of ASD when on a genetic background that predisposes children towards poorer social skills [112]. Similar hypotheses have been advanced for environmental factors like maternal immune activation [113]. Indeed, most copy number variations associated with ASD have also been associated with a wide range of other conditions. Genetic evidence suggests that copy number variations and common variation associated with ASD may affect different biological processes [114]. Larger mutations may alter the degree to which neurodevelopmental trajectories are buffered against environmental or other genetic perturbation [115, 116], with specificity then linked to those perturbations. If this is the case, trying to figure out how mutations that apparently have widespread effects lead to relatively specific symptoms may be a fruitless endeavour. Indeed, robust ‘autistic-like’ phenotypes in mice

with fragile X syndrome mutations are only seen on a limited range of genetic backgrounds [117], potentially critical to understanding the failure of recent trials inspired by mechanisms affected by the fragile X syndrome mutation. However, such accounts need to explain why some genetic syndromes like Williams syndrome are not associated with high rates of ASD.

Thirdly, it is critical to understand the role of adaptation in shaping the ASD phenotype. The brain is an organ of adaptation at multiple spatial and temporal scales [111]. These adaptive processes could be relevant to ASD in a number of ways. Firstly, deficits in adaptation could directly contribute to ASD. For example, homeostatic processes act to regulate inhibition/excitation ratios, and disorders/insufficiency of homeostasis [118] or autoregulation in general [71] have been posited as unifying frameworks in ASD. Neurotransmitter systems like GABA or neuropeptides like vasopressin may thus need to be balanced within an optimal range, rather than generally up- or downregulated by treatment. Secondly, alterations that occur during particular time windows could cause long-term effects but be rapidly masked by subsequent compensatory processes [119]. In this case, adaptive processes would make it impossible to identify the original causes of ASD in the mature brain. Thirdly, adaptive processes may produce symptoms of ASD that represent optimal functioning for that individual brain, given its early processing constraints [111]. If this is the case, boosting adaptation may actually result in more symptoms of ASD. Finally, adaptive or compensatory processes may not be specific to ASD but may produce co-occurring symptoms. For example, recent gene expression studies indicate that immune-related markers emerge over the first two decades of life [22]. Increased cytokine and other inflammatory responses have been linked to depression [120], and so these responses may relate (as cause or consequence) to the common co-occurrence of conditions like depression in individuals with ASD. The likely critical role of adaptation indicates that pharmaceutical development will require us to disentangle adaptive or compensatory responses from primary causal pathways.

Summary

Although the number of clinical trials of novel therapies for ASD is increasing, there has been much discussion of how to accelerate the pace of translation to the clinic [121, 122]. We need better measures with which to stratify participants for inclusion in trials and to measure the effects of those trials on the processes we think are impaired. This involves moving from group-level neuroimaging measures that are inconsistent across studies and have low reliability to identifying robust proxy biomarkers of treatment success. Such biomarkers should be developed not only from theoretical models of what we think underpins autism symptoms, but also from bottom-up measures of the pathophysiological processes implicated by genetic work and animal models. We also need translatable biomarkers that are sensitive to the same systems across species and can move with a drug from preclinical to clinical work; public-private partnerships can be valuable in this endeavour [123]. Further, we need a deeper understanding of how genetic and pathophysiological variation maps onto brain circuits and then onto emergent cognitive functions during development, and how this shapes final common

pathways to symptom development. This will require emphasis on longitudinal studies that measure brain and behavioural development in genetically characterized populations, coupled with computational models and use of large normative data sets on gene expression and circuit function. Finally, we need to understand the complex interactions between different neurotransmitter and neuropeptide systems over developmental time, including the role of compensatory changes, and an appropriate target may be to achieve balance, rather than to uniformly boost or suppress activity in particular systems. Despite these challenges, new insights mean that treatment development for ASD is poised to enter a new frontier of translational opportunity.

Epidemiology of autism

Charles R. Newton

Introduction

The epidemiology of autism has generated much interest recently, mainly because of the reported dramatic increases in the prevalence of autism in the last few decades and the controversy surrounding vaccines and autism. These reports have led to speculation of the causes and intensive study of the changing epidemiology of autism in some countries. This chapter provides a background to the epidemiology, particularly the global burden of disease and changes in the prevalence of autism in the last few decades and the risk factors that may contribute to these changes in epidemiology. In addition, financial burden and premature mortality are discussed.

Epidemiological concepts of autism

The epidemiology of autism is complicated by the difficulty in determining its onset and the changes in the criteria used for the diagnosis over time. Autism is widely considered as a life-long condition that occurs in genetically susceptible individuals, who may be exposed to other influences either *in utero* or after birth. The diagnosis of autism is rarely made before 18 months of age, although parents will often have concerns before that age. The age of diagnosis varies considerably, being influenced by the presence of symptom severity (particularly earlier in those with greater intellectual disability), socio-economic status (later in those with lower socio-economic status), parental concerns, and geographical region since this is determined by public awareness, expertise, and facilities for diagnosis [1]. Thus, determination of the onset is difficult, which makes calculating the incidence (new cases per population per unit time) problematic. The incidence is a more robust epidemiological measurement than prevalence (number of cases per population at point in time), particularly when examining the secular trends and identifying risk factors. However, incidence measurements may underestimate the burden of a condition if there is premature mortality (see Premature mortality, p. 267) or if there is spontaneous remission (this is rare in autism, since the diagnosis is stable throughout life, although the severity of symptoms may change). Most of the epidemiological studies have reported prevalence, since they are conducted on referral databases (which are susceptible to

bias, particularly ascertainment and assessment bias) or cross-sectional surveys with differing methodologies (postal surveys, community door-to-door surveys). Comparison between cross-sectional surveys are problematic, since the results are influenced by different methodologies, including identifying all the people within the denominator, tools used to screen for autism, age of the subjects, expertise of the final diagnosis, and diagnostic criteria. Comparison of the subjects identified with autism from surveys and established databases of autism may show significant discrepancies [2]. Birth cohorts may be more informative but are expensive and difficult to conduct.

Prevalence of autism

The initial studies measuring the prevalence of autism in the 1960s and 1970s reported low frequencies, with prevalences from 0.7 to 4.6 per 10,000, mainly using Kanner's description of the diagnosis [3] (Table 27.1). The DSM-III criteria published in 1980 [4] was used in most studies of that decade, with prevalences reported from 2.0 to 13.8 per 10,000 (Fig. 27.1). In this era, the comparison between the studies was complicated by use of varying methods for case ascertainment, different age groups studied, and some studies using the Kanner's criteria, Lorna Wing's triad [5], or Rutter's definition [6]. In the 1990s, the prevalences reported were considerably higher, with a prevalence of 60/10,000 reported from Sweden [7]. The analysis of the secular trends was complicated by the use of ICD-10 [8] and the introduction of DSM-IV published in 1994 (Table 27.1). From the year 2000, the reported prevalence of autism was consistently and considerably higher, ranging from 11.0 to 157 per 10,000. Most of these studies used either DSM-IV or ICD-10 criteria for autism. Since 2010, the prevalence of autism in some countries has been reported as even higher, with a prevalence of 140/10,000 in the United States across all age groups [9] and 260/10,000 in South Korean children [10].

Causes of reported increased prevalence of autism

Since the original delineation of autism by Kanner in 1943 [3], the conceptualization of autism has undergone significant changes

Table 27.1 Studies measuring the prevalence of autism in the 1960s and 1970s

	Kanner (1943) ¹	Rutter and Schopler (1978) ²	Wing and Gould (1978) ³	DSM-III ⁴	DSM-III-R ⁵	DSM-IV ⁶
Social communication	1. Profound lack of affective contact	1. Impaired social development which is out-of-keeping with the child's intellectual level	1. Impairment in social communication	1. Lack of responsiveness to others	1. Impairment in reciprocal social interaction (at least two from a list of five items, comprising specified clinical examples)	(A) Qualitative impairment in social interaction, as manifested by at least two of the following: 1. Marked impairments in the use of multiple non-verbal behaviours such as eye-to-eye gaze, facial expression, body posture, and gestures to regulate social interaction 2. Failure to develop peer relationships appropriate to the developmental level 3. Lack of spontaneous seeking to share enjoyment, interests, or achievements with other people, (for example, by lack of showing, bringing, or pointing out objects of interest to other people) 4. Lack of social or emotional reciprocity (note: in the description, it gives the following as examples: not actively participating in simple social play or games, preferring solitary activities or involving others in activities only as tools or 'mechanical' aids)
Language		2. Delayed and deviant language development that also has certain defined features and is out of keeping with the child's intellectual level	2. Impairment in verbal and non-verbal communication	2. Language absence or abnormalities	2. Impairment in verbal and non-verbal communication (at least one from a list of six items)	(B) Qualitative impairments in communication, as manifested by at least one of the following: 1. Delay in, or total lack of, the development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication such as gesture or mime) 2. In individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others 3. Stereotyped and repetitive use of language or idiosyncratic language 4. Lack of varied, spontaneous make-believe play or social imitative play appropriate to the developmental level
Behaviour	2. Repetitive, ritualistic behaviour, which must be of an elaborate kind	3. 'Insistence on sameness', as shown by stereotyped play patterns, preoccupations, or resistance to change	3. Repetitive, ritualistic behaviour	3. Resistance to change or attachment to objects	3. Markedly restricted repertoire of activities and interests (at least one from a list of five items)	(C) Restricted, repetitive, and stereotyped patterns of behaviour, interests, and activities, as manifested by at least two of the following: 1. Encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus 2. Apparently inflexible adherence to specific, non-functional routines or rituals 3. Stereotyped and repetitive motor mannerisms (for example, hand or finger flapping or twisting, or complex whole body movements) 4. Persistent preoccupation with parts of objects

(continued)

Table 27.1 Continued

	Kanner (1943) ¹	Rutter and Schopler (1978) ²	Wing and Gould (1978) ³	DSM-III ⁴	DSM-III-R ⁵	DSM-IV ⁶
Other features	Other features include: 3. An anxiously obsessive desire for the preservation of sameness in the child's routines and environment 4. A fascination for objects, which are handled with skill in fine motor movements 5. Mutism or a kind of language that does not seem intended for inter-personal communication 6. Good cognitive potential shown in feats of memory or skills on performance tests, especially the Séguin form board			4. Absence of schizophrenic features	4. In a total of at least eight from among the 16 items listed	A total of six (or more) items from (A), (B), and (C), with at least two from (A) and one each from (B) and (C) (III) The disturbance is not better accounted for by Rett's disorder or childhood disintegrative disorder
Onset	Kanner also emphasized the onset from birth or before 30 months	4. Onset before 30 months		5. Onset before 30 months		(II) Delays or abnormal functioning in at least one of the following areas, with onset prior to age of 3 years: (A) Social interaction (B) Language as used in social communication (C) Symbolic or imaginative play

Fig. 27.1 (see Colour Plate section) Prevalence of autism since the 1960s to 2015 according to the diagnostic criteria.

[11]. The definition has changed from a discrete disorder, based upon Kanner's description, to the concept that autism is part of a spectrum of disorders characterized by impaired social communication with differing degrees of severity. More recently, autism has been considered as a continuum, in which the diagnosis depends upon the number and severity of autistic traits. These differences in the concepts of autism have largely brought about the changes in the diagnostic criteria but have been influenced by changing conceptualization of mental health disorders and the complexity of the genetic basis.

The changes in the diagnostic criteria have had a major impact on the epidemiology of autism, from subjects with intellectual disability defined in Kanner's original description to DSM-IV and ICD-10 which are much more inclusive, encompassing higher-functioning individuals such as those with Asperger's syndrome. Thus, the prevalence of autism in London in the UK was three times higher with the reclassification of cases by ICD-10 criteria, compared to those defined by Kanner's criteria in the original study [12]. Many of these additional cases are a result of diagnostic substitution, in which cases of autism were previously diagnosed as other conditions. In the 1960s and 1970s, many cases of autism would have been classified as intellectual disability. In an analysis of special education requirements across the United States, Shattuck showed that many children initially diagnosed with intellectual disability were subsequently diagnosed with autism, and the increase in prevalence of autism was associated with a reduction in intellectual disability during this period [13]. In the UK, analysis of the General Practitioner Research Database demonstrated that the incidence of autism from the 1988 birth cohort rose from 4/10,000/year to 25/10,000/year in the 1997 birth cohort, and again this increase was attributed to changes in the diagnostic criteria [14].

Increased public and medical awareness of autism is likely to have increased the prevalence of autism over time. Parents of children with communication difficulties are more likely to take their children for assessment and ask about the diagnosis of autism. The formation of advocacy groups, for example Autism Speaks in the United States and the National Autism Society in the UK, has certainly increased public awareness and possibly led to an increase in referrals for assessment. Furthermore, parents are more likely to have their children assessed for autism nowadays, since in many Western countries, there is an increase in financial, psychological, and therapeutic support for families with autism than previously. Health care workers are more likely to entertain the diagnosis, and autism is now an established component of undergraduate teaching for health and educational professionals. Autism diagnostic services has increased, which, although they may be self-servicing, have arisen for perceived needs in communities. There has been an increase in national (Denmark [15]), medical [16], and educational [13, 17] registries in the 1990s. However, interpretation of the secular trends in these registries is problematic, since the reports often do not account for the many confounding factors such as increasing population, decreasing age of diagnosis, or changes in referral patterns and availability of services.

Changes in biological risk factors and in the prevalence of autism

The changes in a number of biological risk factors may have influenced the secular changes in the prevalence of autism. Increasing paternal age is associated with an increased risk of developing autism [18], and the paternal age has increased. Some drugs, for example sodium valproate, or alcohol use during pregnancy are associated with autism, and these may have contributed to the increase in the 1980s and 1990s. The influence of these factors in the last decade is likely to have decreased, given the increased awareness of the effects on the fetus [19]. The incidence of perinatal factors, for example prematurity, associated with autism has increased, and survival of affected neonates has improved [20]. Migration is associated with autism in some countries, for example Sweden, and this has increased in the last few decades [21]. In contrast, the incidence of other risk factors associated with autism, for example rubella and thalidomide exposure, has decreased.

Prevalence of autism across the world

The global burden of autism has not yet been defined accurately. Although there are many epidemiological studies from North America, Europe, and Japan, there are few studies from the remainder of the world. Thus, in a recent review of mental disorders of children, there were no data on any disorders in 124 of the 187 countries [22]. In particular, there were no studies on the prevalence of autism in Africa, South and Central Asia, Central and Latin America, and Eastern and Central Europe. In another review, the median prevalence from the available studies was 17 (range 3–94) per 10,000 in 36 studies conducted since 2000, with the median prevalence of all pervasive disorders as 62 (range 1–189) per 10,000 from 32 studies during the same time period [23]. There was no significant difference between these estimates between the studies conducted in Europe, North America, and Western Pacific.

Global burden of autism

The Global Burden of Disease (GBD) was set up in the 1990s to compare the burden between countries and monitor secular trends. The GBD is usually presented in disability-adjusted life years (DALYs), which is the sum of years lost to life (YLLs) + years lived with disability (YLDs). The latter, in turn, is derived from incidence \times disability weight. The disability weight in the 1990s was determined by expert opinion, but in the most recent estimations, the disability weight has been derived from interviews conducted across the world [24]. However, these interviews did not assess the disability weights associated with autism.

The global burden of autism, as measured with DALYs, was 337.8 million in 1990 and had increased by 38% to 467.6 million in 2010; however, this increase could be attributed to the population growth, with no increase in DALYs per capita [25]. Standardized by age and sex, this equated to 111 DALYs per 100,000 population [95%]

uncertainty interval (UI) 77–154], but with 170 DALYs per 100,000 males (95% UI 119–237) and 50 DALYs per 100,000 females (95% UI 35–68).

Sex ratio

The male predominance of autism was recognized by Kanner, and subsequently confirmed by later studies. Overall the ratio of males to females is 4.2:1 [26], but it depends upon the phenotype, in particular the degree of intellectual disability. As the intelligence quotient decreases, the ratio between males to females also decreases.

Risk factors

Autism has high heritability, with twin studies suggesting that heritability ranges from 64% to 91% [27], with the estimate partially explained by the phenotype being studied. However, the genetic basis of autism is complex, with multiple genes involved by a variety of abnormalities such as copy number variants, common genetic variants, etc. It is likely that a multitude of genetic factors influence the susceptibility of an individual to develop autism, but there may be environmental factors that influence the genetic propensity [28]. The complex genetic basis of autism is outside the scope of this chapter, and the reader is referred to some excellent reviews [29–31].

There are a number of risk factors associated with autism, including parental acquired risk factors, and intrauterine, perinatal, and postnatal risk factors. Increasing paternal age (>50 years) is associated with a small, but significant, risk (relative risks of 1.5) of autism [18, 32, 33]. Advanced maternal age (>40 years) is also associated with an increased risk, but the relative risk is smaller than that with older fathers. In addition, young mothers (<20 years) have an increased risk [18]. However, given the relatively low relative risks and the inconsistency between studies, the importance of these factors is not well established.

Exposure to intrauterine infections, drugs, and other insults is also associated with autism. Rubella infection during pregnancy was the first infection to be associated with the development of autism. Initial studies suggested that 4–7% of affected fetuses develop autism [34], and the risk is increased in those children who had other features of congenital rubella syndrome. Further studies report the prevalence may be as high as 12% [35]. Other infections, such as cytomegalovirus [36], influenza, and parvovirus, have been documented with autism, but the epidemiological data are weaker than those with rubella. Likewise, some parasitic infections, such as toxoplasmosis and tick-borne infections, have weak and inconsistent associations with autism [37].

In a meta-analysis of papers published by 2007, maternal infection during pregnancy (OR 1.18; 95% CI 0.76–1.83), vaginal infections (OR 0.49; 95% CI 0.22–1.09), and maternal fever (OR 1.24; 95% CI 0.76–2.04) were not associated with autism [38]. However, when the analysis was limited to the four studies that controlled for multiple covariates or used sibling controls; exposure to intrauterine infections was significantly associated with autism (OR 1.82; 95% CI 1.01–3.30). Two recent population-based studies from Denmark and Taiwan have similar results. In the Danish study, admission to hospital due to maternal viral infection in the first trimester [adjusted

hazard ratio (aHR) 2.98; 95% CI 1.29–7.15] and maternal bacterial infection in the second trimester (aHR 1.42; 95% CI 1.08–1.87) was associated with autism in the children, but no association was found between any maternal infection and autism (aHR 1.14; 95% CI 0.96–1.34) [39]. In the Taiwanese study of 4184 children with autism, two or more outpatient visits for genital infection [adjusted odds ratio (aOR) 1.34; 95% CI 1.12, 1.60] and bacterial infection (aOR 1.24; 95% CI 1.06, 1.43) were associated with autism [40].

More recently, considerable interest has been generated by immunological activation during pregnancy. Maternal autoantibodies to fetal brain proteins are associated with the development of autism [41]. Immunoglobulin G (IgG) reactivity against fetal brain proteins was found in the plasma of 7 of 61 American mothers (11.5%) of children with autism, but not in 62 mothers of typically developing children ($p = 0.006$) or 40 mothers of children with non-ASD developmental delay ($p = 0.04$) [41]. Further studies have identified that the antibodies are against fetal brain tissue, and not adult brains. In addition, in a systematic review, maternal autoimmune diseases were associated with autism (pooled OR 1.34; 95% CI 1.23–1.46), including maternal thyroid disease [42].

The association between vaccines and the development of autism has been controversial, with a highly publicized study discredited [43]. Vaccination of children occurs at the ages when children are most likely to first show the features of autism. Thus, it is not surprising that many people think that there is an association between vaccination and autism. Since the original, but discredited, publication suggesting a link between mumps, measles, and rubella vaccination and the development of autism, there has been considerable work to assess the association with this vaccine. The most robust studies have not found an association, in particular, the analysis of the Danish national database [15] and a case-control study based upon the British General Practice Register [44].

In addition, a meta-analysis of a number of vaccines have not found an association between any of these vaccines and autism [45]. The cohort data revealed no relationship between vaccination and autism (OR 0.99; 95% CI 0.92–1.06), and there was no relationship between autism and the measles, mumps, and rubella vaccine (OR 0.84; 95% CI 0.70–1.01) or the adjuvants used such as thimerosal (OR 1.00; 95% CI 0.77–1.31) or mercury (OR 1.00; 95% CI 0.93–1.07). The case-control data found similar results. Although the immunological activation induced by vaccination may lead to CNS manifestations, currently there is no evidence to support vaccination is associated with autism.

Other maternal factors thought to be associated with autism include gestational diabetes, nausea/vomiting, and bleeding during pregnancy. Gestational diabetes is associated with autism in a number of studies, and a recent retrospective longitudinal cohort study in California in the United States found that the risk of autism was associated with maternal type 2 diabetes (birth year aHR 1.33; 95% CI 1.07–1.66) and gestational diabetes diagnosed at 26 weeks or earlier (1.42; 95% CI 1.16–1.75) adjusted for maternal age, parity, education, household income, race/ethnicity, history of comorbidity, and sex of the offspring [46]. In a meta-analysis using a random effects model to calculate the summary effects, nausea/vomiting (1.48; 95% CI 1.03–2.14) and bleeding during pregnancy (1.81; 95% CI 1.14–2.86) were associated with autism [38].

Prematurity (gestational age <37 weeks) and low birthweight (<2.5 kg) often occur together, and without accurate estimates

Fig. 27.2 (see Colour Plate section) Associations between autism and estimates of exposure to individual traffic-related and criteria air pollutants. PM₁₀, particulate matter <10 µm in diameter; PM_{2.5}, particulate matter <2.5 µm in diameter; NO₂, nitrogen dioxide; NO, nitrogen oxide; O₃, ozone; CO, carbon monoxide. Exposure measured during developmental windows: PC, peri-conceptual; 1, trimester 1; 2, trimester 2; 3, trimester 3; P, pregnancy; Yr 1, first postnatal year. We recalculated parameters to reflect a change in the exposure comparison, to be consistent with other comparisons in the figure, involving calculations assuming that parameters were normally distributed.

Reproduced from *Curr Probl Pediatr Adolesc Health Care*, 44(10), Kalkbrenner AE, Schmidt RJ, Penlesky AC, Environmental chemical exposures and autism spectrum disorders: a review of the epidemiological evidence, pp. 277–318, Copyright (2014), with permission from Mosby, Inc.

Fig. 27.3 (see Colour Plate section) Associations between autism and estimates of exposure to pesticides. DE metabolites, diethyl phosphate metabolites of organophosphate pesticides; DM metabolites, dimethyl phosphate metabolites of organophosphate pesticides. Exposure measured during developmental windows: CNS, a priori period of central nervous system development (7 days pre-fertilization to 49 days post-fertilization); a period of development (26–81 days post-fertilization); 1, trimester 1; 2, trimester 2; 3, trimester 3; P, pregnancy; Yr 1, first postnatal year. Other results not reported as measures of association with confidence intervals included pesticides that were determined not to be associated with increased autism risk and were not included in subsequent analyses from Roberts *et al.* 138: pesticide classes (cholinesterase inhibitors, copper-containing compounds, fumigants, avermectins, halogenated organics, N-methyl carbamates, pyrethroids, and thiocarbamates) and individual pesticide compounds (1,3-dichloropropene, chloropicrin, cypermethrin, fenarimol, methyl bromide, norflurazon, bromacil acid, chlorpyrifos, dazomet, glyphosate, molinate, oxadiazon, bifenthrin, diuron, metam-sodium, myclobutanil, and paraquat).

Reproduced from *Curr Probl Pediatr Adolesc Health Care*, 44(10), Kalkbrenner AE, Schmidt RJ, Penlesky AC, Environmental chemical exposures and autism spectrum disorders: a review of the epidemiological evidence, pp. 277–318, Copyright (2014), with permission from Mosby, Inc.

of gestational age and monitoring growth during the intrauterine period, it is difficult to differentiate between the risks associated with these factors. Although prematurity has been shown to be associated with autism in some studies, it was not significantly associated with autism in a meta-analysis [47]. A meta-analysis of studies has shown that intrauterine growth retardation is also associated with autism, with risk ratios from 1 to 2 [47, 48]. Other perinatal factors associated with autism identified in the meta-analysis include multiple births [summary effect size 1.77 (1.23–2.55)], being born in summer [1.14 (1.02–1.26)], breech presentation [1.81 (1.21–2.71)], cord complications [1.50 (1.00–2.24)], fetal distress [1.32 (1.09–2.12)], birth injury [4.90 (1.41–16.94)], maternal haemorrhage [2.39 (1.35–4.21)], low Apgar score at 5 minutes [1.67 (1.24–2.26)] [47].

There is considerable interest in the relationship between toxins and autism. In a rigorously conducted review on autism and toxins, the authors selected papers on the following criteria: population-based human (epidemiological) research, robust statistical tools, individual-level data on autism diagnoses, environmental–chemical measurements with exposures around conception or during pregnancy or the first postnatal year, and with valid comparison, including appropriate sample selection and accounting for confounders and adequate sample sizes to generate precise measures of association [49]. In this study, there was an association between autism and measures of mixed air pollutant exposures and diesel particulate matter (Fig. 27.2) and different-size air pollutants and nitrogen dioxide, but not with ozone or carbon monoxide. Associations were stronger for exposures in the third trimester of pregnancy and the first year of life, compared to earlier in pregnancy. In this review, there was a suggestion that volatile organic compounds, for example benzene and heavy metals (lead, mercury, manganese), may be associated with autism, but the ORs were not high or consistent across studies. The evidence for an association between a number of pesticides and autism was more convincing (Fig. 27.3). There was little evidence of the association between polychlorinated biphenyls, flame retardants, non-stick chemicals, or biphenol-A; evidence for some phthalates are more suggestive [49].

Premature mortality

There has been little research on the premature mortality associated with autism. Standard mortality ratio (SMR) is used to compare mortality of a condition with the background population adjusted for age and sex. In early studies, the SMR of autism ranged from 1.9 in Denmark to 2.6 in the United States.

In a recent update of the Danish study, the SMR was 1.93 (CI 1.26–2.82), with the SMR higher for females (SMR 4.01; CI 1.73–7.90) than for males (SMR 1.57; CI 0.93–2.48) [50]. During the 45 years of follow-up, the SMR varied between 1.42 and 1.98, while the SMR for females varied between 3.17 and 5.22. The most common causes of the 26 deaths in this cohort were unnatural causes (suicide = 2, suffocation = 2), epilepsy (8 had epilepsy, with 4 stating that epilepsy contributed to their death), and infections.

In an analysis of a population database in Sweden, the authors compared 27,122 ASD probands, diagnosed between 1987 and 2009, with sex-, age-, and county of residence-matched controls ($n = 2,672,185$) [51]. They found that 706 (2.60%) of people with autism died, compared to 24,358 controls (OR 2.56; 95% CI

2.38–2.76). Mortality occurred in most diagnostic categories, with the patterns of mortality influenced by sex and intellectual disability.

Financial costs

Autism, as a life-long disorder, is associated with significant costs to the family and society. It was estimated that the annual total costs in 2011 associated with autism was about £3.1 billion in the UK and 250 billion USD in the United States, assuming 40% have intellectual disability [52]. The presence of intellectual disability increases the costs up to five times, compared to those without intellectual disability, depending upon age. The discounted lifetime costs of autism without intellectual disability were £0.92 million in the UK and 1.43 million USD in the United States, while those of autism with intellectual disability were £1.5 million in the UK and 2.44 million USD in the United States [52]. These costs are likely to be underestimates, since autism is often not diagnosed in older people. Thus, one forecast suggests that the total ASD-attributable costs in the United States will rise to over 450 billion USD by 2025 [53].

Conclusions

The burden of autism is well established in North America and Europe, but data from other continents, particularly Africa and Asia, are limited. The apparent increase in the prevalence of autism in North America and Europe is likely to be caused mainly by an increase in awareness and a change in diagnostic criteria. The interaction between genetic susceptibility to autism and environmental factors needs further examination. There is no evidence that autism is associated with vaccines, but its relationship with immunological responses needs further examination. Autism is associated with premature mortality and engenders considerable costs.

Genetics of autism spectrum disorders

Abha R. Gupta, Thomas V. Fernandez, and Ellen J. Hoffman

ASD heritability and early genetic investigations

Autism spectrum disorder (ASD) has long been recognized as a heritable disorder, based on family and twin studies. Monozygotic twin concordance rates have been reported to be approximately 60% for the full syndrome and 90% for the broad spectrum. In contrast, dizygotic twin concordance has been reported to be relatively low, approximately 3–15%, depending on the diagnostic criteria used. These data support the conclusion that the observed familial clustering is largely the result of genetic factors and translate into an estimate of heritability that places ASD among the most strongly genetic of all neuropsychiatric conditions [1–7].

Establishing high heritability has encouraged the search for genetic variants that are enriched in ASD. Early insights into ASD risk genes came from recognition that children with rare syndromes of known genetic causes (for example, fragile X syndrome, tuberous sclerosis complex, Angelman syndrome) have high rates of ASD diagnosis, ranging from approximately 10% (Duchenne muscular dystrophy) to 80% (Phelan–McDermid syndrome) [8–10]. Initially, there was great hope that genetic linkage and candidate gene association studies would complement these syndromic observations and rapidly yield a wealth of new insights about ASD genetic susceptibility loci.

Linkage analysis assesses the probability that a given phenotype and particular genetic markers are transmitted together from one generation to the next. Association studies typically investigate one or a number of known, common genetic polymorphisms that lie within or near pre-determined candidate genes of interest, comparing allele frequencies in cases vs controls. Such association studies have been popular over the last few decades, owing, in part, to the practicalities of subject recruitment and greater theoretical power to detect common susceptibility variants of relatively small effect, compared to linkage studies [11–14]. However, linkage and candidate gene association studies in ASD, and in nearly all complex neuropsychiatric disorders, have yielded very few reproducible findings. This is likely due to previously underappreciated factors such as locus and allelic heterogeneity, clinical heterogeneity, and differing inclusion criteria, inadequate control for population stratification, and insufficiently powered study cohorts, especially when studying common alleles with small effect sizes [15–17].

Due to these limitations, and coinciding with microarray technological advancements that delivered affordable high-density genotyping platforms, about 10 years ago, there was a shift in methodology from candidate gene association to genome-wide association studies (GWAS), simultaneously testing hundreds of thousands to millions of common single-nucleotide polymorphisms (SNPs) for association with disease. Querying SNPs throughout the genome eliminates the need to previously select candidate variants, allowing for hypothesis-neutral investigations. This method also yields data that allow rigorous matching for ancestry between cases and controls, an aforementioned confounder in earlier association studies. The primary challenge in GWAS is the large number of independent comparisons performed, requiring a widely accepted genome-wide significance threshold of $p \leq 5 \times 10^{-8}$. Given the heterogeneity of complex disease, large sample sizes are required to achieve this level of significance. Nevertheless, this technique led to renewed excitement in the field around the potential for variant and risk gene discovery. However, in ASD, none of the candidate genes emerging from earlier association or linkage studies have reached the statistical threshold for genome-wide significance using GWAS [18, 19], suggesting either that these candidate genes had initial false-positive associations or that the current GWAS cohorts lack sufficient statistical power to detect common variant association. Nevertheless, efforts on this front continue; recent data suggest that one promising way to reduce genetic heterogeneity in ASD, and thereby improve statistical power, under the GWAS framework may be to focus analysis on intermediate core phenotypes that accompany the disorder [20].

A windfall of success in ASD risk gene discovery

To date, the most fruitful studies for identifying risk genes in ASD have been those focusing on rare, large-effect variants in the protein-coding regions (exome) of the genome. In addition to the genes implicated in rare syndromic forms of ASD, rare point mutations in the *NLGN3X* and *NLGN4X* genes (*Neurologin 3X* and *4X*) were the first replicated findings in non-syndromic (idiopathic) ASD [21, 22]. Soon after, driven by technological advances that allowed for the detection of genome-wide rare *de novo* mutations (detected in the probands, but not the parents), several studies reported an increased rate of *de novo* copy number variants (CNVs) in ASD and confirmed

risk loci identified by the clustering of such variants in certain genomic regions among unrelated individuals with ASD [23–39].

Similarly, *de novo* coding single nucleotide variants (SNVs) and insertion–deletions (indels) have been found by whole-exome sequencing studies to contribute to ASD risk. In particular, likely gene disrupting (LGD) *de novo* variants (for example, nonsense, splice site, frameshift) are enriched in ASD and have proven to be a powerful avenue for identifying individual risk genes by the finding of multiple such variants in the same gene in unrelated individuals [40–45].

Owing mainly to *de novo* genotyping and sequencing studies, dozens of high-confidence ASD risk genes have been discovered, out of an estimated target of 500–1000 genes underlying ASD risk [46]. A recent analysis of all available *de novo* whole-exome sequencing and CNV data from >5000 families in the Autism Genome Project and the Simons Simplex Collection identified 65 ASD risk genes and six CNV regions [32]. Several online databases are updated regularly with the latest findings regarding ASD risk genes and loci, supported by evidence from ongoing sequencing and genotyping studies [47–50].

Based on currently available data, there is an important contribution to ASD risk from rare *de novo* and rare inherited variation. Rare genetic variants are believed to cause approximately 10–30% of ASD [32, 46, 51], and each individual variant can confer significant risk on its own, for example, making an individual 30–50 times more likely to develop ASD. Despite the fact that all of the ASD risk genes and loci to date have emerged from rare variant studies, the largest component of genetic risk in ASD is believed to derive from common genetic variants of additive effect. When considered as a whole, the contribution of common genetic variation is estimated between 15% and 50% [52–54]. Yet, the increase in ASD risk by an individual common variant is very small, on the order of 5–10%, and no common risk loci have yet been definitively identified. To find common variants of small effect, future efforts will need to study even larger cohorts than those included in studies to date.

Stepping towards an understanding of ASD biology

Now that there are clear, successful avenues for risk gene discovery in ASD, it is possible to begin asking whether identified genes are involved in common biological processes, whether they are expressed in particular brain regions, during certain developmental time periods, and whether their gene products are enriched in certain cell types. Already, we are seeing that ASD risk genes are more likely to be expressed in cortical pyramidal neurons during mid-fetal development [55, 56]. Furthermore, gene set enrichment analyses are showing that ASD risk genes and loci are converging onto a smaller number of biological processes, including chromatin remodelling, transcriptional regulation, synaptic functioning, Wnt and MAPK signalling, and interactions with the *FMR1* (*fragile X mental retardation 1*) gene [24, 27, 30, 41, 42, 57]. In this way, variant discovery provides an important foothold for identifying risk genes and for beginning to understand ASD neurobiology. However, it is critically important to study the downstream consequences of the identified variants to refine our understanding of disease pathophysiology and pave the way for earlier diagnosis, therapeutic interventions, and novel treatments.

Importance of modelling ASD variants

Once candidate genes have been identified, the most important and challenging next step is gaining an understanding of how disruption of these risk genes affects basic processes of nervous system development, resulting in behavioural dysfunction. That is, identification of ASD-associated genes has the potential to provide a critical window into neurobiological mechanisms underlying ASD. For example, some of the earliest insights into the neurobiology of ASD came from animal models of monogenic syndromes that are associated with an increased risk of ASD, including fragile X syndrome (FXS) and tuberous sclerosis complex (TSC). Here, ‘knockout’ mouse models lacking the function of the genes that are causative for these syndromes provided the first evidence for pathophysiological mechanisms underlying ASD and revealed possible pathways for therapeutic targeting. However, recent large-scale whole-exome sequencing efforts of affected individuals have led to a rapidly expanding list of ‘high-confidence’ ASD risk genes, which has made modelling ASD-associated variants increasingly challenging. While these risk genes represent seemingly disparate functions, ranging from ion channels and cell adhesion molecules to chromatin remodellers and transcription factors, there is emerging evidence that they converge on common mechanistic pathways such as synapse function, chromatin modification, transcriptional regulation, Wnt signalling, and targets of the fragile X mental retardation protein (FMRP) [42, 57–60]. In this way, these studies have revealed pathways that are likely to play a key role in ASD. Moreover, to keep pace with the increased rate of gene discovery, scientists are now employing new cellular, molecular, and computational strategies, which allow for the simultaneous analysis of multiple risk genes and are beginning to shed light on fundamental questions in ASD neurobiology. For example, these studies aim to elucidate the specific developmental stages and neuronal cell types, that is, when and where ASD risk gene function is most critical for brain development. Another objective of functional studies is to leverage the growing number of risk genes to uncover neurobiological pathways that can serve as targets for novel pharmacotherapies. Therefore, recent studies modelling ASD-associated variants are playing a pivotal role in advancing the field from risk gene discovery to the elucidation of neurodevelopmental mechanisms and targeted pharmacological treatments.

Insights from models of monogenic ASD-associated syndromes

Early insights into the neurobiology of ASD came from animal models of monogenic syndromes that are associated with increased autism risk, as mentioned. FXS is the most common inherited cause of ASD and is a notable example of how modelling the loss of function of a single gene can result in the identification of novel biological pathways and potential therapeutic targets [61]. Studies of mice lacking the function of the *FMR1* gene, which is disrupted in FXS, led to the metabotropic glutamatergic receptor (mGluR) theory of FXS. Specifically, mouse knockouts of *FMR1* were found to exhibit an increase in a form of synaptic plasticity—long-term depression (LTD), which is dependent on protein synthesis and mGluR activation [62]. Therefore, excessive mGluR signalling and LTD were

proposed as a potential mechanism underlying abnormal structural and behavioural phenotypes in mice lacking *FMRI* function [62], including altered dendritic spine structure in adult cortical neurons, hyperactivity, and learning deficits [63, 64]. Indeed, multiple studies have shown that inhibition of mGluR signalling is able to reverse physiological, structural, and behavioural abnormalities in animal models of FXS, ranging from the mouse to the fly [65–70] (reviewed in [71]), leading to clinical trials of mGluR antagonists [72]. While the efficacy of these agents has yet to be demonstrated in human patients with FXS, modifications in clinical trial design, such as administering the medication to younger patients for a longer duration and developing more precise efficacy measurements, may improve outcomes [73].

TSC, which is caused by heterozygous mutations in the *TSC1* or *TSC2* genes, is another example of a syndrome associated with an increased risk of ASD that led to the identification of an important signalling pathway with relevance to ASD. Specifically, these genes encode proteins that function as negative regulators of the mammalian target of rapamycin (mTOR) pathway, which is involved in protein synthesis and cell proliferation [74]. This discovery led to the hypothesis that inhibitors of mTOR, such as rapamycin, might serve as potential therapeutic agents. Interestingly, rapamycin was found to reverse learning and social deficits in mouse models of TSC [75, 76], paving the way for clinical trials of this class of medications. In addition, mutations in the *PTEN* gene (*Phosphatase and Tensin Homolog*), which also negatively regulates mTOR, are associated with an increased risk of ASD and macrocephaly [77–80], providing further evidence for this pathway in the neurobiology of ASD. Rapamycin was also found to reverse macrocephaly and behavioural abnormalities, including anxiety and social deficits, in a conditional mouse knockout in which *PTEN* function was disrupted in post-mitotic neurons [81]. Clinical trials are currently under way to investigate the effect of mTOR inhibitors on cognition in children and adolescents with *PTEN* mutations (<http://www.clinicaltrials.gov>).

Other examples of monogenic syndromes associated with ASD that have shed light on relevant molecular mechanisms include Rett syndrome, caused by mutations in the *MECP2* gene (*Methyl-CpG binding domain-2*), and neurofibromatosis type 1, caused by disruption of the *NF1* gene (*Neurofibromin 1*) [61]. In addition, with the increased rate of gene discovery in idiopathic ASD from whole-exome sequencing, together with more detailed clinical characterization of individuals carrying variants in specific risk genes, there is growing evidence that each of these ASD-associated genes may represent a subtype of ASD with shared clinical features [57]. For example, recent studies have suggested that the high-confidence ASD genes *CHD8* (*Chromodomain Helicase DNA Binding Protein 8*), *DYRK1A* (*Dual Specificity Tyrosine Phosphorylation Regulated Kinase 1A*), *POGZ* (*Pogo Transposable Element Derived with ZNF Domain*), and *GRIN2B* (*Glutamate Ionotropic Receptor NMDA Type Subunit 2B*) may represent distinct ASD syndromes [82–85]. Therefore, animal models of each of these genes have the potential to reveal biological pathways that are uniquely disrupted due to gene loss and to identify specific pharmacological targets, providing a ‘personalized medicine’ approach to developing new treatments. For example, point mutations in the *SHANK3* gene (*SH3 and multiple ankyrin repeat domains 3*), which encodes a post-synaptic scaffolding protein at excitatory synapses, as well as deletions of the chromosome region 22q13.3, which includes this gene, are associated with Phelan–McDermid

syndrome, which is characterized by ASD, intellectual disability, seizures, and dysmorphic features [86]. Physiological and motor deficits in mice in which *SHANK3* function was disrupted were rescued by treatment with insulin-like growth factor 1 (IGF-1) [87], which promotes synaptogenesis [88]. IGF-1 was also found to reverse deficits in excitatory signalling in an induced pluripotent stem cell (iPSC) model of Phelan–McDermid syndrome [89] and rescued abnormal phenotypes in mouse and iPSC models of Rett syndrome [90, 91]. These preclinical studies led to a pilot clinical trial of nine individuals with Phelan–McDermid syndrome, in which IGF-1 showed some benefit in treating social deficits and repetitive behaviours, though larger studies are needed [92].

Modelling ASD risk genes in animal systems

Animal models offer distinct advantages for the functional analysis of ASD risk genes. Firstly, animal models allow for the investigation of the role of risk genes in neural circuits in a live, behaving organism, which is not possible using *in vitro* approaches [93]. Secondly, risk gene function can be studied along a developmental trajectory, including embryonic stages in animal models [94], which is critical for understanding the role of ASD risk genes, given that many of these genes are expressed embryonically. Thirdly, animal knockouts provide a platform for identifying novel pharmacological pathways and studying the *in vivo* effects of drugs targeting these pathways [93]. Moreover, emerging cellular and molecular technologies are expanding the range of scientific questions that can be addressed using animal models. For example, a recently developed method CLARITY allows for high-resolution, three-dimensional imaging of intact mouse brains [95]. Other new techniques, such as optogenetics and genetically encoded calcium indicators, allow scientists to assess the circuit-level and behavioural effects of activating a subset of neurons (engineered to express a light-activated channel) [96–98] and to visualize neural activity in an awake, behaving animal [99, 100]. Further, CRISPR (clustered regularly interspaced short palindromic repeats)/Cas9 technology, a highly efficient and flexible method for generating targeted mutations [101], has revolutionized the ability to model ASD-associated mutations in both *in vivo* and *in vitro* systems. In addition, there is increasing interest in using smaller, less complex organisms, such as the zebrafish and *Drosophila*, to model ASD risk genes, given their experimental tractability for conducting large-scale phenotyping analyses and high-throughput pharmacological screens [70, 93, 102]. While these systems are less conserved than mice, in comparison to humans, at the genetic and structural levels, it is anticipated that future studies will capitalize on the advantages of multiple animal models for the functional analysis of ASD genes.

At the same time, there are clear limitations to modelling ASD-associated genes in animal systems. Firstly, it is impossible to fully recapitulate human behaviours in animals, given the limits of face validity [93, 94, 103]. Secondly, pharmacological candidates identified in animal models may not translate to effective treatments in humans. The example of mGluR antagonists in FXS highlights these challenges, including identifying the optimal age, duration of medication administration, and outcome measurements in human studies, which are not easily translated from preclinical studies [73]. Thirdly, animal systems cannot fully recapitulate the genetic

diversity of an individual, which may shape clinical presentation. Despite these drawbacks, animal models provide an important *in vivo* approach for elucidating the role of ASD risk genes in basic mechanisms of neurodevelopment and circuit-level function.

Human induced pluripotent stem cell modelling of ASD risk genes

Another approach to modelling ASD-associated mutations is the use of human iPSCs. The scientific basis for iPSC generation was reported in a landmark study which demonstrated that adult human dermal fibroblasts could be reprogrammed into a pluripotent state by four transcription factors: Oct3/4, Sox2, Klf4, and c-Myc [104]. These cells could, in turn, be differentiated into any cell type, including neural cells. Protocols have been developed to differentiate iPSCs into specific neural populations, including electrically active GABAergic, glutamatergic, and dopaminergic neurons; astrocytes; and oligodendrocytes [105, 106]. This approach also enables the analysis of patient-derived cells during the course of neural differentiation, from iPSCs to neural progenitor cells (NPCs) to mature neurons. In addition, a series of assays can be performed on these cells, including transcriptional profiling studies; analyses of neuronal morphology; synapse formation and function; and neuronal migration, differentiation, and proliferation—providing a rich database for assessing the effect of patient mutations on cellular and physiological phenotypes. Further, neural cells can be grown as three-dimensional organoids, which, to some extent, can recapitulate features of early human brain development and allow for the analysis of simple network activity [105, 107]. To model ASD-associated mutations using iPSCs, scientists have adopted two main experimental strategies: (1) generating iPSCs from cells obtained from individuals with ASD carrying a mutation in a particular risk gene; and (2) genetically engineering iPSCs generated from the cells of an unaffected individual using the CRISPR/Cas9 system to introduce a mutation identified in an individual with ASD. The former approach captures the genetic background of the patient, which is highly relevant to ASD, where clinical presentation may be influenced by a combination of rare *de novo* and transmitted variants, along with common variants, while the latter method allows scientists to compare ASD-associated mutations in an isogenic background, providing a readout of the effects of the variants alone on cellular phenotypes. Another approach utilizes morphological analysis and transcriptional profiling of iPSCs generated from individuals with idiopathic ASD (unknown aetiology), which has also provided insights into neurobiological mechanisms in ASD [108].

There are several notable advantages of using iPSCs for the functional analysis of ASD risk genes. Firstly, unlike animal models, iPSCs allow for the analysis of cellular phenotypes in the genetic background of a patient, which can play a critical role in shaping the clinical presentation [109]. Secondly, multiple sequence variants or large CNVs found in an individual with ASD are difficult to model in animals but are present in patient-derived iPSCs [110]. Thirdly, the use of iPSCs offers key advantages over studies of post-mortem tissue [110, 111], which can be confounded by environmental or treatment effects over the lifetime of an individual and cannot provide electrophysiological or other functional information. Fourthly, iPSCs are amenable to high-throughput pharmacological screens

to identify compounds that reverse cellular or electrophysiological phenotypes associated with a particular variant, which can complement drug screens in animal models where the same risk gene has been disrupted. Consistent with the goals of personalized medicine, patient-derived iPSCs provide an individualized platform for the discovery of potential new treatments. Nonetheless, limitations of iPSC modelling include the inability to assess the effect of mutations on circuit-level or behavioural phenotypes in an intact nervous system. In addition, generating iPSCs, NPCs, and mature neurons is a time-intensive process, such that it may take 2 months to reprogramme source cells into iPSCs and differentiate iPSCs into NPCs, and 3–4 months to generate neural cells. Further, because reprogramming cells involves inducing genome-wide epigenetic changes [112], it is important to analyse epigenetic patterns before and after iPSC generation, though iPSCs from individuals with Angelman and Prader–Willi syndromes were found to retain the appropriate patterns of DNA methylation [113]. Taken together, iPSC modelling of ASD-associated variants has enabled scientists to, at least partially, overcome the challenge of obtaining living human brain tissue for study, revolutionizing the functional analysis of ASD risk genes at the cellular and molecular levels.

ASD risk gene network analysis

While ASD risk genes may be associated with distinct clinical features that define subtypes of the disorder [57], there is evidence that many of these genes converge on common neurodevelopmental pathways that provide critical insights into ASD biology, as mentioned [42, 57–60]. Despite the important mechanistic insights gained by modelling individual risk genes, one at a time, in animal or iPSC models, given the rapid rate of ASD gene discovery, this single-gene approach is becoming increasingly challenging. Here, advances in computational tools, which allow for the simultaneous analysis of hundreds of ASD-associated genes using a systems or network-based approach, are beginning to illuminate common neurodevelopmental mechanisms across these genes [60]. Specifically, studies have harnessed the BrainSpan transcriptome data set, which includes human gene expression data from the brains of 57 typically developing individuals and encompasses multiple anatomical regions and a range of developmental stages, from early fetal stage to late adulthood [114, 115], to elucidate when and where ASD risk genes might play critical roles in the developing brain [60]. In one study, researchers constructed gene co-expression networks around high-confidence ASD genes utilizing the BrainSpan data set and assessed these networks for enrichment of an additional set of probable ASD-associated genes, identifying mid-fetal glutamatergic projection neurons in cortical layers V–VI as a point of convergence [56]. Another study used weighted gene co-expression network analysis to construct co-expression networks using the BrainSpan data set and mapped ASD-associated genes onto these networks [116]. This study found enrichment of ASD risk genes in glutamatergic projection neurons in superficial cortical layers II–IV, though a weaker enrichment signal was also detected in deep layers [116]. Therefore, these types of analyses provide a spatiotemporal readout of when and where ASD genes are likely to function in brain development, which is expected to inform future functional studies of these genes in model systems [60]. Taken together, network-based approaches,

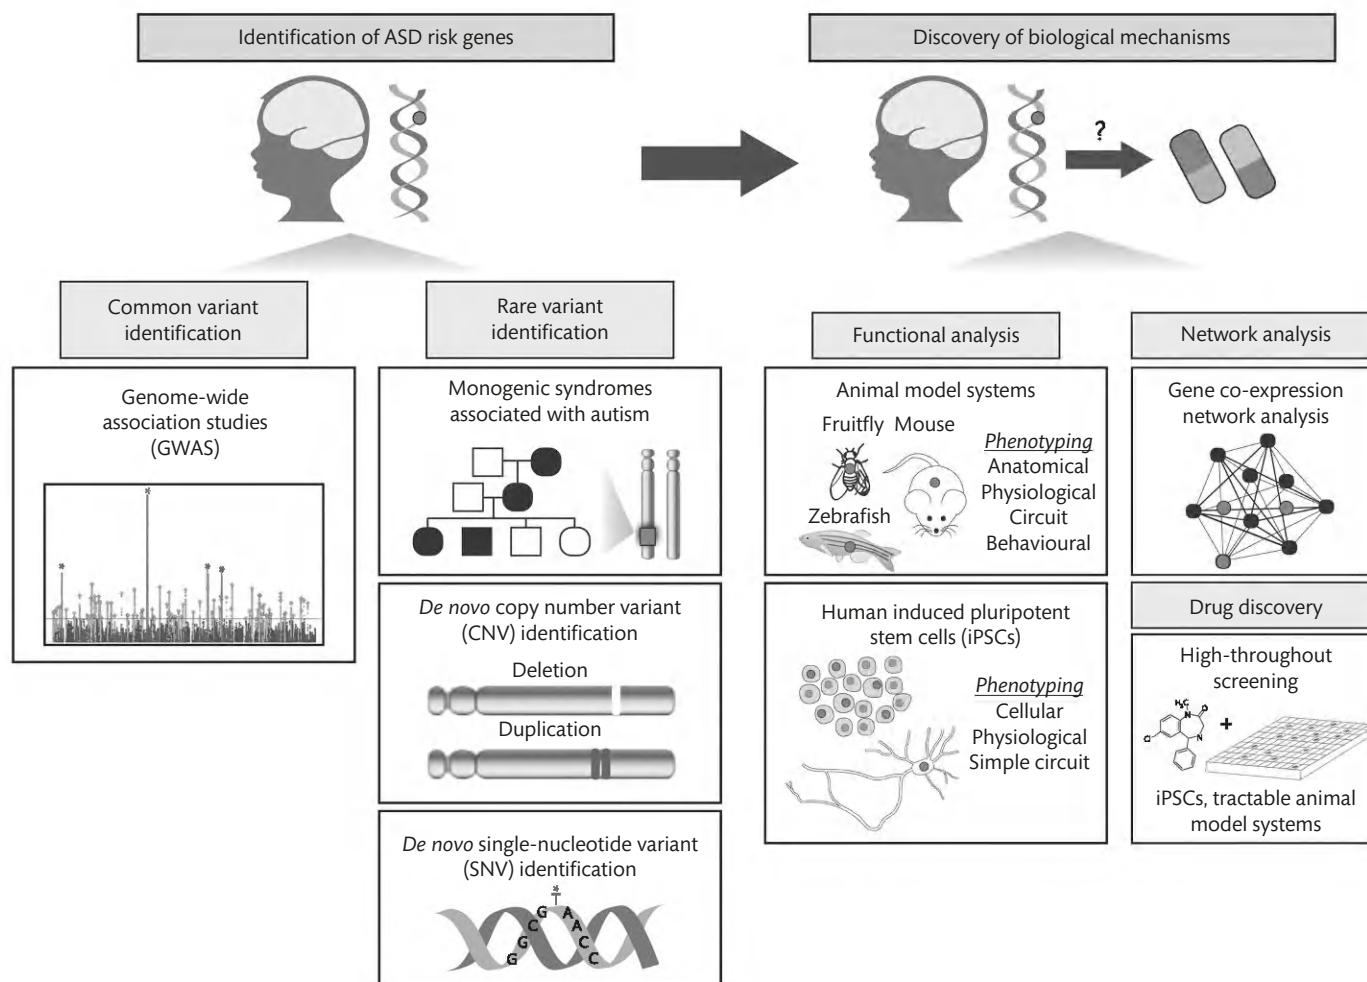

Fig. 28.1 Schematic representation of the pathway from the identification of risk genes to the discovery of biological mechanisms in ASD. Risk genes associated with ASD are identified by a variety of techniques: genome-wide association studies, linkage analysis, chromosomal microarray (to identify CNVs), and whole-exome/genome sequencing (to identify sequence variants). Functional analysis aims to bridge genetics and neurobiology by determining the impact of variants on biological systems through *in vivo* and *in vitro* approaches such as animal model systems and induced pluripotent stem cells. Network analysis aims to accomplish this through computational approaches such as gene co-expression studies. The discovery of biological mechanisms is expected to identify novel targets for pharmacological intervention in ASD, the ultimate goal of this research.

along with *in vivo* and *in vitro* models of ASD-associated genes, are anticipated to advance our understanding of the basic neurobiology of ASD and provide a path towards the development of mechanism-based treatments. Fig. 28.1 summarizes the pathway from the identification of risk genes to the discovery of biological mechanisms in ASD.

Clinical genetics testing in ASD

Although the genetic contribution to ASD is well established, there has been much debate over the years as to the most appropriate laboratory tests to pursue in individuals with ASD. Clinical genetics testing is an important component of the medical evaluation of all patients with a diagnosis on the spectrum, from severely to mildly impaired, for a number of reasons. As has been described, there is substantial overlap between ASD and some genetic syndromes such as FXS and TSC. The identification of a known genetic syndrome allows the clinician to provide anticipatory guidance regarding

medical and developmental trajectories to caregivers. This is especially critical if there is additional organ involvement. For example, FXS can also cause vision problems, such as strabismus and amblyopia, and hypotonia. The benign tumours which characterize TSC can disrupt the function of not only the brain, but also multiple other vital organs such as the heart, lungs, liver, and kidneys. Establishing a genetic aetiology can help in obtaining needed care and services and avoid the pursuit of further, unnecessary diagnostic tests. Another important reason for clinical genetic testing is that the identification of variants and whether they are *de novo* or inherited through the testing of family members can have implications for genetic counseling. The parents of an affected child may want to know their chances of having subsequent affected children, and aunts and uncles may want to know if a variant is being passed through a family.

The American College of Medical Genetics and Genomics (ACMG) has provided the most detailed guidelines for clinical genetics testing in ASD [117]. These guidelines are structured as two tiers of tests, with the first tier expected to have higher diagnostic yield. If first-tier tests are negative, second-tier tests may be pursued.

After completion of a three-generation family history to identify a potential mode of inheritance for the disorder, clinical geneticists should determine if a known genetic syndrome is present, guided by a thorough history and physical examination which includes a detailed dysmorphology exam. If a specific syndrome or metabolic disorder is suspected, targeted testing should be performed. If a syndrome that is firmly associated with ASD is diagnosed, the ACMG does not consider further testing necessary. These syndromes include 22q11.2 deletion, Angelman, CHARGE, FXS, Prader–Willi, Rett, and TSC, among others [117]. In the absence of a known syndrome, chromosomal microarray analysis (CMA) should be obtained. Either through array-comparative genomic hybridization (aCGH) or an SNP array, CMA will detect chromosomal deletions and duplications. This test has replaced karyotypes since the International Standard Cytogenomic Array Consortium has concluded that CMA has a higher yield than karyotyping [118]. DNA testing for FXS is recommended for all male patients and for those female patients with clinical features of FXS or a positive family history. If all first-tier tests are negative, clinical geneticists can consider specific gene tests, such as looking for variants in *MECP2* and *PTEN*, and brain magnetic resonance imaging (MRI) if indicators are present.

The ACMG estimates that, for idiopathic ASD, a minimal clinical genetics evaluation consisting of CMA and FXS testing will have a combined diagnostic yield of approximately 10–15%. A comprehensive evaluation, guided by the two-tiered approach, is estimated to identify an aetiology in 30–40% of individuals with ASD [117]. Although the ACMG does not currently recommend specific gene testing in idiopathic ASD other than for FXS, *MECP2*, and *PTEN*, it is expected that ASD gene panels will become increasingly valid as researchers continue to dissect the genetic aetiology of ASD, as discussed in this chapter.

Imaging of autism spectrum disorders

Christine Ecker and Declan Murphy

Introduction

Autism spectrum disorders (ASD) encompass a group of life-long neurodevelopmental conditions that are characterized by deficits in social communication, social reciprocity, and repetitive and stereotyped behaviours and interests [1]. ASD are typically diagnosed during early childhood using behavioural observations and/or clinical interviews, with clinical symptoms persisting across the human lifespan in roughly 90% of all cases [2]. Over the last decade, prevalence estimates for ASD have consistently been rising—from about 2–4 individuals per 10,000 children in the 1960s and 1970s to about 1 in 68 children in 2014 (that is, roughly 1.4% of the general population) [3]. While this increase in prevalence may partially be due to modifications to diagnostic criteria, improved assessment tools, and/or increased awareness, the rise in prevalence also highlights the growing need for developing novel pharmacotherapies and behavioural interventions designed to effectively target the core symptoms of ASD. Yet, developing treatment and interventions for ASD remains a challenge. ASD is accompanied by a large degree of inter-individual variability, both phenotypic and causative, which has so far hampered large-scale clinical trials. For example, genetic studies implicate more than 100 different genetic and genomic loci in ASD [4], which, in turn, interact with environmental factors to give rise to complex behavioural phenotypes. Consequently, there is a large degree of heterogeneity in the time course, severity, and profile of symptoms expressed by ASD individuals. Current research efforts are thus directed towards disentangling the large degree of complexity associated with ASD, and to establish homogenous subgroups or ‘strata’ of individuals with a common genetic and (neuro)biological make-up. Here, neuroimaging studies employing magnetic resonance imaging (MRI) are absolutely crucial, as they offer unique insights into the anatomy and functioning of the brain *in vivo*.

In this chapter, we review and critically discuss ‘state-of-the-art’ *in vivo* neuroimaging findings examining ASD, with a particular focus on studies investigating brain structure and connectivity. Firstly, we will review the findings of neuroimaging studies examining early brain development in ASD. These studies predominantly focus on the neurodevelopmental trajectory of global brain measures that may underpin regional differences in brain anatomy typically observed during late childhood and adolescence in ASD. We

will then examine how the atypical developmental trajectory during early brain development may lead to differences in brain connectivity in ASD, which are accompanied by atypical patterns of cortical gyrification. Last, we will present the findings of a growing number of neuroimaging studies examining differences in the neurobiology of ASD between men and women.

Atypical brain development during early childhood in ASD

It is well established that ASD is accompanied by an atypical development of the brain and developmental perturbations to the formation of the brain’s micro- and macro-circuitry. Early cross-sectional studies show that the brain of toddlers with ASD is—on average—larger in total volume than the brain of typically developing (TD) children between the ages of 2–4 years [5]. This increase in total brain volume is paralleled by an increase in head circumference, which has been reported in several cross-sectional and longitudinal studies (for example, [6]). The early enlargement of the brain seems to disappear between 5 and 6 years of age, when developmental trajectories of ASD individuals and TD controls intersect [7]. After this age, no significant increase in total brain volume is typically reported in ASD. Taken together, these early findings led to the suggestion that the brain in ASD may undergo an atypical trajectory of maturation, which is characterized by a period of increased growth during toddlerhood, followed by a period of reduced or arrested growth during childhood, and possibly a period of accelerated decline in total brain volume over the remaining lifespan [8] (Fig. 29.1). These early cross-sectional studies have been confirmed by more recent longitudinal studies of brain development in ASD. For example, a recent investigation by Lange *et al.* (2015) examined atypical brain development in ASD from early childhood into adolescence and found: (1) significantly increased brain volumes in young children with ASD; (2) intersecting growth curves between 10 and 15 years of age; and (3) significantly decreased brain volume during adolescence [9]. While there is some variability with regard to the reported age range, when growth curves intersect, these findings suggest that the size of the brain in ASD lies within the ‘normal’ range during early adolescence, when between-group differences in total brain volume are minimal. However, how this relates to the

Fig. 29.1 Differences in the neurodevelopmental trajectory of brain maturation in ASD individuals and TD controls across the human lifespan.

severity of autistic symptoms is currently unknown. Furthermore, despite the absence of significant between-group differences in total volume around adolescence, it is likely that the atypical developmental trajectory of brain maturation prior to this time interferes with the development of large-scale neural systems, which reflects regional, rather than global, differences in ASD.

Typical brain development occurs in a highly ‘orchestrated’ fashion where the development of phylogenetically younger cortical areas (for example, higher-order association areas in frontal and temporal lobes) builds on the development of phylogenetically older brain regions (for example, occipital and parietal regions) [10]. However, evidence suggests that frontal–temporal regions mature earlier and faster in ASD individuals than in TD controls [11]. These early deviations from the typically synchronized developmental trajectory would therefore also be expected to impact on the development of brain connectivity. For example, a study by Wolff *et al.* (2012) examined structural brain connectivity in 6-month-old infants at high genetic (that is, familial) risk of ASD (for example, siblings of individuals with a confirmed diagnosis of ASD). In high-risk infants who receive a diagnosis of ASD at the age of 2 years, perturbations in the development of white matter fibre tracts are already visible at 6 months, relative to low-risk infants without ASD [12]. Moreover, a more recent study by the same research group also reported a significant increase in area and thickness of the corpus callosum, which structurally connects the two hemispheres of the brain, in infants with ASD scanned at 6 months of age [13]. Taken together, these studies suggest that the early atypical development of the cortical grey matter in ASD is accompanied by differences in white matter fibre tracts that can be observed as early as 6 months of age—that is, before the first symptoms typically manifest (around 1–2 years of age). Yet, there remains some debate on the particular time point during early development when grey matter differences first arise in ASD. For example, no significant increase in head circumference has been reported in ASD during the first year of life [14]. There are two studies reporting an enlargement of the brain in 2-year olds [15, 16], but direct evidence of a significant enlargement of the brain during the first year of life remains missing. It thus

remains unclear whether the early brain overgrowth in toddlers with ASD reflects an ongoing neurodevelopmental process, which is accompanied by an accelerated rate of growth during early childhood, or—alternatively—constitutes the end result of an early developmental perturbation prior to the age of 2 years.

Early brain overgrowth in ASD—a biomarker or simply ‘the tip of the iceberg’?

Despite the large body of evidence supporting the original reports of an early overgrowth of the brain in ASD, it remains contentious how relevant macrocephaly is for ASD and whether an early increase in total brain volume may potentially be used as an early biomarker for the condition. For instance, while the brain in ASD may—on average—be larger than the brain in TD individuals, macrocephaly (that is, an increase in head circumference of >2 standard deviations above the average for that age, or larger than the 98th percentile) is only observed in about 20% of all individuals with ASD across studies [14]. This implies that in about 80% of ASD individuals, significant clinical enlargement of the head or brain is absent. Thus, early markers of total brain volume or head circumference may not reflect a neurobiological mechanism that is common to all individuals on the ASD spectrum. As pointed out by Lainhart *et al.* (2006), it may therefore be that the early brain overgrowth occurs in a specific neurobiological subtype (or ‘stratum’) of ASD individuals only and may hence be used for stratification, rather than for diagnostic purposes. Alternatively, macrocephaly may represent the ‘tip of the iceberg’, that is a general tendency towards an increased head and brain size in ASD individuals [17]. In this case, an increase in head size may be indicative of the risk for ASD, rather than of the condition itself. A number of recent studies also call for a revision of population norms, which are used to define what is clinically ‘abnormal’. For example, a study by Raznahan *et al.* (2013) suggested that the increased head circumference in ASD might reflect a bias in population norm, rather than a replicable pattern of dysregulated brain growth [18], particularly when examining patient populations in the mental health setting. In future investigations, it will thus be of importance to account for variations in population norms, which may affect the size of expected effects when comparing psychiatric populations with normative populations.

Head circumference is also correlated with various epidemiological measures such as biological sex, age, weight and height, and genetic ancestry. Such non-ASD measures may therefore also impact on population norms, and hence significant between-group differences, and so need to be accounted for in the statistical model [19]. Based on these findings, there is also some evidence to suggest that the early brain overgrowth in ASD may reflect an early pattern of general physical (that is, somatic) overgrowth, rather than being specific to the brain, and particularly in boys with the condition [20]. Taken together, these studies highlight the importance of considering wider contextual issues when interpreting the findings of traditional studies reporting early brain overgrowth in ASD. Overall, therefore, it seems that measures of total brain volume and/or head size may offer neither sufficient sensitivity (that is, ability to detect an effect or disease if it is present) nor specificity (that is, ability to detect the absence of an effect or disease if it is not present) to be employed as a biomarker for ASD.

Brain structure and functioning across later childhood and adolescence in ASD

While the neurodevelopmental trajectory of brain maturation during early development is well characterized in ASD, less is known about the trajectory of brain development during late childhood and adolescence. In contrast to the differences in total brain volume observed during early life, brain development during later childhood and adolescence in ASD seems to be dominated by an accelerated age-related decline in volume. Typically, the pre-pubertal increase in grey matter volume is followed by a post-pubertal loss, resulting in an inverted U-shaped trajectory across the human lifespan [21]. There is evidence to suggest that the typical attrition of grey matter volume after reaching its peak during early adolescence is accelerated in ASD individuals during adolescence and adulthood. For example, the longitudinal study by Lange *et al.* (2015) noted previously found an accelerated decrease in total grey matter in ASD individuals after the age of approximately 15 years, which was accompanied by a reduced growth rate of total white matter [9]. These findings are in agreement with a previous longitudinal study by Hardan *et al.* (2009) in a smaller sample, who also reported a significantly greater decrease in total grey matter volume during late childhood and early adolescence in ASD 8- to 12-year olds over a period of 30 months [22]. Notably, the study by Hardan *et al.* (2009) also reported that the accelerated decrease in total grey matter volume is accompanied by significant reductions in cortical thickness. This is of importance, as total grey matter volume is, by definition, a product of two separate neuroanatomical features, namely cortical thickness and surface area, both of which: (1) are mediated by different sets of genes; (2) have a different phylogeny; and (3) represent distinct aspects of the cortical architecture (for example, [23]). Accelerated age-related cortical thinning has also been reported by cross-sectional studies investigating regional, rather than global, differences (for example, in temporal and parietal brain regions) [24, 25]. The age-related decrease in cortical thickness also seems to be accompanied by a

decrease in surface area. For instance, a more rapid decline in surface area in ASD with increasing age has been reported on the global [26], as well as regional, level [27]. Taken together, these findings suggest that the trajectory of brain maturation in ASD differs across distinct stages of development, which are dominated by an accelerated increase in volume, followed by an accelerated age-related decline in adulthood (Fig. 29.1).

Moreover, while neuroimaging studies investigating early brain development in ASD have predominantly focused on age-related differences in total brain volume, studies examining the neurobiological underpinnings of ASD during late childhood and/or adolescence mostly focus on regional differences in brain anatomy and functioning. Using more 'fine-grained' techniques such as voxel-based morphometry (VBM) or functional magnetic resonance imaging (fMRI), it is also possible to link specific autistic symptoms and traits to neuroanatomical or functional abnormalities in individual brain regions. Overall, the core components of wider neurocognitive systems that mediate the cluster of behavioural symptoms typically observed in ASD are well established. By large, these include: (1) fronto-temporal and fronto-parietal regions; (2) the amygdala–hippocampal complex; (3) the cerebellum and basal ganglia; and (4) the anterior and posterior cingulate cortices (for a review, see [28]) (Fig. 29.2). As might be expected, many of these brain regions include the set of brain regions that mediate functions related to social cognition and emotional processing, which are also commonly termed the 'social' and 'emotional' brain [29]. The core components of the 'emotional brain' include: (1) sub-cortical regions such as the amygdala, nucleus accumbens, and hypothalamus; and (2) cortical regions such as the orbitofrontal cortex (OFC), the anterior cingulate cortex (ACC), and the medial prefrontal cortex (mPFC) (reviewed in [30]). Furthermore, the extended neural systems mediating social–emotional processing include the superior and anterior temporal lobes (STL and ATL), the posterior cingulate cortex (PCC), the temporo-parietal junction (TPJ), the somatosensory cortex, and the intraparietal sulcus (see also [29]). Many of these regions have also been found to be atypical

Fig. 29.2 The neurocognitive systems underlying ASD. Core ASD regions (orange areas) include the ventromedial prefrontal cortex (VMPFC), the orbitofrontal cortex (OFC), the superior temporal gyrus (STS), the amygdala, and the anterior cingulate cortex (ACC). Extended ASD regions (green areas) include the inferior frontal gyrus (IFG), the posterior parietal cortex (PPC), the cerebellum, the hippocampus, the fusiform gyrus, the pons (PN), the basal ganglia (BG), the thalamus, and the supplementary motor area (SMA).

in ASD not only structurally (as described previously), but also functionally. For example, fMRI studies examining deficits in theory of mind [31], face processing [32], perception of biological motion [33], self-referential cognition, and empathy [34] in ASD have reported functional abnormalities in many of the regions that mediate social and emotional processing.

In addition, there is large degree of overlap between the neural systems implicated in ASD and the neural circuitry mediating obsessive-compulsive disorder (OCD), which highlights the close symptomatic link between ASD and OCD. For example, a study by Russell *et al.* (2005) showed that individuals with ASD and OCD had similar frequencies of obsessive-compulsive symptoms, despite at a lower level of symptom severity, with only somatic obsessions and repeating rituals being more common in the OCD group [35]. In OCD, obsessive-compulsive symptoms have been linked to the so-called cortico-striato-thalamo-cortical (CSTC) circuitry (also known as the frontostriatal or corticostriatal model), which comprises the thalamus, the OFC, ACC, and striatum [36]. Neuroanatomical differences in these regions have also been reported in ASD. For instance, individuals with ASD show an increase in the rate of growth of the caudate nucleus, one of the two integral parts of the striatum, which was observed between 10 and 12 years of age [37]. Moreover, the increased rate of growth in the caudate nucleus was significantly correlated with the severity of repetitive behaviours in ASD, thus suggesting that the neurodevelopmental trajectory of the caudate nucleus may offer a neurobiological marker for stereotypic and repetitive behaviours in ASD [37]. Comparison between the neurobiological underpinnings of OCD and ASD shows that the cortical abnormalities observed in ASD may not be unique to, nor causal for, the condition. Rather, similarities and/or differences in neurobiological phenotypes may be associated with similarities/differences in clinical symptom profiles. New research frameworks, such as the Research Domain Criteria (RDoC) initiative (<http://www.nimh.nih.gov/research-priorities/rdoc/index.shtml>) that considers mental disorders along dimensions of symptoms and neurobiological measures, rather than distinct categories, will thus be crucial for future investigations aimed at establishing distinct and common genetic or molecular pathways across disorders.

Atypical brain connectivity in ASD

The early perturbations to the developmental trajectory of brain maturation in ASD are not only likely to yield anatomical and functional differences in isolated brain regions, but have also been suggested to interfere with the formation of the brain's neurocircuitry—commonly known as the human ‘connectome’ [38]. However, the notion of atypical brain connectivity in ASD is complex, involving abnormalities with the grey and white matter (for example, [39]), and different levels of integration [40]. Consequently, there is significant heterogeneity in analytical frameworks used to examine brain connectivity in ASD, and in reported results. Overall, however, connectivity analysis methods may be subdivided into: (1) approaches aimed at investigating structural brain connectivity; and (2) approaches aimed at examining functional brain connectivity (Fig. 29.3).

Structural connectivity (that is, the existence and degree of structural white matter connection in the brain) has so far mostly been

examined using voxel-wise analysis of the white matter and diffusion tensor imaging (DTI). For instance, VBM studies showed that individuals with ASD have spatially distributed reductions in regional white matter volume during childhood [41], adolescence [42], and adulthood [43]. The results of such voxel-wise analyses are, however, inherently difficult to interpret due to methodological limitations (for example, issues related to image registration and/or segmentation) and cannot also unequivocally be linked to particular fibre tracks. For localization purposes, techniques such as DTI are better suited, as they allow the three-dimensional reconstruction of particular fibre tracks in order to examine tract-specific measures of structural white matter connectivity. In ASD, DTI studies have reported neuroanatomical differences in a number of white matter tracts that include the corpus callosum [44], the arcuate fasciculus [45], the limbic pathways [46], and the amygdala-hippocampal complex [47]. A number of DTI studies have also reported differences in the basal ganglia [48], the cerebellum [49], and the cortico-spinal tract [50]. In many of these tracts, reports point towards a reduced degree of structural white matter connectivity in ASD, and this contributed to the notion of ASD being a ‘neurodevelopmental disconnection’ syndrome [51] that is characterized by deficits in global (that is, large-scale) brain connectivity. Such deficits in connectivity have also been observed on the functional level.

Functional connectivity is generally defined as the degree of ‘temporal coherence’ between two neurophysiological signals and can be quantified, based on correlations between fMRI or EEG time series acquired in the presence of a stimulation paradigm or while the brain is ‘at rest’. Early fMRI studies examining functional connectivity during task performance suggested that the brain of individuals with ASD may exhibit a reduced degree of long-distance functional connectivity, and this has been reported during executive functioning [52], sentence comprehension [53], and working memory tasks [54]. However, more recent studies show that patterns of both hypo- and hyperconnectivity can be observed when combining findings across studies [55]. Taken together, this indicates: (1) either that findings are inconsistent across studies; or (2) that the concept of atypical brain connectivity is more complex than originally assumed. A similar picture of mixed results comes from studies examining resting-state fMRI connectivity in ASD—with researchers arguing in favour of under-connectivity [56], over-connectivity (for example, [57]), or unique patterns of both under- and over-connectivity, depending on the particular set of brain regions examined [58]. It is important to note, however, that measures of functional connectivity are very sensitive to even minor methodological differences, and this most likely underpins a significant proportion of the variability in findings. For example, Thai *et al.* (2009) highlighted the influence of differences in activation response between ASD individuals and TD controls, which may affect the degree of functional connectivity observed within and across groups, in addition to the selection of particular regions of interests and general constraints in temporal and spatial resolution [59]. Choices in some aspects of image processing can also affect the results [55]. Finally, there is evidence to suggest that the size (and sign) of the effects of connectivity analyses are age-dependent and may therefore vary as a function of the particular developmental stage under investigation [60]. Such methodological factors thus need to be accounted for in future studies examining functional connectivity in ASD. So far, however, the large variability in findings across studies has hampered the interpretability of the

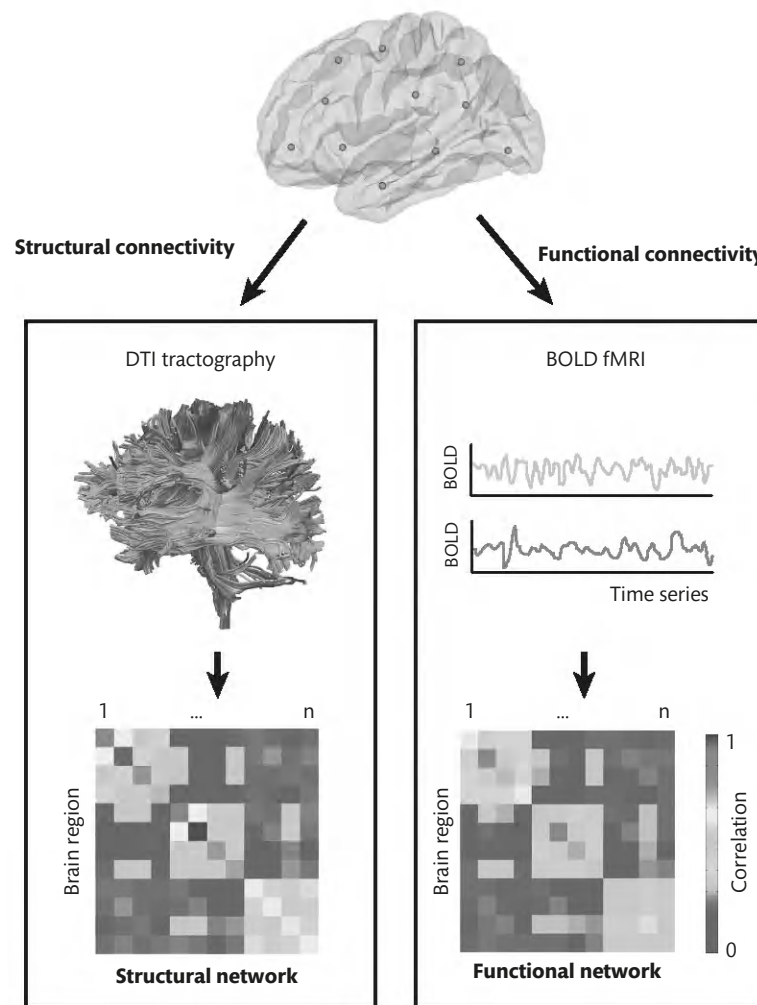

Fig. 29.3 (see Colour Plate section) Schematic illustration of the underlying concepts behind atypical structural and functional brain connectivity in ASD.

results, and a consistent overarching concept that can explain atypical functional brain connectivity in ASD has yet to emerge.

Atypical cortical gyrification in ASD—a retrospective window into early cortical expansion

The notion of atypical brain connectivity has also been discussed in light of recent studies examining cortical gyrification in ASD. As the cortex expands during development, it eventually needs to fold to fit an increasing surface area into the restricted space of the skull. Based on the evidence of early brain overgrowth in ASD (see previous section), which seems to be driven by an accelerated expansion of the cortex [61], it is therefore likely that the brain in ASD not only differs in structure and connectivity, but also in shape (that is, geometry). More specifically, an accelerated and more pronounced expansion of the cortex is expected to be associated with a higher degree of cortical folding, as well as atypical patterns of cortical gyrification. Yet, studies investigating measures of cortical geometry, rather than volume, are rare, and the few existing studies have led to variable findings. Most of these studies are based on the so-called gyrification index (or GI) [62]. This measures the degree

of cortical folding (Fig. 29.4). Using the GI, Hardan *et al.* (2004) examined gyrification in a coronal slice of the prefrontal cortex in ASD. They reported that children and adolescents with ASD showed greater prefrontal cortical folding than TD controls, while no significant between-group differences were observed in adults [63]. This early report thus agrees with the notion that early expansion of the cortical surface in ASD might result in increased cortical folding.

The findings of more recent investigations examining cortical gyrification in ASD are, however, variable. Most of these recent studies utilized high-resolution surface reconstructions of the left and right hemispheres of the brain that can subsequently be used to estimate the degree of gyrification at each location on the cortical surface. For example, the so-called local gyrification index (*lGI*) measures gyrification at more than 300,000 different locations (that is, vertices) where the *lGI* at a given vertex is computed as the ratio between the surface of a circular patch on the outer smooth surface of the brain and the surface of the corresponding patch on the inner pial surface (Fig. 29.4). Hence, similar to the original GI, the *lGI* at a point reflects the amount of cortex buried within the sulcal folds in the surrounding area [64]. Studies utilizing the *lGI* have so far reported: (1) significant increases in gyrification in bilateral posterior brain regions in males with ASD, compared to TD controls

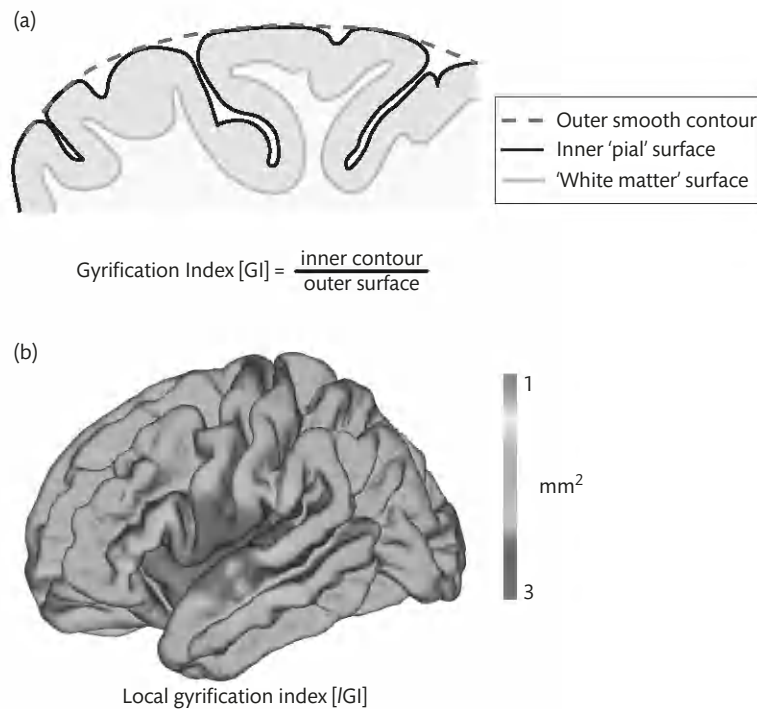

Fig. 29.4 (see Colour Plate section) Computation of the gyrification index (GI) as the ratio between the inner (i.e. pial) surface of the brain and the outer smooth contour. The GI can be calculated within brain slices in 2D (a) and at each location on the cortical surface in 3D (b).

(12–23 years of age) [65], and significant reductions in the LGI (2) in the left supramarginal gyrus in males aged 8–40 years [66] and (3) in the right inferior frontal and medial parieto-occipital cortices in children with ASD [67]. Last, atypical cortical gyrification in ASD has been demonstrated, using a variety of alternative metrics of cortical folding, including measures of sulcal morphometry [68], sulcal depth [69], and gyral complexity [70]. Thus, there is considerable variability in findings reported by existing neuroimaging studies, with regard to both the degree of atypical gyrification and the particular regional pattern of gyrification in ASD.

While these divergent findings can be partially explained by differences in sample size, participant demographics, and analytical techniques, evidence also suggests that patterns of cortical gyrification are highly variable across individuals, even in normative populations, and that both genetic and non-genetic factors contribute to the formation of cortical gyri [71]. For example, Kates *et al.* (2009) examined the amount of GI concordance in monozygotic twin pairs, in which only one had a diagnosis of ASD, and in typically developing unrelated controls. It was found that cortical folding patterns across most brain regions are highly discordant within monozygotic twin pairs, although children with ASD and their co-twins both exhibited increased cortical folding in the right parietal lobe [72]. This finding is in contrast to conventional measures of brain anatomy (for example, total or regional brain volumes), which are highly concordant between twins and might thus be largely genetically determined [73]. Moreover, cortical folding is not significantly correlated with total brain weight or volume, or with body weight and length, which are under strict genetic control [62]. Measures of gyrification thus seem to be particularly sensitive to environmental (that is, non-genetic) factors and reflect a degree of plasticity that is independent of overall brain size [74]. Thus, to elucidate the

contribution of genetic and non-genetic factors to brain development in ASD, various cortical features, including those of cortical gyrification, should be examined to account for the large amount of phenotypic inter-individual variability typically noted between individuals with ASD.

Neuroimaging studies examining sex differences in ASD

As mentioned in the introduction, ASD is accompanied by a large degree of inter-individual heterogeneity. Recent research efforts are thus directed towards establishing genetically and/or biologically homogenous subgroups of individuals that might, in turn, benefit from the same—or a similar—approach to treatment. One way of reducing the phenotypic heterogeneity associated with ASD is to stratify individuals by demographic characteristics such as age, intellectual ability, and also biological sex. An increasing number of studies are therefore now directed at establishing whether the neurobiology of ASD significantly differs between men and women. However, studies examining females with ASD are relatively rare.

So far, most of our understanding of the neurobiological underpinnings of ASD comes from studies examining male participants exclusively. For instance, it is estimated that there are about eight structural, and 15 functional, neuroimaging studies in males for every one neuroimaging study examining females [75]. The overrepresentation of studies examining males is primarily due to the increased prevalence of ASD in males, with an average male-to-female prevalence ratio of approximately 4:1 [76]. Thus, females with ASD are relatively rare and hence more difficult to recruit than males. The reasons for the male-preponderant prevalence of ASD is

largely unknown. However, it has been suggested that there are sex differences in the clinical phenotype of ASD, which may impede the diagnosis in females. For example, males with ASD have been reported to show more ‘externalizing’ behavioural problems (that is, actions directed towards the external environment) than females. Such externalizing behaviours include aggressive behaviour, hyperactivity, reduced pro-social behaviours, and repetitive/restricted behaviours and interests [77]. Females with ASD, on the other hand, have been suggested to show more ‘internalizing’ behaviours such as anxiety and depression and/or other affective symptoms [78]. Also, females with ASD may have a greater ability to camouflage difficulties, particularly in the social domain [79]. Taken together, such differences in terms of the clinical phenotype of ASD may impact on our ability to diagnose the condition in females, which will, in turn, affect prevalence estimates. Consequently, little is currently known about the neurobiology of ASD in females.

In terms of brain anatomy, some of the early neuroimaging studies suggest that the degree of cortical abnormality observed in girls with ASD may be significantly greater, as compared to boys. For instance, Bloss and Courchesne (2007) reported a larger deviation from same-sex TD controls among girls vs boys with ASD, in temporal grey and white matter volumes and in grey matter volume of the cerebellum [80]. Girls with ASD have also been reported to differ more robustly in amygdala volume from TD girls between the ages of 1 and 5 years, in comparison to the differences between boys with ASD and TD boy controls [81]. While there are also reports of a similar degree of cerebral enlargement for both boys and girls (for example, [82]), findings across studies suggest that girls may need to deviate more from their respective normative population than boys in order to demonstrate a clinical ASD phenotype. This observation also supports aetiological models proposing that while females are likely to carry a higher genetic load for ASD than males, females may also have a higher ‘threshold’ (that is, minimum liability sufficient to cause ASD) for reaching affection status than males (reviewed in [83]). Alternatively, female-specific protective factors that may include environmental, biological, and/or epigenetic mechanisms may counteract the genetic liability for ASD in females overall, so that a comparable threshold would affect a smaller proportion of females in comparison to males (see also [84]). In this case, one would expect the cortical pathology of ASD to be significantly modulated by biological sex.

There are few imaging studies to date that have examined the degree to which biological sex modulates the regional anatomy of the brain, and of those that are available, most are based on assessing sex-by-diagnosis interactions within a general linear model (GLM). For instance, Lai *et al.* (2013) performed a VBM analysis and found significant sex-by-diagnosis interactions in several white matter clusters that also showed a significant difference in white matter volume between males and females [85]. Notably, no significant sex-by-diagnosis interactions were reported when examining regional grey matter volume. Similarly, Beacher *et al.* (2012) reported significant sex-by-diagnosis interaction in: (1) total white matter volume; (2) regional grey matter volume of the right inferior parietal lobe; and (3) diffusion measures in the corpus callosum, cingulum, and corona radiata [86]. Last, a recent study examined local gyrification in males and females with ASD and TD controls—reporting that the degree of gyrification in the ventromedial/orbitofrontal cortices was significantly modulated by biological sex [64]. Overall, these studies

suggest that the neuroanatomy of ASD differs significantly between males and females and that biological sex attenuates the cortical pathology of ASD. Treating biological males and females as distinct genetic and/or biological subgroups may thus reduce the large degree of phenotypic heterogeneity that is characteristic for ASD and also help us better examine the neurobiological underpinnings that undermine risk and resilience for neurodevelopmental conditions.

Conclusions

Over the last two decades, human neuroimaging studies have played a crucial role in establishing the cortical mechanisms that underlie the cluster of behavioural deficits typically observed in ASD. Most importantly, it is known from neuroimaging studies that ASD is accompanied by an atypical developmental trajectory of brain maturation, which leads to differences in brain anatomy and connectivity. In turn, insights arising from the examination of the brain *in vivo* can inform genetic and/or molecular investigations, to help elucidate the underlying genetic and/or molecular mechanisms of ASD. This also demonstrates that the role of neuroimaging in mental health research is transitioning into being an integral part of ‘translational research’, which integrates findings across multiple disciplines and translates them into the real-world clinical settings (that is, ‘from bench to bedside’). For instance, in the future, neuroimaging approaches may be used to assist (for example, in combination with clinical interview) the diagnosis/stratification of ASD into more biologically homogenous subtypes and/or to predict response to treatment. Here, it will be crucial to shift the analytical focus from the group-level statistical inference to the individual (that is, case) level—for example, using multivariate pattern classification (MVPC) techniques (for example, [87]). Moreover, such techniques make it possible to take into account complex and multivariate biological features and are hence particularly well suited to characterize conditions with a complex genetic and neurobiological architecture such as ASD. However, the application of these approaches in the clinical setting remains a vision for the future, and there is currently a lack of studies validating models established in the research (that is, investigative) setting on independent clinical validation samples. If successful, however, these new approaches may one day prove invaluable in helping to diagnose, treat, and characterize ASD.

Management and treatment of autism spectrum disorders

Emily Simonoff

Introduction

Autism spectrum disorder (ASD) is characterized by pervasive impairments in reciprocal social communication and restricted and repetitive behaviours and interests (RRBIs). These characteristics are typically evident early in life, and while the course is variable, impairments persist across the life course. Diagnostic terminology has recently changed in the US DSM-5 [1], in which childhood autism, Asperger's syndrome, atypical autism, and pervasive developmental disorders are all subsumed under the umbrella category of ASD. This change occurred because of inconsistency in the use of different diagnostic subtypes within ASD [2] and also in recognition of the broad spectrum of severity, both across and within individuals over their life course. Life course variability in the manifestations of ASD may reflect changes emanating from within the individual, such as acquisition of language, or the implementation of environmental accommodations such as an ASD-oriented education or employment.

While the diagnostic criteria for ASD are based on the core symptoms of social communication and RRBIs, co-occurring disorders of development and mental health are the rule. In relation to cognition, approximately half of those with ASD also have an intellectual disability (ID), as defined by an intelligence quotient (IQ) of below 70 [3], and over half of those with normal non-verbal intelligence have a specific language impairment [4]. Motor co-ordination problems are more loosely defined, but population studies indicate that three-quarters of children with ASD score in the impaired range on structured assessments [5]. Psychiatric disorders are also highly prevalent, with aggregate rates in the region of 70% [6–9]. A heterogeneous range of medical conditions are also common in ASD, with about 15% of people having a causal medical/genetic disorder [10, 11] and a further proportion having coexisting, but not causal, conditions such as epilepsy. Finally, people with ASD have impairments in adaptive function, the competence to undertake a range of everyday activities, including personal care, communication with others, and organization, and these impairments exceed that expected on the basis of their IQ. This impacts significantly on the degree of independence achieved by people with ASD across the full IQ range. Hence, the comprehensive management and treatment of

people with ASD requires a wide-ranging approach to a diverse set of conditions.

Because ASD is a developmental disorder starting in early life but continuing throughout life, the manifestations often vary considerably and the goals of parents/carers and people with ASD often change over time in relation to treatment goals (Fig. 30.1). In early childhood, following diagnosis, there is often a focus on interventions that will minimize or eradicate core ASD symptoms, including the development of effective communication strategies and optimization of learning. In later childhood, co-occurring mental health problems are more obvious. The importance of peers and the challenges experienced in initiating and maintaining these relationships are more evident. During later adolescence and adulthood, concern may focus on improving adaptive function and increasing independence (both typically lagging behind learning), and widening participation in education, employment, or community life. Although some behaviour problems may ameliorate, often anxiety depression become more prominent. In early childhood, ASD is often viewed by parents as a condition to 'eradicate'; however, many adults living with ASD embrace their autistic identity but want help with specific concerns, such as employment and other aspects of the 'neurotypical' environment, and with managing their mental health [12]. This changing perspective means that clinicians and services need to be patient-centred and flexible in their approach, as well as help to shape realistic goals and targets.

Many individuals with ASD, including those with average to above average intellectual ability, need support throughout their lives. The ethos in adult mental health services is to enable patient independence and ensure confidentiality. However, people with ASD are frequently anxious about health appointments and find it difficult to tolerate busy waiting rooms. Their difficulties with communication, emotional literacy, and perspective-taking can interfere with their ability to give a full and accurate account of their symptoms and experiences. Their need for support in health care appointments is recognized in the National Institute for Health and Care Excellence (NICE) guidelines for adults with ASD [13]. Throughout this chapter, we refer to 'patients and their families,' recognizing that

Mid childhood/early adolescence <ul style="list-style-type: none"> • Manage mental health problems • Optimize education, including extra help/special school placement • Facilitate friendships • Maintain harmonious family life 	Mid childhood/early adolescence <ul style="list-style-type: none"> • Manage mental health problems • Optimize education, including extra help/special school placement • Facilitate friendships • Maintain harmonious family life 	Adulthood <ul style="list-style-type: none"> • Manage mental & physical health • Identify employment opportunities • Develop independence • Identify social and support outside family • Find ways to improve quality of life

Fig. 30.1 Management and treatment priorities change across development.

in childhood, this is typically parents and in adulthood, it may involve other family members or carers.

General approach to treatment and management of ASD

The focus of this chapter is on the management of both core symptoms of ASD and co-occurring psychiatric conditions. These can be extremely variable, and a personalized approach is required.

The autism team

Because of the range of core and co-occurring symptoms, clinical input is needed from multiple disciplines within health, as well as from education, employment, social care, and the voluntary sector. Furthermore, as ASD is a chronic condition, services should recognize that the needs of people with ASD are long term and that models of care developed for episodic conditions may not meet their needs. In England, therefore, the NICE has recommended that every local authority should have an 'ASD team', which may be virtual, but where the relevant professionals can be brought together to consider and manage the needs of individual patients [14].

The diversity of needs mandates that health services are multidisciplinary in their composition. When younger children are involved, paediatric input is essential to consider underlying and associated medical/genetic disorders. Neurological expertise should be available across the lifespan. From mid childhood onwards, psychiatrists and psychologists are core members of the autism team, in relation to the diagnosis and management of ASD and additional mental health problems. Speech and language therapists are also essential to work with ASD patients with varying levels of verbal communication. Occupational therapists play an important role in the management of motor impairments and the sensory atypicalities that are often distressing and impairing. Occupational therapists may also provide useful input in relation to employment. Usually outwith the clinical team, but essential to meeting the needs of patients, are close links with education, including special education, and social care.

Principles of intervention

Building on strengths

The cognitive profiles and learning styles of people with ASD, while diverse, are often different from those of non-autistic, typically developing people of the same age and ability level. Often these differences are viewed as impairments that will interfere with effective treatment, but a neurodiversity perspective would instead highlight the strengths to be enhanced and drawn upon. These may include good visuo-spatial memory, attention to detail, and willingness to

follow rules and instructions carefully. In developing an intervention plan, individual strengths should be systematically elicited through interviews, questionnaires, and cognitive assessment of the patient.

Identifying and prioritizing intervention targets and goals

ASD is a severe and pervasive disorder that affects every aspect of life. As discussed in the following sections, while there is emerging evidence that some interventions may improve core symptoms, these are far from curative, and the overwhelming majority of people with ASD continue to experience significant impairment. Treatment of co-occurring mental health problems typically results in less amelioration than might be expected in other patient groups. The reasons for this reduction in effectiveness remain uncertain. One possibility is that co-occurring conditions have a different aetiology in ASD, and hence the target(s) or underpinning mechanisms for intervention are different. Another possibility, particularly for non-pharmacological treatments, is that people with ASD are not able to use the intervention in the way intended because of ASD-related differences such as cognitive strategies. Alternatively, it is possible that the true effect of such interventions is similar in people with ASD, but the effects are difficult to detect and measure in the context of their ASD. Regardless of the reason, a general observation is that people with ASD often remain significantly impaired in their functioning, following a course of evidence-based intervention. Therefore, clinicians should work with patients to set realistic goals.

An additional challenge is the typical presentation of co-occurring conditions may mean that patients and their families have multiple treatment targets. The establishment of a sequence of priorities should consider which symptoms are most impairing, most likely to respond to interventions, and likely to have a knock-on impact on other symptoms.

Monitoring of treatment benefits and adverse effects

The co-occurrence of core ASD symptoms and additional mental health problems may hinder the ability of patients and family informants to identify improvement in target symptoms. A first step is psychoeducation about which of the patient's symptoms are related to core ASD symptoms and which to co-occurring disorders. Treatment planning should include a discussion of which symptoms are targeted by specific interventions. In monitoring treatment benefits, structured scales, whether standardized or bespoke, are helpful for both patients and clinicians. Autistic patients frequently find it useful to rate their symptoms on a Likert scale, which provides the clinician with quantitative information about improvement. A baseline measure should be obtained before initiating treatment.

Similarly, structured and systematic monitoring for possible adverse effects is essential. The impairments experienced by ASD patients in communication, emotional literacy, and verbalizing

physical sensations may mean that they do not recognize these and volunteer this information at clinical reviews. At the same time, patients with ASD may have more day-to-day variability, which can affect the assessment of benefit and also lead to misattribution of variability as adverse effects. The use of routine monitoring measures can help to disentangle variability from treatment-related benefits and adverse effects.

Specific considerations for pharmacological interventions

Over and above the principles outlined, patients with ASD may be more sensitive to psychoactive medications. This means that they should be commenced on low doses, titrated more gradually to a therapeutic dose (which is sometimes lower than for other patient populations), and monitored more frequently. It is good practice in all patients to use as few medications as possible to manage symptoms. This is even more the case in ASD where drug interactions could be more likely to precipitate adverse effects. Hence, every attempt should be made to optimize the dose of individual medications. Notwithstanding this, many patients require multiple medications and a distinction should be made between the use of multiple drugs for a single symptom complex (polypharmacy) and the need to use drugs targeting different, co-occurring symptoms, which may be essential to a comprehensive approach to management.

Particularly in younger patients and those with ID, it can be difficult to undertake routine medical investigations, such as blood tests, that are normally expected for the initiation and monitoring of medication. In discussion with parents or legal guardians, the clinician should make a judgement and recommendation about the relative risks and benefits of an intervention when routine monitoring is difficult or impossible. It is also often possible to be opportunistic in obtaining investigations when the patient is undergoing other medical procedures.

General considerations for psychological interventions

As with other groups, patients with ASD and their families are keen to have access to psychological interventions. Clinicians are sometimes concerned about the appropriateness of talking treatments with patients whose communication skills are impaired. However, strategies for adaptation, for example modified cognitive behavioural therapy (CBT), are now available and have been evaluated in clinical trials, with positive effects, as described in the following sections. Before commencing psychological work, it is helpful to undertake a cognitive assessment to gain a better understanding of the patient's cognitive level. Clinicians may be misled by patients' 'chattiness' into assuming they have good receptive language when, in fact, their abilities are significantly compromised. The principles of adapted CBT for people with ASD include establishing emotional literacy, using visual materials to support the work, both in sessions and as part of the intervention, and additional practice in multiple settings to aid generalization. Autistic patients may continue to benefit into adult life from family members as co-therapists, as often used with younger children.

Other non-pharmacological interventions

Clinicians should be aware of the importance of other modalities of support or intervention. While there is increasing interest in neuromodulation, there is at present no evidence for its use in ASD. However, education for youth and appropriate supported (where

necessary) employment for adults are among the most important ways of optimizing life chances and improving quality of life. The acquisition of educational levels and adaptive skills is often slower in people with ASD but continues into adult life. In recognition of this, many countries have legislated that people with ASD have the right to state-supported education past the age mandated for typically developing people. Clinicians often have a key role in highlighting elements of the educational or employment environment that will foster development and well-being.

Specific treatments and interventions

The following sections on treatment are organized by symptom domain, and within each section, interventions are considered according to type. Where evidence is stratified or limited by age, this is indicated.

Treatment of core symptoms of ASD

Although the diagnosis of an ASD requires the presence of both social communication impairments and restricted RRBIs, there is evidence that these domains are underpinned by separate, correlated genetic architecture [15]. Furthermore, the current evidence suggests that the effects of interventions are relatively specific. Psychological interventions have focused on social communication and learning, with little evidence of transfer of effects to RRBIs. Conversely, the limited evidence for pharmacological interventions suggests that may be principally useful in managing RRBIs.

Social communication

At present, there is no good evidence that pharmacological interventions improve social communication, although a number are being investigated. While there is evidence suggesting secondary improvement in social communication when co-occurring disorders, for example attention-deficit/hyperactivity disorder (ADHD) [16] or irritability [17, 18], are treated, this is likely to be mediated by improvement in the original target symptoms, rather than having a direct effect. They should not be used in the absence of the primary symptoms.

There is emerging evidence for psychological interventions aimed at improving social communication in young children, from toddlers through the early school years. In evaluating the evidence in relation to psychological interventions, it is important to focus on studies with objective and/or blinded outcome measures, as unblinded parent reports are subject to bias and placebo effects [19]. In relation to parent-mediated interventions, a randomized controlled trial (RCT) in the UK that aimed to improve parental sensitivity to their children's behaviour failed to find a significant effect on child social communication at the end of the trial but did find an effect on parental sensitivity [20]. Interestingly, a follow-up 5–6 years later demonstrated significant benefit for the treatment group on a blinded outcome measure of social communication (but not language level) [21]. Several RCTs in the United States have reported similar findings [22–24].

There is also emerging evidence for the benefits of structured social skills programmes, whether parent-mediated [25–27] or school-based [28]. This evidence applies from early to mid childhood, for example age 5–6 years, through to adolescence.

Applied behavioural analysis (ABA) is a popular approach with a focus on intensive behavioural work to help autistic children acquire specific skills. Early evaluation suggested that while specific skills might be learnt, the intervention did not generalize to meaningful improvements in ASD [29]. In line with the early findings, a structured variation—the Early Start Denver Model (ESDM)—has been more carefully evaluated recently, with follow-up findings at 1 and 2 years. This revealed improvements in the treated group in IQ and adaptive function, but not in ASD symptoms [30], with these gains no longer being significant at the 4-year follow-up [31]. Studies combining classical ABA and joint attention training approaches have reported benefits for proximal target symptoms, but it is unclear whether these effects generalize to outcomes more closely linked to real-life functioning [32, 33].

In adults, observational studies suggest that behavioural or social learning approaches may be helpful, but the evidence from RCTs is very weak, with only one study which failed to find significant benefit of a social learning programme [34]. There are a range of other interventions to consider for adults with ASD which may benefit their adaptive function and quality of life, without specifically improving social communication skills. These include structured life skills programmes for those who have difficulty with organization or social isolation and CBT-based programmes to reduce the risk of victimization [35]. However, the evidence base is weak.

Research shows that the following treatments are *not* of benefit, exclusion diets have no benefit, and the once-touted treatments of secretin, hyperbaric oxygen, and chelation therapy may be harmful [36].

Restricted and repetitive behaviours and interests

Despite early findings suggestive of benefit, selective serotonin reuptake inhibitors (SSRIs) should not be used to treat RRBIs. Early, but small, studies of fluoxetine in children [37] and adults [38] and fluvoxamine in adults [39] were superseded by a large trial of citalopram in youth, which failed to identify beneficial effects and demonstrated adverse effects in the treated group [40]. These aggregate findings, along with a few other studies, were combined in a Cochrane review that did not support the use of SSRIs for RRBIs in ASD [41]. As for social symptoms, both risperidone [42] and aripiprazole [43, 44] significantly reduced stereotypic behaviour in secondary analyses where autistic children were selected, based on high levels of irritability. The interpretation of these findings should be that where high levels of irritability are present, such drugs may have wide-ranging benefits. There are no trials suggesting psychological interventions directed at RRBIs are useful.

Sensory symptoms

The recent revision of DSM-5 included for the first time sensory atypicalities as part of the diagnostic criteria [1]. They are subsumed under the domain of RRBIs. Sensory atypicalities include both hyper- and hyposensitivity, as well as unusual interests to one or more domains of sensation. The study of sensory atypicalities has been held back by a lack of good measures of sensory experiences and behaviours. Recommendations from occupational therapists include the use of stimuli that provide alternative sensations such as squishy balls, weighted blankets and vests, eye protectors, and massage. There is weak (because of small sample size and non-blinded outcomes) RCT evidence for the benefit of occupational therapy

in one structured intervention of 30 sessions [45] and similarly for massage [46]. Although they have been popular, the evidence on weighted vests does not support their use [47].

Treatment of common co-occurring mental disorders

As highlighted previously, co-occurring psychiatric disorders are the rule in people with ASD. The reasons for this are only partly understood. Twin studies indicate that co-occurrence with other neurodevelopmental disorders, such as ADHD, tics/Tourette's syndrome, and ID is predominantly due to shared genetic risk factors [48]. This does not apply to co-occurring emotional symptoms where shared genetic factors are very small [49]. For the latter group of symptoms, it is more likely that features of ASD, impairments in cognitive processing, including social cognition, and executive function are mediators for emotional disorders [50]. Differences in behavioural style may render people with ASD more likely to experience adverse environmental and life events, including bullying [51], and they may have greater difficulty in adaptive responses when they have occurred. Others have argued that the high level of co-occurring psychopathology merely reflects inaccuracies in diagnostic boundaries and that these should be broader and more inclusive to reflect the patterns of observed symptoms. A benefit of conceptualizing these symptom domains as co-occurring disorders is that it encourages clinicians to identify and treat them, drawing upon the wider intervention evidence base in the absence of ASD-specific studies.

Attention-deficit/hyperactivity disorder

Population studies suggest 30–50% of children with ASD meet criteria for ADHD [8, 9]. Diagnostic classification systems prior to DSM-5 precluded the diagnosis of ADHD (hyperkinetic disorder in the International Classification of Disease) in the context of ASD; hence, much of the relevant research refers to people with high levels of ADHD or hyperactivity symptoms. For all practical purposes, the patients included in pharmacological trials would meet formal diagnostic criteria for ADHD or hyperkinetic disorder and they are referred to in the following sections as having ADHD for ease of discussion.

There are RCTs supporting the benefits of methylphenidate, atomoxetine, and guanfacine in youth with ASD and ADHD. Methylphenidate has been evaluated in four RCTs, with a meta-analytic effect size of 0.66 [52] and about half being classified as responders [53]. This contrasts with effect sizes in the region of 0.8–1.0 in typically developing youth with ADHD [54] and 80–90% of responders [55]. Furthermore, rates of adverse effects are higher, with 18% in the largest study being withdrawn due to adverse effects in one study [53].

Atomoxetine has been evaluated in a small [56] and medium-sized [57] trial. Both reported significant improvements with active treatment over placebo, but effect sizes were not reported. In the larger study, only 21% were responders under the usual criteria (vs 9% in the placebo group) [57], compared to 57% and 25%, respectively, in the smaller study [56]. However, rates of adverse effects were low, with only two withdrawals across both studies. A two-by-two RCT (atomoxetine vs placebo, parent training vs no psychological intervention) showed benefits for all three active arms (atomoxetine plus parent training, atomoxetine alone, and parent training alone), with effect sizes of between 0.57 and 0.98, compared to no treatment. The active arms could not be distinguished statistically [58].

Most recently, guanfacine has been evaluated in ASD and ADHD in a medium-sized study showing a large effect size (>1), with 50% of the active group classed as responders vs 9% of the placebo group [59]. Adverse effects leading to withdrawal were present in 13%, and lethargy early in treatment was prominent.

The only RCT evidence for psychological intervention comes from the atomoxetine/parent training study described, in which the effect size against no active treatment was 0.6 [58]. In contrast to the pharmacological trials, this was not a blinded outcome, as parents were the recipients of the intervention, as well as the informants on ADHD, so the magnitude should be viewed with caution [60].

In summary, there is good evidence for pharmacological interventions in ADHD among youth with ASD. However, the effects are mostly smaller than in typically developing youth and the rate of adverse effects is higher. Therefore, careful monitoring is required when prescribing. Different classes of medication should be tried sequentially if benefits are inadequate or the drug is poorly tolerated. There are no adult studies to draw upon; therefore, extrapolation from the experience in children and adolescents is necessary. The findings of parent training highlight the importance of including psychological approaches to intervention and is consistent with the NICE update on ADHD, in which it is recommended that parent training is offered to all parents of children with ADHD [61].

Anxiety and obsessive-compulsive disorders

Rates of anxiety disorders vary widely across studies, from about 30% to 80%, depending on populations and measurement [62]. With regard to pharmacological interventions, there have been no RCTs targeting anxiety disorders among patients with ASD. Trials of both fluoxetine and citalopram failed to show an impact on obsessional symptoms [37, 40], and these trials were likely measuring RRBIs, rather than obsessive-compulsive disorder (OCD).

A meta-analysis of eight RCTs of adapted cognitive behavioural therapy (CBT) for anxiety in children and adolescents indicates benefits, with an aggregate effect size of 1.2 [63]. Child-reported outcomes from five studies revealed a lower meta-analytic effect size of 0.68. As above, these large effects should be viewed with caution, as the informants were not blind to treatment allocation and four of the trials used waitlist controls. In addition, the samples are selected to include youth of higher intellectual ability. In adults, the evidence for CBT is more anecdotal. One medium-sized trial of CBT for OCD in adolescents and adults with ASD failed to find a treatment effect against generic anxiety management [64]. The sample sizes were probably not large enough for a comparison against an active intervention, and both the rate of response (45% vs 20%) and effect sizes (0.33 vs 0.05) were suggestive of superiority for CBT that warrants further investigation.

When possible, CBT should be the first-line treatment. Pharmacologically, in the absence of ASD-specific data, treatment should follow that used in typically developing individuals, with the provisos described in relation to low doses and gradual titration. Medication should be considered when CBT is ineffective or unsuitable because of patient characteristics, including anxiety that is too severe for such an approach.

Depression

Rates of depression appear to be low in children with ASD [9] but affects up to 50% of adults [7]. There is even less evidence base for

ASD-specific treatment of depression. One extremely small study of fluoxetine in adults failed to find an effect but was underpowered to reach any conclusions [65]. There is a similar lack of evidence in relation to psychological interventions for depression. Treating depression should follow recommendations for people without ASD, but when psychological interventions are used, they should be adapted to be ASD-specific.

Tics

Tics are common in ASD [8, 9] but importantly need to be differentiated from mannerisms, stereotypies, repetitive behaviours, and complex rituals. This usually requires direct observation. As in typically developing people, tics should only be treated when they are impairing and then the aim of treatment should be to manage impairment, rather than eradicate the tics. Psychoeducation is important, as families and teachers often do not appreciate the involuntary nature of tics. In individuals without ASD, a recent meta-analysis of RCTs reported good to moderate quality evidence for the benefits of the alpha-2 adrenergic receptor agonists clonidine and guanfacine and dopamine antagonists/partial agonists [66]. This review also judged the trials for habit reversal to be of good quality and demonstrating efficacy. These findings should guide intervention in ASD.

Behaviours that challenge

One of the most common and impairing presentations among people with ASD is that of 'behaviours that challenge others' or 'challenging behaviour'. Over the years, a number of terms have been used to reflect these behaviours, which comprise aggressions directed at the self or others and severe non-compliant behaviour, frequently with high levels of irritability. These behaviours may vary in their intensity and frequency but are of concern when they impact on an individual's ability to participate in everyday activities such as family life, school attendance, employment, or leisure activities. Such behaviours are common in people with ASD and more frequent than in other conditions causing similar impact on intellectual functioning [67, 68]. Behaviours that challenge have been conceptualized in different theoretical perspectives, which are not mutually exclusive. In the comprehensive approach to their management, all need to be considered.

Social learning models of behaviours that challenge view these as maladaptive learnt responses. Applied behaviour analysis (ABA) aims to identify the causes and responses that are driving its reinforcement. There is an extensive ABA literature of individual patients and case series demonstrating how learning principles can be used to break the cycle of these behaviours. Although there is a lack of group-based RCTs, the literature includes examples demonstrating the causal role of contingent response, in which the response to a challenging behaviour is modified, leading to a reduction in the behaviour, followed by a return to the original contingencies, which leads to a return of the unwanted behaviour. All clinicians working with these patients demonstrating challenging behaviour should have a good understanding of functional behavioural analysis in order to take a history that elicits antecedents, behaviours, and consequences. ABA in its classical form is undertaken by psychologists and behaviour modification therapists who make use of a range of operant conditioning principles; it can be time-consuming but is an important treatment modality for behaviour that challenges.

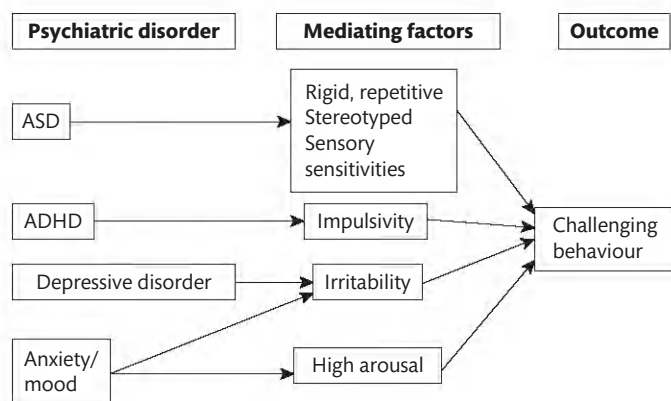

Fig. 30.2 Conceptual framework linking psychiatric disorders to behaviour that challenges.

Behaviours that challenge may also arise as a consequence of conditions causing pain or discomfort. Painful conditions are more common in ASD, either due to the high rates of causal or associated medical conditions. Even higher-functioning autistic individuals often have difficulty identifying bodily sensations and linking them to their emotional state and behaviour. Hence, these should always be considered, especially when there is a sudden increase in challenging behaviour.

Behaviour that challenges may also be an external manifestation of an underlying psychiatric disorder (Fig. 30.2). The presentation of psychiatric disorders may be atypical and more difficult to identify because of poor communication skills and emotional literacy. For example, in autistic individuals, anxiety may present as irritability [69]. The link between different psychiatric disorders and behaviours that challenge has been demonstrated in adults with ID [70]. Clinicians should assess for psychiatric disorders that may underpin behaviours that challenge.

In the absence of identifying another psychiatric disorder, there is evidence for treating behaviour that challenge described as ‘irritability’ with dopamine antagonists/partial agonists, most notably risperidone and aripiprazole. Both drugs have robust acute and medium-term benefits [71, 72]. However, they may also have significant adverse effects, which include weight gain and somnolence, and for risperidone, raised prolactin levels [73, 74]. Clinical impressions that aripiprazole may have fewer adverse effects are not at present confirmed by research; a small head-to-head comparison, which was likely underpowered, failed to detect differences in rates of short-term adverse effects [75].

A trial comparing risperidone alone vs risperidone and parent training in children revealed significantly greater improvement in adaptive function in those receiving the combination intervention, and medication doses were marginally (not significantly) lower than in the medication only arm [76]. Based on all these findings, in conjunction with clinical consensus, NICE recommends that behavioural treatment should be the first-line intervention for behaviour that challenges. Medication should only be first line when circumstances do not permit a behavioural intervention, and where this is the case, a behavioural intervention should be added as soon as possible. Conversely, if a behavioural intervention is inadequate, medication augmentation should be considered. Although medication retains its effectiveness in the

medium term, there are real concerns about long-term safety. Ideally, the use of antipsychotic medication should be seen as an opportunity to develop other strategies for behavioural management, with the aim of reducing or eliminating medication, wherever possible.

Sleep problems

Although sleep problems are very common in people with ASD, particularly those with associated ID [77], research on their management is very limited. Sleep onset and maintenance are the most common problems. The causes are likely multifactorial; there is emerging evidence for biological differences in melatonin production and circadian patterns. Co-occurring medical disorders may play a role, and sleep apnoea should be considered. Psychiatric disorders, such as anxiety, depression, and ADHD, are all linked to sleep problems in people without ASD, and these are of higher prevalence in ASD. People with ASD often have maladaptive bedtime routines that cause or exacerbate sleep problems.

One trial of melatonin in children with developmental disabilities included a large proportion with ASD [78]. The protocol required that eligible families first receive a manual on behavioural management of sleep. Following this, over one-third of children no longer met inclusion criteria, highlighting the benefits of psychosocial intervention. Among those completing the trial, parent diaries indicated a benefit of melatonin for sleep latency and total sleep time, while actigraphy on a subsample confirmed the effect on sleep latency only. Recommendations from NICE place priority on behavioural management strategies, particularly the implementation of a sleep hygiene programme. Where this is insufficient, melatonin can be considered but should only be extended when there is clear benefit and then for a limited time period [36].

Conclusions and research directions

ASD is a severe, pervasive, and lifelong disorder. Although there is an increasing understanding of its aetiology, this has only begun to translate into theoretically derived approaches to intervention. In relation to core symptoms of ASD, most promising at present are psychosocial interventions aimed at improving social communication. A better understanding of their long-term impact is required. Pharmacological approaches to core symptoms have recently focused on molecules implicated in biological pathways that appear to be different in people with ASD, but there is insufficient evidence to recommend their use in clinical practice. A programme of clinical trials is needed to escalate the rate of progress.

Co-occurring psychiatric disorders are exceedingly common in ASD and form an important consideration in the comprehensive management of ASD. There is a good evidence base for the treatment of ADHD and ‘irritability’ or behaviour that challenges, and some evidence to guide practice for anxiety disorders. However, for many other psychiatric disorders, there is a lack of therapeutic research in ASD, leaving clinicians reliant on the evidence base for patients without ASD. Because of the differences in biology and cognitive make-up, such extrapolation may be inappropriate. There is an urgent need for treatment trials in affective and sleep disorders. Different intervention modalities should be considered, both on their own and in combination.

The development of new, reliable, sensitive, and unbiased objective outcome measures should aid the progress and interpretation of clinical trials. Finally, environmental interventions, including those based in education and employment, have the potential to produce large gains in well-being and quality of life.

Core dimensions of attention-deficit/hyperactivity disorder

Eric Taylor

Introduction

The concept of attention-deficit/hyperactivity disorder (ADHD) arose from neurological formulations but does not entail them, and the modern definition describes a set of behavioural traits. A condition consisting of pervasive and persistent inattention and/or impulsiveness is validated by its predictive power. It is associated with the presence of brain changes and genetic inheritance, as well as treatment response and prognosis [1]. The historical evolution of the concept is described by Taylor [2]; it began with the idea that some behavioural problems in children arose, not from social and familial adversity, but from subtle changes in brain development. Nowadays, however, the definition comes from specific and observable behaviour traits without assumption of cause. 'Attention Deficit/Hyperactivity Disorder' (ADHD) in DSM-5 [3] and 'Hyperkinetic Disorder' in ICD-10 [4] describe a constellation of *overactivity*, *impulsivity*, and *inattentiveness*.

These core problems often coexist with other difficulties of learning, behaviour, or mental life, and the coexisting problems may dominate the presentation. This coexistence, to the psychopathologist, emphasizes the multi-faceted nature of the disorder; to the sociologist, a doubt about whether it should be seen as a disorder at all; to the developmentalist, the shifting and context-dependent nature of childhood traits. For clinicians, ADHD symptoms usually need to be disentangled from a complex web of problems. It is worthwhile to do so because of the strong developmental impact of ADHD and the existence of effective treatments. Public controversy continues, but professional practice in most countries makes ADHD one of the most commonly diagnosed problems of child mental health.

Clinical features

Hyperactivity

The idea of hyperactivity is an excess of undirected movement. It is not totally dependent on context and cannot be reduced to non-compliance; physical measures of activity level have indicated that it is higher in children with ADHD than in controls, even during

sleep [5]. It is, however, partly dependent upon context—it is often inhibited by a novel environment, creating a pitfall for the inexperienced diagnostician who may exclude it incorrectly because it is not manifest during observation at a first clinic visit. It may not be shown in situations where high activity is expected such as the games field or energetic play. The key situations where it is evident are familiar to the child and where calm is expected, such as visiting family friends, attending church, at mealtimes, during homework, and—often the most troublesome—at school, during class.

Impulsiveness

Impulsiveness means action without reflection—often described as a failure to 'stop and think'. The term covers premature, unprepared, and poorly timed behaviours—such as interrupting others and giving too little time to appreciate what is involved in a school task or a social situation.

It can also refer to several neuropsychological changes such as failure to inhibit inappropriate responses, aversion to delay, and speed/accuracy tradeoffs. These are indeed more common in children with ADHD and may well underlie some of the observed behaviour changes, but they are not constant and are not part of the diagnosis.

DSM-5 sets out a list of observable behaviours that together define a dimension of hyperactivity-impulsiveness. They can be summarized as:

- Often fidgeting.
- Often leaving seat.
- Often running or climbing inappropriately.
- Often unable to play quietly.
- Often unable to be still when required.
- Often talking excessively.
- Often blurting out answers prematurely.
- Often having difficulty in waiting.
- Often interrupting or intruding on others.

Six of these nine problems need to be present—or five of them for people aged over 17—as a criterion for the diagnosis. Experienced clinicians will sometimes find it infeasible, or even misleading, to make a pedantic count and may be guided by the overall impression

of an unmistakable deviation from what is expected for an individual of given chronological and developmental age.

Inattentiveness

Inattentiveness means disorganized and forgetful behaviour—short-sequence activities, changing before they are completed, with lack of attention to detail and failure to correct mistakes. These are behavioural observations, not psychological constructs. On a cognitive level, ‘attention deficit’ is not always an accurate description; the performance of affected children does not always fade with time on a task any more than that of ordinary people, and the presence of irrelevant information (‘distractors’) does not necessarily worsen their performance disproportionately to that of other people [6]. Cognitive changes of several kinds are indeed seen more frequently than in typically developing people. These changes go beyond attention and executive function [7]; the recognition of inattentiveness depends on descriptions and observations of behaviour, rather than on tests of performance.

DSM-5 provides a list of nine possible features that are often present to excess. They can be summarized briefly as:

- Lack of close attention to details; careless mistakes.
- Difficulty in sustaining attention on tasks or play.
- Not listening when spoken to.
- Not following instructions or finishing tasks.
- Difficulty organizing tasks and activities.
- Avoiding tasks that require effort.
- Losing things that are needed for activities.
- Distractible by outside stimuli.
- Forgetfulness in daily activities.

Six of the problems should be present for the full diagnosis (or five in adult life). Care is needed to avoid confusion with oppositional behaviour. For example, ‘not following instructions’ is intended to imply that instructions are forgotten or not attended to, but the behaviour can also be shown for reasons of wilfulness and defiance. Careful description, or witnessing the behaviours complained of, is necessary to identify the quality of disorganization. The recognition of the disability therefore needs an experienced professional. The diagnostician also needs to recognize that the behaviours can be modified by the context. Tasks with a strong incentive, or that are inherently rewarding and engaging, may well elicit a much improved performance. Good focus on a shoot-em-up computer game, or good self-control at the first visit to the office, should not be taken to exclude the diagnosis.

Further requirements for diagnosis

Developmental inappropriateness

Inattention and impulsive over-activity both need to be judged in terms of what is clearly excessive for the individual’s developmental level. Either is sufficient for a diagnosis; when both are present, then the combination should be noted. In the previous version of DSM-IV, there was an expectation that predominantly inattentive, predominantly impulsive, and mixed subtypes should be distinguished. A longitudinal study, however, has found that they do not behave as subtypes over time—one tends to turn into another. They are,

accordingly, now referred to only as ‘presentations’. Nevertheless, clinical experience suggests that there are important differences in children who are not just ‘predominantly’, but *exclusively*, inattentive. Dreamy children, who are sluggish, rather than excitable, in temperament can still have enough problems in their attention that their education is seriously compromised. They will need much more focus on educational progress, and less on risk for antisocial development, than their disruptive contemporaries—and indeed much more psychological research than has yet been forthcoming.

Pervasiveness and persistence

Pervasiveness across situations and over time is another important part of the clinical picture. One is trying to identify a trait in the person, not simply a quality of the environment that elicits restlessness. The extent of pervasiveness is the main distinction between the DSM-5 definition of ADHD and the ICD-10 definition (currently under revision) of hyperkinetic disorder (HKD). The latter specifies that all three of the cardinal features—impulsiveness, over-activity, and inattentiveness—should be present, pervasively and persistently, across home, school, or work, and in other situations. HKD is therefore, in effect, a subtype of ADHD [8].

Disability

Impairment in social, academic, or occupational functioning is also a necessary condition for the full diagnosis. The necessity for this is somewhat controversial. The extent to which the features of ADHD impose a disability is very variable. Careful parents and responsive teachers can help a child to achieve their potential, in spite of the struggle to focus and self-organize. Conversely, a highly academic school may impose demands for achievement that entail a real disability for children who have only minor difficulties in concentrating. Furthermore, in comorbid cases, it can be hard to tell whether the impairment is due to the ADHD itself or to the coexisting difficulties (see Associated features, p. 302).

The level of impairment of function that is required for the diagnosis accounts for a good deal of the great variation in prevalence between different studies and different places [9] (see Chapter 33). A full assessment will separate caseness and impairment, and accept both as important in making the formulation and clinical plan.

Associated features

Many other behavioural changes characterize some children with ADHD. They are, for instance, often irritable and their emotions can flash very rapidly when provoked. They may sleep badly (and this, in turn, can contribute to poor concentration). They can be aggressive to other people and non-compliant to authority. They can also be charming, humorous, inquisitive, and intuitive. None of these, however, are either constant in ADHD or confined to those with ADHD. They are worth noting, but they do not make the diagnosis.

Modifying features

Inattention and impulsive over-activity both need to be assessed in light of the effects of age, gender, and developmental level.

The first 3 years

A 'difficult temperament' in early childhood includes over-activity and poor self-regulation and can have a harmful effect on parent-child relationships. Some children do indeed present a whirlwind of activity, but the normal range is very great and the concept of inattentiveness is hard to apply at this age. The exploration of the world by toddlers is typically short-lived, but intense. A diagnosis of ADHD would be insecure.

Age 3–6 years

ADHD behaviours are clearly recognizable by this age, and there is a strong likelihood of persistence into the school years [10]. It can still be difficult to distinguish between behaviour problems at home resulting from impulsiveness and those from headstrongness and anger. The presence or absence of inattentiveness is therefore important for diagnosis, but the issue is often not pressing because parent training is an effective intervention for behaviour problems at home and should be available for parents with children at risk, without waiting for a formal diagnosis.

Age 7–11 years

Attention span increases during the early school years, and most children with ADHD will be able to sustain interest for some 3 minutes—more, if the activity is unusually attractive. Hyperactivity is reflected in running and climbing in situations that expect calm. School and peer demands make ADHD behaviours impairing; the tolerance of families and culture at large help to determine whether ADHD is seen as a problem, and this is a very common age for referral and diagnosis. Hyperactivity (as opposed to inattentiveness alone) becomes important in generating aggressive and antisocial behaviour and delinquency. The extent to which there is a poor social outcome depends upon both genetic and environmental influences [11], including gene–environment interactions such as that found in a study in which a catechol-O-methyltransferase (COMT) gene polymorphism, together with low birthweight, predicted the development of antisocial symptoms in those with ADHD [12].

Age 12–18 years

During adolescence, there is maturing in the abilities of self-control. Attention span may well have risen to 10 minutes at a time, but the demands of classrooms will typically expect much more. Academic failure becomes increasingly salient in the young people's lives. Hyperactivity may now be reflected only in fidgeting and a strong feeling of a need to be 'up and away'. Emotions can become unregulated in most teenagers, but especially so in those with ADHD. Some children with ADHD will become more reflective, but the demands for self-control rise as well, and so the young people still tend to be more impulsive and inattentive than their peers. Indeed, even those who had never been clinically diagnosed or referred for help were still four times as likely to merit a psychiatric diagnosis by the time they were 17 years old in a longitudinal population study [13]. Those who continue to show hyperactivity are at increased risk for other problems, notably aggressive and antisocial behaviour, delinquency, and motor traffic accidents. Substance misuse may be appearing, largely attributable to coexisting problems of conduct and social dysfunction.

Adult life

By adult life, most will no longer meet full diagnostic criteria for ADHD, but most will retain some functional impairment related to hyperactivity and the impairment is present at lower levels of the number of criteria than is the case in childhood [14]. DSM-5 therefore adjusted the number of symptoms expected for diagnosis, from six to five. Inattention may now be reflected in incomplete assignments, procrastination, and mind-wandering. Over-activity may be confined to an inner feeling of restlessness. Impulsiveness may now be a matter of recklessness and poor decision-making. Emotional lability is often a major part of the presentation and is closely linked to the level of the ADHD problems themselves [15].

There is also an expectation that the symptoms should have started in childhood, that is, before the age of 12 years. They may well not have been diagnosed at the time, and indeed they may not even have been impairing. Bright children may have been able to achieve satisfactory academic progress, and those without significant oppositional problems may well have fitted harmoniously into family life. ADHD features may only have become impairing when adult life presented greater demands for responsibility and scheduling. Recent research from a longitudinally studied cohort has identified adults who presented ADHD features but did not show them when they were studied in their childhood [16]. These 'adult-onset' people were different from those whose ADHD had been continuous throughout development, in ways that cast doubt on whether they could be considered as showing a neurodevelopmental disorder—they were less likely to have affected family members and cognitive deficits, and more likely to have used cannabis and other drugs.

A key difficulty in current knowledge is that of making an accurate diagnosis when adults present for the first time [17]. Adults may be mistaken in their recall of their childhoods, and the subjective aspects of their condition may be rather different from those that other people observe. The account of somebody who knows the patient well—perhaps a spouse or a work partner—is very desirable but does, of course, need interpreting in light of their own interests in a diagnosis. People who knew the individual as a child can be very helpful informants, for example through a telephone interview, and there may be school records available. Simply the giving of a diagnosis comes as a relief to some who have puzzled over the reasons for their failures and can liberate problem-solving approaches.

Gender

Females are less likely than males to be rated as over-active, impulsive, or inattentive during childhood. The ratio is usually about 2–3:1 in population surveys, and those girls who are affected are no less likely than affected males to become impaired in social and academic functioning [18]. Diagnostic rates in series of children referred to clinics usually yield much wider ratios, and it may well be that boys are preferentially identified in the community as needing help. Affected girls are often more troubled by inattention than over-activity and may often suffer more than boys from impairment of peer relationships. In current knowledge, the same criteria should be applied to both genders. Clinicians, however, should guard against dismissing girls who are not disruptive as being unaffected by ADHD.

Developmental level

The diagnosis should only be made when the problems are out of keeping with the developmental level. Intellectual disability is very likely to include problems of concentration. Psychometric assessment is therefore advised before assuming that attentiveness is disproportionately affected in such cases or that this deficit is responsible for poor achievement. Over-activity/impulsiveness is usually assessed with reference to what would be expected in a typically developing child whose chronological age would correspond to the developmental age of the child being assessed. The validity of this approach deserves the attention of researchers.

Diagnostic problems

Description of the symptoms makes them sound easy to recognize, and indeed the problems are usually very salient, disruptive to other people, and common causes of referral to health and special education services. Nevertheless, there are pitfalls in the diagnosis, making it necessary for a specialist assessment to be undertaken before the diagnosis is given.

Differentiation from normality

The behaviours of ADHD are continuously distributed in the population (see Chapter 33). The level that is considered normal or acceptable will vary from one culture to another and from one rater to another. To be diagnosed, it should be excessive not only for the child's age but also for the developmental level, present across situations and time, and giving rise to significant distress or dysfunction.

Confusion of cardinal and associated features

Many behavioural problems—such as temper tantrums, sleeplessness, aggression, and disobedience to adult authority—are common in children with ADHD and may be the key reasons for presentation. It is easy to make the mistake of diagnosing ADHD when only disruptive behaviour is present. Some of the confusion comes from the ambiguity of 'impulsiveness'. Behaviours, such as calling out in class and interrupting others, can indeed come from a difficulty in holding oneself back, but they can also represent deliberate flouting of the rules. Direct observation can usually make the distinction—watching either the children tackling tasks requiring them to stop and think in the clinic or their natural behaviour in the classroom. Inattentive behaviour also helps to make the diagnosis of ADHD and is less confounded by oppositionality.

Reliance on non-expert judgements

Judgements about whether behaviours occur 'often' and are atypical demand considerable familiarity with the usual range of variation. The diagnostician will acquire this in the course of training and experience; experienced teachers will be excellent judges, but inexperienced or overstressed parents may identify the problems at a low level of hyperactive behaviour or suppose that an abnormal level is only to be expected in childhood. It is usually helpful to obtain a detailed behavioural account, rather than rely on an overall judgment of 'over-activity' or 'failure to concentrate'.

Contradiction between sources may occur and lead to arguments between parents and teachers. This may be due to different

expectations, the emotional relationship of raters with the child, or children behaving very differently in contexts that vary in the demands placed on the children. The clinician needs to understand the full context of the way involved adults describe the child.

Difficulties in recognition in the presence of coexisting problems

It is commonplace for children whose problems meet the criteria for ADHD to show other patterns of disturbance as well. This is often, confusingly, called 'comorbidity'—confusing because it implies that the other pattern is a distinct disorder, which is only one of the explanations for coexisting problems. Clinicians need to understand the relationships for two reasons, so that they do not make or miss the diagnosis of ADHD and so that they can make good strategies for treating ADHD in the presence of other disorders and other disorders in the presence of ADHD.

Conduct and oppositional disorders

The most common association, and the best researched, is with conduct and oppositional disorders. Nearly half the children with hyperactive behaviour in a community survey showed high levels of defiant and aggressive conduct as well, but the associations of the two problems were different, with hyperactivity (but not conduct problems) being associated with delays in motor and language development [19]. When both ADHD and conduct problems were present, the combined condition ('hyperkinetic conduct disorder' in ICD-10) showed the associations of both disorders. ADHD is therefore not to be diagnosed by the absence of conduct disorder features, but by the clear presence of the core problems of inattentiveness and disorganization.

Tourette's disorder and multiple tics

A different kind of differential is presented by children with Tourette's disorder. Their motor restlessness may indeed represent the coexistence of ADHD but can result directly from tics. If a child's tics are very frequent and numerous, then their repetitive and stereotyped nature may not be apparent and they may be seen simply as restless fidgetiness. Again, direct observation of the pattern of over-activity is the key. When there is doubt, filming the child and subsequent slow-motion review may make repetitive patterns evident.

Autism spectrum disorders

Children with autism have clear and characteristic impairments of language, communication, and social development. Spectrum disorders, however, can raise diagnostic challenges. Children with ADHD alone often show language delays (usually of an expressive nature with oversimple utterances, by contrast with the receptive difficulties and idiosyncratic patterns of autism). Their attention difficulties may make them unresponsive to the overtures of others in a way that can simulate the social obliviousness of people in the spectrum of autism, and they are often friendless—not because of lack of interest in others, but because of the capacity of hyperactive behaviour to irritate other people. Indeed, attention problems can extend to perseveration on certain activities, such as video games, which may be mistaken for the restricted interests of autism. All these factors can lead to ADHD being mistaken for autism, but the reverse can happen too. There are other reasons for over-active behaviour in autism. Firstly, stereotyped patterns of driven over-activity can

be seen; they are not disorganized or impulsiveness and are often made worse by change and novelty (which usually reduce the over-activity of ADHD). Secondly, episodic bursts of extreme activity can be seen and may be best regarded and treated as catatonic. Thirdly, akathisia may result from neuroleptic medication, or irritable restlessness from anticonvulsants, and it will be necessary to establish a clear history that ADHD has been a persistent trait.

Attachment disorders

Reactive attachment disorder (RAD) may share with ADHD a disinhibited style of relating to other people (an unreserved, but shallow, making of social contact). Children with RAD, however, tend to be controlling rather than disorganized, and vigilant rather than inattentive, and inattention and impulsiveness are not cardinal features of RAD—so it is not difficult to recognize both patterns when present in an individual child. The confusion in practice often comes from theoretical misconceptions. Those caring for neglected or abandoned children may consider that the diagnosis of ADHD cannot be accurate because the cause of the children's problems is clearly to be found in their early deprivation. The causal pathway may indeed be that of neglect (though genetic inheritance and fetal damage also need considering); but ADHD is a descriptive category, not an explanatory one. If the pattern of ADHD is present, it still needs recognizing—not least because the cause of the ADHD behaviour does not seem to determine the response to stimulant medication and children who have encountered neglect or abnormal early attachment may still have their ADHD problems reduced by medication.

Bipolar disorders

Both ADHD and manic conditions are characterized by over-activity, overtalkativeness, a sensation of whirling thoughts, and often irritable mood. The distinction is made by the presence in bipolar disorder of episodicity, euphoria, and grandiosity.

In all these differential diagnoses, the principle is to establish that the individual shows not only over-active or inattentive behaviour, but also the specific pattern of ADHD. Experienced judgement may be required, and the practice of diagnosing on the basis of questionnaire scores alone carries risks of both overidentification and missing cases.

In adult life, there are still more possibilities for misdiagnosis. The most common reasons for uncertainty are in distinguishing from atypical bipolar disorder and the effects of substance misuse. 'Personality disorder' is sometimes applied, and indeed ADHD shares with personality disorders a long-standing trait quality but can also be a more precise way of describing the difficulties presented. Differentiation from the normal range of variation can be difficult in the absence of clear standards. The task of the diagnostician is harder when adults are presenting for the first time if only self-report is available; the self-description of hyperactivity may be a form of self-depreciation.

Methods of recognition

Rating scales

Questionnaire ratings by parents or teachers are very useful for screening purposes and monitoring interventions. Many are available; the most famous are those from Conners which yield several

different scoring systems [20], derivatives such as the Iowa Conners, and the Strengths and Weaknesses of ADHD-symptoms and Normal-behavior (SWAN) and Swanson, Nolan, and Pelham (SNAP) scales [21]. Other scales were developed directly from the DSM criteria such as the ADHD Rating Scale [22] and the Vanderbilt ADHD Rating Scale [23]. Furthermore, several general-purpose scales include subscales comprising problems of over-activity and inattention such as the widely used Child Behavior Problems Checklist (CBCL) [24] and the Strengths and Difficulties Questionnaire (SDQ) [25]. They are particularly suitable for initial screening and triage. Free access from the Internet is available for SNAP-IV and SWAN (<http://www.myadhd.com/snap-iv-6160-18sampl.html>) and SDQ (<http://www.sdqinfo.org>).

Many of these rating scales have similar strengths and weaknesses [26]. In group studies, they give a reasonably good discrimination between people with a clinical diagnosis of ADHD and controls from the ordinary population, with an effect size of about two standard deviations, implying a substantial overlap. This discrimination is probably somewhat better for the special-purpose ADHD scales than for the general-purpose scales. Test-retest reliability is typically around 0.7; all are sensitive to the effects of medication. Agreement between teachers and parents is typically rather low. The SWAN scale was developed with a wider range of scores for each item (including both 'far above average' and 'far below average')—so it will yield a more Gaussian distribution in a population survey than most other instruments. All scales, used as a population screen, leave a fair number of individuals misclassified and are liable to many false positives. The questionnaires are best seen as a first stage of screening, not as defining casehood.

For adults, a variety of self-report measures have been developed and are reviewed by Davidson [27]. The Wender Utah scales were particularly important in the early conceptualization of adult ADHD [28], but—like other rating scales—they tend to overidentify. An Adult ADHD Self-Report Scale (ASRS-v1.1) [29] is a symptom checklist developed for the WHO. It can be downloaded from: http://www.caddra.ca/pdfs/Guidelines_ENG_ChangesJuly2012.pdf

Informant interview

A detailed interview with parents (or other main caregivers) is the most informative single method for assessing children and adolescents. The aim is to go beyond their overall ratings of problems to an understanding of what actual behaviours are the basis for ratings. It is helpful to obtain a description of key situations such as getting ready for school, playing with toys, drawing, mealtimes, homework, and family excursions. Parents will usually have very good recall of attention and activity control, even if their knowledge about the normal range is limited. Professional judgement can then be applied to whether those descriptions indicate abnormality of development.

Standardized interview schedules are also available. Some are highly structured and can be delivered by non-clinicians such as the Diagnostic Interview Schedule for Children (DISC) [30]. Others are more interactive, can be delivered flexibly, and expect the interviewer, rather than the respondent, to be the specifier of what is rated (as described previously). Examples of these 'semi-structured' instruments would be the Child and Adolescent Psychiatric Assessment (CAPA) [31] and the Schedule for Affective Disorders and Schizophrenia for School Age Children (K-SADS) [32]. They

are time-consuming, sometimes too much so for routine clinical practice, but can ensure a full cover of salient features.

Interviewing should, of course, go beyond the making of a single diagnosis. It should include other problems, social and intellectual development, emotional life, and any physical problems. It can also be helpful—when possible—to interview teachers, not only to gain a full impression of the child in the classroom, but also to be seen to do so lest teachers form the impression of a less-than-comprehensive evaluation.

Psychiatric interview

Interview with the child is valuable for the observation of attention and social interaction that it yields, and for understanding a child's view of their predicament. Children, however, are not good witnesses about their own concentration and impulse control, and even affected adults are not good at describing themselves in these terms. The experience of ADHD is usually one of suffering the reactions evoked from other people, or one of repeated failure. Adults often describe an experience of whirling and interrupted thoughts (in the absence of manic features), and some children will say the same, especially if treatment has enabled them to make a comparison with another way of being.

Observation

Direct observation of the child in the clinic, or during psychometric testing, can give a vivid idea of the nature of their problems in attending. Do they take time to appreciate what they are being asked to do? Is the tempo of their activity increased? Can they slow down when asked? Are they distracted by the setting? Do they complete tasks or play activities? Similarly, observation of play and task performance in natural settings can be valuable in confirming or qualifying the accounts of informants. The effect of the presence of the observer needs to be taken into account in making judgements.

Investigations

Assessment needs not only to distinguish ADHD from related disorders, but also to consider whether the ADHD pattern may result from remediable causes. The anamnestic history is by far the most productive investigation. It should include whether hearing problems have been excluded by previous testing (and if not, an expert assessment should be arranged), and any injuries or diseases potentially damaging to the brain. The strengths and weaknesses of the family environment need to be assessed; they may dictate the choices of treatment. Physical examination should be sufficient to detect congenital anomalies, skin lesions, and motor abnormalities that can be the pointers to a neurological cause. Psychometric assessment is desirable whenever there are problems at school, both to generate an idea of developmental level against which the 'developmental inappropriateness' of behavioural symptoms can be judged and to detect barriers to learning that may be the reason for inattentiveness. Special physical investigations are not routinely necessary. EEG often yields evidence of immaturity, but this does not advance assessment much and is not routinely indicated. It is valuable in the investigation of epilepsy and in the rare cases when deterioration of function suggests the possibility of a degenerative disorder. Blood tests should be planned only on the basis of history and examination but may include tests of thyroid function, lead (in high-lead areas), chromosomal integrity (including fragile-X probe) when there is

other evidence of developmental delay, and specific DNA tests when there is clinical suspicion of a phenotype such as that of Williams syndrome.

Communicating the diagnosis

Unlike most psychiatric conditions, a diagnosis of ADHD is often sought by parents and welcomed by them. Its image of being a physically caused neurological disease is often perceived as a relief from the stigma of mental disorder. On the other hand, the media controversy over whether it is a 'real' disorder and over the use of controlled drugs leaves some parents confused and fearful.

Assessment on the principles described will have led to an individual formulation of the nature and causes of the impairment. Extended explanation is worthwhile in the longer term. An oversimple description in terms of a chemical deficiency in the brain may seem a useful starting point but can lead to unrealistic expectations for treatment and frustration with the doctor or, worse, with the child. A model of chronic disability is in keeping with the evidence from longitudinal studies but needs to be modulated by the good outcome for some children, the improvement for most, and the ability of warm and encouraging parenting to reduce the risks for antisocial behaviour in later childhood and adolescence.

Children's understanding of their problems is also worth a good deal of effort. Little research has so far addressed the issue, but it is important to their ability to cope. They need to know that their problem is understood, that treatments are available, that they can influence their outcome by their own actions, and that the people around them understand all this and can be encouraging. Positive role models are useful—some successful sports stars, performers, politicians, and business people have outed themselves as having, and sometimes using, ADHD. Explanations need to be repeated, as the young people mature and expect a fuller and more interactive discussion.

Explanation is often needed by teachers as well. They may need to revise their expectations of the level of challenge with which the child can cope, and for some, frustration can lead to antagonism towards the child's family. If they already see ADHD as a neurological disease, then the frequent observations of changeability in the children and of the ability to cope sometimes with difficult tasks may make them reject a neurological cause—and, with it, the diagnosis and validity of drug treatment. They may need to know that physical and psychological factors can both enter into the child's presentation and that the effect of medication does not depend on the aetiology.

Explanation often leads on to basic advice about helping the children's development. The first steps with parents are to establish whether there is already a framework of frequent warm interactions and effective ways of giving instructions and following up children's actions with consistent patterns of reward or loss of reward. If this does not already exist, then a parent training group is often helpful. Both a supportive atmosphere and the teaching of skills in behaviour modification seem to be necessary. The target behaviours for modification are often the ones most troublesome to parents—disobedience and aggression—rather than restlessness or inattentiveness specifically.

Liaison with schools should include advice on the severity of the problem and the intensity and nature of extra help that will

be required. Teachers will often be able to share good practice in classroom management. One of the principles is to maintain good stimulus control, for instance by having the affected child at the front of the class under the teacher's eye. Another is to find opportunities for the children to let off physical energy (they can sometimes be used as messengers between classrooms) and to learn in short chunks. Variety and interest in the material to be learnt or understood are useful. Transitions between activities in the classroom are often the time for children to become disorganized, and the child with ADHD should be the first to change activity, with the teacher's supervision. Individual attention is probably the most effective resource in the classroom, but it is also very demanding—a classroom assistant may help to achieve it. Star charts for younger children and token economy systems for older ones are often recommended but usually depend upon the system used for the rest of the class.

In summary, this section has presented a picture of ADHD and a severe form—HKD—as disabilities that change with development and are often accompanied by other problems that can mask it or themselves be masked by it. They are rewarding challenges for diagnosis and treatment in adulthood, as well as during childhood and adolescence.

Basic mechanisms and treatment planning/targets for attention-deficit/hyperactivity disorder

Barbara Franke and Jan K. Buitelaar

Introduction to ADHD biology

Although the first description of an ADHD-like disorder dates back nearly 250 years to 1775 [1], the aetiology of ADHD and the basic mechanisms underlying the disorder are still relatively poorly understood. Hypotheses about mechanisms have been defined at different levels, including cognitive, neurophysiologic, and molecular theories and models.

Cognitive functioning in ADHD

As explained in Chapter 31, ADHD is a behaviourally defined disorder. However, cognitive deficits have been studied as an integral part of it. Individuals with ADHD have, on average, a 7- to 12-point lower IQ than non-ADHD matched controls [2]. This association seems to be partly explained by shared genetic risk factors between ADHD and IQ [2]. Initial theories claimed ADHD to be due to a single core cognitive deficit, for example in sustained attention [3], non-optimal regulation of the energetic state, and selected problems in activation [4], weak inhibitory control, that is, the capacity to voluntarily inhibit or regulate prepotent attentional or behavioural responses [5] or delay aversion and/or altered sensitivity to reward [6]. However, from more recent work in both children and adults, it is clear that ADHD is characterized by deficits in relatively independent cognitive domains, and that there is a large heterogeneity in the cognitive deficits across individual patients (for example, [7, 8]). Executive functioning deficits are seen in visuo-spatial and verbal working memory, inhibitory control, vigilance, and planning. Reward dysregulation in patients with ADHD is reflected in suboptimal and more risky decisions and preference for immediate, compared with delayed, rewards. Other domains impaired in ADHD are temporal information processing and timing, speech and language, memory span, speed processing, response time variability, arousal/activation, and motor control [1]. Although most ADHD patients show deficits in one or two domains, some have no deficits, and very few show deficits in all domains. Attempts to identify subgroups with homogenous cognitive

profiles have revealed four cognitive subtypes in a community sample of control children and among subjects with ADHD [9]. This was replicated in a sample of adults with ADHD and adult controls [10]. It supports the view that at least part of ADHD's cognitive heterogeneity is nested within normal variation. It is, however, unclear whether these subtypes predict treatment response or course. It is also unclear whether cognitive deficits cause ADHD symptoms, though cognitive deficits appear to moderate the development of the clinical phenotype [11, 12].

Neuroimaging findings in ADHD

Chapter 35 summarizes our current understanding of the brain structural and functional correlates of ADHD (see also [1, 13]). Briefly, alterations have been observed in virtually all neuroimaging modalities applied to the study of the ADHD brain, including structural and fMRI, EEG, and MEG. Grey matter structure, both cortical (thickness and surface area) and subcortical (volume), seems to be less affected in adults than in children with ADHD [14, 14a]. In functional activation studies in children with ADHD, hypoactivation relative to comparison subjects was observed mostly in systems involved in executive function (fronto-parietal network) and attention (ventral attentional network). Significant hyperactivation in ADHD relative to comparison subjects was observed predominantly in the default, ventral attention, and somatomotor networks. In adults, ADHD-related hypoactivation was predominant in the fronto-parietal system, while ADHD-related hyperactivation was present in the visual, dorsal attention, and default networks [15]. Most central to the mechanistic models of ADHD are MRI findings showing structural differences between patients with ADHD and normally developing individuals in the basal ganglia, especially the different components of the striatum (for example, [14]) and a potential structural and/or functional dysregulation of fronto-subcortical-cerebellar connections, which are of importance in controlling attention and salience thresholds, motor behaviour, inhibitory control, and response to reward [1, 13].

Atypical brain activity underlying multiple cognitive processes and resting state activity has further been reported in EEG and ERP studies. Abnormal ERP activity has been found in both children and adults with ADHD, in association with attentional allocation, inhibition, response preparation, and error processing [16]. Preparation–vigilance measures were also predictive of remission of ADHD over adolescence into adulthood [16]. Similarly, atypical patterns of quantitative EEG frequency have been observed, mostly as increased power of low-frequency theta activity and/or decreased power of fast beta activity [17]. Excessive theta/beta ratio cannot be considered a reliable diagnostic measure of ADHD but may be useful as a prognostic measure [18].

Importantly, the brain alterations seen in ADHD are heterogeneous, with individual patients showing different patterns of alterations and individual neuroimaging findings having very limited effect sizes. As a result, neuroimaging has not found its way into diagnostic protocols for ADHD, nor has it been predictive for treatment planning [19, 20].

Molecular neurobiology of ADHD

Knowledge about the molecular neurobiology of ADHD has so far largely relied on serendipity and coincidental findings, for example from medication studies and work on animal models. Additional evidence for the involvement of particular pathways comes from genetics as well as first metabolite biomarker studies. For example, a comprehensive meta-analysis of potential biomarkers found several measures, specifically noradrenaline, monoamine oxidase, 3-methoxy-4-hydroxyphenylethylene glycol, and cortisol, to be significantly altered in blood and urine of drug-naïve/drug-free patients with ADHD, compared to healthy individuals [21]. Some of the metabolites were also associated with symptom severity of ADHD and/or the response to ADHD medication.

Monoaminergic neurotransmission pathways in ADHD

The serendipitous finding that methylphenidate (MPH) treats ADHD symptoms originally directed research into the role of dopaminergic neurotransmission in the aetiology of the disorder. This effort was soon extended to include noradrenaline pathways, given the realization that MPH is not selective to the dopamine synapse, but also blocks noradrenaline transporter function. Later, serotonergic neurotransmission has also been found to be involved.

Dopamine

The neurotransmitter dopamine is involved in regulation of motor activity and limbic functions, but also in attention and cognition, especially executive functioning [22] and reward processing [23–25]. It is a key contributor to behavioural adaptation and to anticipatory processes necessary for preparing voluntary action following intention [26]. Thus, the function of dopamine maps well onto those domains implicated by the signs and symptoms observed in people with ADHD. Further, dopamine circuit dysfunction has been implicated in ADHD by different experimental evidence [27].

Dopamine-producing cells are localized in the midbrain substantia nigra pars compacta and the ventral tegmental area. From there, three projection pathways can be distinguished: the nigrostriatal pathway, which originates from the substantia nigra and projects to the dorsal striatum (caudate nucleus and putamen); the mesolimbic pathway, which projects from the ventral

tegmentum to limbic system structures, in particular the ventral striatum (nucleus accumbens), hippocampus, and amygdala; and the mesocortical pathway also originating in the ventral tegmental area, which projects to the cerebral cortex (the medial prefrontal areas, in particular) [28].

As indicated previously, the dopamine transporter—which is the most important molecule in the regulation of dopamine signalling in most areas of the brain—is the main target of stimulants like MPH and also dexamphetamine, the most frequently used prescription drugs for the treatment of ADHD symptoms. Blockade of the dopamine transporter leads to an increase in dopamine concentration, particularly in parts of the basal ganglia that have the highest expression of the transporter, that is, the striatum [29, 30]. This effect is due to the blockade of the transporter molecule in the case of MPH [31] and due to both transporter blockade and stimulation of dopamine release/block of breakdown through monoamine oxidase in the case of dexamphetamine [32]. The dopamine transporter protein (DAT) and its gene *DAT1* (official name *SLC6A3*) have thus received the most attention in research of mechanisms underlying ADHD. In animal models, knockout of the *DAT1* gene produces elevated dopaminergic tone and hyperactivity in the mouse [33]; the latter is also observed upon knock-down of the dopamine transporter in the fruit fly *Drosophila melanogaster* [34]. The neonatal 6-hydroxy-dopamine lesioned rat model also implicates the dopaminergic system in ADHD-like behaviour [35]. Neuroimaging studies of the dopamine transporter in humans with PET suggest increased dopamine transporter activity in ADHD, compared with healthy individuals [36, 37], and evidence for depressed dopamine signalling has been inferred from alterations in dopamine receptors seen in PET [38]. Disturbed dopamine signalling has also been suggested by findings of genetic studies. Genetic polymorphism in the 3'-regulatory region of the *DAT1* gene has been the subject of most studies. Meta-analyses have supported significant associations of this genetic variation in the gene, albeit different versions of the gene in children and adults with ADHD [39–41]. Furthermore, an analysis of genetic variants in a larger group of genes involved in ADHD suggested an association of this set of genes with the severity of symptoms in children with the disorder [42].

Noradrenaline

Noradrenaline signalling is intimately linked to the dopamine system because noradrenaline is a downstream product of the metabolism of dopamine. Noradrenaline neurotransmission regulates important higher cognitive functions, such as working memory and inhibitory control, primarily through its projections originating in the locus coeruleus and innervating multiple areas of the cortex, the thalamus, and cerebellum [27]. Innervation of the prefrontal cortex (PFC) by noradrenaline pathways is thought to be particularly important for understanding ADHD. Noradrenaline and dopamine signalling are intimately linked in the PFC, that is, they influence each other in optimizing PFC performance in cognitive tasks [43–45]. A role of noradrenaline in ADHD is implied by the inhibition of the noradrenaline transporter (NET) by MPH and dexamphetamine (in addition to DAT) [27, 44]. Moreover, atomoxetine, a selective NET inhibitor, is effective in the treatment of the cardinal symptoms of ADHD and some of its comorbidities [46, 47], as are several other prescription drugs with noradrenergic, but not dopaminergic, properties, like

guanfacine and clonidine [27]. While this is potent evidence that altering noradrenaline signalling can ameliorate the symptoms of ADHD, less evidence is available to link it to ADHD aetiology per se. This may primarily be due to the concentration of research effort on the dopaminergic pathways and the large overlap between dopamine and noradrenaline synthesis and function. No animal models for ADHD based on altering genes involved directly in noradrenaline signalling have yet been described, but many models actually implicate both dopamine and noradrenaline neurotransmission circuits [48]. PET of the NET has been inconclusive, thus far [49]. Genetic studies of a number of noradrenaline receptors and the NET have not produced convincing evidence for the involvement of these genes either [40, 50].

Serotonin

Serotonin is involved in regulating mood and emotion, and also plays an important role in inhibition, one of the executive cognitive deficits observed in ADHD [51]. The neurons of the raphe nuclei in the midline of the brainstem are the main source of serotonin in the brain. Axons of neurons in the higher raphe nuclei spread out to the entire brain, with strong projections, for example, into the PFC, while axons originating in the lower raphe nuclei project to the cerebellum and spinal cord (see also Chapters 11 and 14). Serotonin signalling is known to affect the regulation of other neurotransmitters, including that of dopamine, which may occur through several mechanisms [52]. Neurotransmission through serotonin was first implicated in ADHD based on paradoxical calming effects of MPH observed in a mouse model lacking DAT [53]; the drug was shown to act by blocking the serotonin transporter in the absence of DAT [54]. Also other animal models with altered serotonin signalling show ADHD-like symptoms and inattention, as well as hyperactivity [51]. In humans, studies have reported reduced levels of peripheral serotonin in patients with ADHD (for example, [55]), but other studies did not find such effects [51]. The exact role of serotonin in ADHD still has to be defined in humans. Serotonin neurotransmission may modulate the severity of ADHD symptoms, rather than being related to ADHD onset [42]. Other theories suggest that it may be the comorbidity, especially with antisocial behaviours (conduct disorder, obsessive-compulsive disorder, aggression) and mood disorders (major depression and/or anxiety), rather than the core symptoms of ADHD, which is influenced by serotonin [51]. Genetic studies of the contribution of the serotonergic system to ADHD have not been fully convincing. However, in a meta-analysis, the serotonin receptor gene *HTR1B* and the gene encoding the serotonin transporter (SLC6A4, 5-HTT, SERT) have been implicated in the disorder [40].

Gene-environment interactions may explain some of the observed inconsistency across studies, as the effect of stress on ADHD symptoms seems to be influenced by genetic variation in the serotonin transporter gene [56]. A recent analysis of a gene set related to serotonergic neurotransmission suggests that variation in serotonergic genes may be associated with disease severity [42]. Tryptophan depletion, which causes reduction in brain 5-HT synthesis, was associated with increases of aggression, inattention, and impulsivity [51]. A retrospective pilot study on the administration of precursors of serotonin and dopamine led to promising results in 85 children and adolescents with ADHD [57]. However, in spite of this supportive evidence for serotonergic involvement in

ADHD, findings from clinical trials with SNRIs, such as venlafaxine and duloxetine, in adults with ADHD are rather mixed (for review, see [51]).

Other neurotransmission pathways in ADHD aetiology

Glutamate

Glutamate is the most abundant excitatory neurotransmitter in the human CNS and is involved in many neuronal functions, including synaptic transmission, neuronal migration, excitability, plasticity, and long-term potentiation [58] (see Chapter 14). The fronto-striatal circuits implicated in impulsivity and compulsivity are notable for their relatively rich glutamatergic receptor density. Glutamatergic projections from the various frontal subregions (orbitofrontal, infralimbic cortex, and prelimbic cortex) to the striatum (and vice versa) play a key role in the regulation of various compulsive behaviours. Glutamate receptor proteins are expressed on the surface of neurons in such a way that they can only be activated from the outside, so glutamate exerts its neurotransmitter function from the extracellular fluid. Glutamate levels are regulated by releasing glutamate to the extracellular fluid and then removing glutamate from it. There are no enzymes located extracellularly that can degrade glutamate, so low extracellular concentrations require active reuptake. Several families of glutamate receptor proteins have been identified and classified as NMDA, AMPA, kainate, and metabotropic receptors [59]. Most, if not all, cells in the nervous system express at least one type of glutamate receptor.

Several candidate genes within the glutamatergic system have been associated with ADHD. For instance, associations have been found for variation in the *GRIN2B* gene with both inattention and hyperactivity symptoms in ADHD [60]. A genome-wide study investigating rare variants found overrepresentation of variants belonging to the metabotropic glutamate receptor genes in several ADHD cohorts [61]. An analysis of a glutamate gene set showed significant association with the severity of hyperactivity/impulsivity of patients with ADHD [62]. Proton magnetic resonance spectroscopy (MRS) studies suggest a possible increase in Glx (a combination of glutamate, glutamine, and GABA) in the striatum across ADHD, OCD, and ASD, and further, an increased Glx signal in the anterior cingulate cortex in children with ADHD and ASD, but a lower Glx signal in adults with ADHD and ASD. This suggests neurodevelopmental changes in fronto-striatal glutamatergic circuits across the lifespan [63]. Glutamatergic agents, such as memantine, an antagonist of the NMDA receptor, are of potential value in the treatment of impulsivity in children and adolescents, including ADHD [64, 65], but large-scale positive trials have not yet been published.

Histamine

Histamine is one of the key neurotransmitters regulating arousal and attention. The cell bodies of histamine neurons are found in the posterior hypothalamus, in the tuberomammillary nuclei. From here, these neurons project throughout the brain, including to the cortex, through the medial forebrain bundle. Histamine neurons increase wakefulness and prevent sleep [66]. In addition, histamine is an important agent in (neuro)immune reactions. Interest in the role of histamine in ADHD has resulted from observations that allergies have an increased incidence in people with ADHD. Indeed, a recent meta-analysis showed that children with ADHD are more likely to develop asthma, allergic rhinitis, atopic dermatitis, and allergic

conjunctivitis than healthy individuals [67]. Similarly, children with allergies appear to have higher ADHD symptom ratings than non-affected children [68]. The histamine H3 receptor subtype is mainly distributed in the CNS and functions as a presynaptic autoreceptor (that reduces histamine release) and a heteroreceptor (that regulates the release of other neurotransmitters). Histamine H3 receptor antagonists and inverse agonists increase the release of brain histamine and other neurotransmitters. The H3 receptor antagonists have been shown to promote arousal in various species, without the psychomotor activation seen with stimulants [69]. Potent histamine H3 receptor antagonists are currently being developed and tested for the treatment of ADHD [70].

Nicotinic acetylcholinergic system

Nicotinic acetylcholine receptors are receptor proteins that respond to the neurotransmitter acetylcholine. Nicotinic receptors also respond to drugs, including the nicotinic receptor agonist nicotine. Nicotine use has been associated with improvement in cognition, attention in particular, in different animal species, healthy human volunteers, and patients with ADHD [71–75]. In addition, the nicotinic acetylcholine neurotransmission system is also implicated in ADHD through genetic findings; a large study of copy number variants found duplications of the gene encoding the $\alpha 7$ -nicotinic acetylcholine receptor (*CHRNA7*), located in the mutation-prone region on chromosome 15q13.3, to contribute to the risk for the disorder [76]. The nicotinic acetylcholine system may be one of the new targets for the development of alternative drugs for ADHD. Nicotine appears to exert its beneficial effect selectively on behavioural inhibition and delay aversion tasks, which are known to have good discriminant validity in distinguishing subjects with ADHD from controls [75, 77]. Stimulation of neuronal nicotinic acetylcholine receptors by nicotine may be mediated directly via changes of cholinergic neurotransmission and/or by modulating the activity of other neurotransmitters, including dopamine (see Dopamine, p. 310). Trials of nicotinic drugs demonstrated beneficial effects in adults with ADHD, with evidence for positive effects on cognitive and emotional domains [78]. There are no approved medications yet for ADHD that target nicotinic acetylcholine receptor function.

The genetic architecture of ADHD

ADHD is a highly heritable disorder, both in children and in adults, with heritability estimates of around 60–80%, based on twin studies [79, 80]. As discussed in Chapter 34, the genetic architecture of ADHD is complex and multifactorial, such that most patients probably carry many genetic risk factors, which are individually of small effect size. Importantly, twin studies as well as molecular genetic studies suggest that there is incomplete overlap between the genetic factors that are involved in ADHD onset and those that are relevant for the persistence of ADHD across adolescence into adulthood [39, 81–83]. Genetic studies can be an ideal starting point to understand the molecular and cellular processes involved in a disease. As for other disorders, genetic approaches include hypothesis-based candidate gene approaches and hypothesis-free genome-wide studies [84]. The first candidate gene-based studies for ADHD, dating back to the 1980s, mainly concentrated on genes related to monoaminergic neurotransmission, based on information on the drugs effective in treating ADHD symptoms described in previous paragraphs [1, 79].

Genome-wide association studies [50] and genome sequencing are now becoming available in increasingly large samples and will eventually allow new hypotheses regarding the basic biological mechanisms of the disorder [1, 84, 85].

The role of the environment

The behaviour of any individual develops from an interplay of nature and nurture; neither genetic nor environmental factors are likely to act in isolation [86]. Different forms of gene–environment interplay (see review in [87]) and gene–environment correlation [88–91] are relevant to ADHD and are also described in Chapter 34. Environmental factors known to increase ADHD risk and/or disease severity and persistence include pre-/perinatal as well as post-natal factors (for example, [1]). Exposures occurring *in utero* and in the early years of life, which are major windows of developmental vulnerability, have the strongest effects on ADHD. The brain is then growing at maximal speed, and the blood–brain barrier provides only partial protection against the entry of substances into the CNS [92]. Prenatal exposures to neurotoxicants, such as organic solvents, pesticides, and flame retardants [93–95], as well as the heavy metals zinc and lead [21], are linked to ADHD. Additional risk from maternal smoking and alcohol use during pregnancy may be partly mediated by genetic factors [96] (see Chapter 34). Postnatally, stressful events like early deprivation [97], harsh parenting practices [88], and composites of early adversity (low social class, marital discord, large family size, paternal criminality, maternal mental disorder, and foster care) [98] are of importance. Particularly informative is a follow-up study of Romanian adoptees, who had experienced severe early deprivation in orphanages during early life prior to adoption. This showed a dose-dependent relationship of the length of deprivation with the risk for development of ADHD-like symptoms [97]. Exposure to increased stress due to negative life events or daily hassles has been shown to exacerbate ADHD core symptoms [56] and may contribute to ADHD persistence. Like genetic risk factors, the effects of any one environmental risk factor are small and, rather than being specific to ADHD, these environmental risks are associated with several psychiatric disorders.

The environmental contribution to ADHD is viewed as an increasingly important target of research, because environmental factors may, in principle, be modifiable, though not always easily in practice. Identification of protective factors is as important as scrutinizing the risk factors, and this may contribute to therapy and prevention in ADHD.

Mechanistic theories underlying ADHD

Hypotheses about the mechanisms underlying ADHD have been defined at molecular, brain neurophysiologic, and cognitive levels. A number of models have been put forward, based on this work, which aim at vertical integration of the information across these domains of function. We mention the more prominent ones here, although there is insufficient evidence yet as to what the most accurate model is to describe the processes underlying ADHD and how the different models relate to each other. In all of them, dopamine and noradrenaline, in some cases in their relation to glutamate, play a central role. Taking into account the important regulatory activities of the monoaminergic neurotransmitters in glutamate signalling (as

Fig. 32.1 Dopamine and noradrenaline are important in regulating glutamatergic neurotransmission in cortical neurons. Noradrenaline amplifies signals coming in from other neurons via NMDA-type glutamatergic receptors, while dopamine reduces background noise. In this way, specificity of signalling of the pyramidal neurons is ensured. Adapted from *J Am Acad Child Adolesc Psychiatry*, 51(4), Arnsten AF, Rubia K, Neurobiological circuits regulating attention, cognitive control, motivation, and emotion: disruptions in neurodevelopmental psychiatric disorders, pp. 356–367, Copyright (2012), with permission from American Academy of Child and Adolescent Psychiatry.

depicted in the schematic in Fig. 32.1 and described in [99]), this is not surprising.

The dynamic developmental model of ADHD was largely based on research on an animal model for ADHD—the spontaneous hypertensive rat. Published by Sagvolden and coworkers in 2005, it supposes low tonic and low phasic dopamine in cortico-striatal loops, resulting in an ineffectiveness to regulate signalling of other neurotransmitter systems. Through the mesolimbic dopaminergic pathway, this is thought to produce altered reinforcement of behaviour and deficient extinction of previously reinforced behaviour, resulting in the rise to delay aversion, development of hyperactivity in novel situations, impulsiveness, deficient sustained attention, increased behavioural variability, and failure to ‘inhibit’ responses (‘disinhibition’). Hypofunction of the mesocortical dopamine pathway is thought to cause attention problems and poor executive functions. Altered nigrostriatal dopamine is linked to impaired modulation of motor functions and deficient non-declarative habit learning and memory [100].

A model for cognitive deficits in ADHD, in which the dopamine and noradrenaline systems and the basal ganglia are central, was proposed by Frank and coworkers, based on computational modelling [101]. They suggested that tonic and phasic dopamine in the striatum is low in people with ADHD and that tonic noradrenaline is high, causing a lowered phasic noradrenaline. According to the model, the lowered dopamine levels should lead to deficits in learning from positive reinforcement. The altered noradrenaline levels may underlie the intra-individual variability observed in people with ADHD. Alterations in the levels dopamine and noradrenaline are viewed as occurring independently [28].

The moderate brain arousal model poses the combination of low tonic with increased phasic dopamine to cause the symptoms of ADHD [102, 103]. This is in contrast to the dynamic developmental model and the basal ganglia model, which suppose both tonic and phasic dopamine to be low in ADHD. The low tonic dopamine results in hypo-arousal when few stimuli are provided to the brain, but also in increased stimulus responsivity of cells in terms of phasic dopamine, resulting in exaggerated responses to environmental stimuli. Since dopamine shows an inverted-U dose–response relationship with performance, both too little and too much dopamine will result in underperformance of the brain, as seen in ADHD [28].

The dopamine transfer theory—a purely theoretical model to explain some of the symptoms of ADHD—supposes that the dopamine response to a reward at the cellular level is normal in people with ADHD, but that it cannot be transferred to a reward-predictive cue due to an insufficient (low) phasic dopamine level [104]. This was hypothesized to result in a delay in the dopamine signal at the level of the cell and the observed reduction of the anticipatory striatal brain activity in people with ADHD [105].

The neuroenergetics model is defined at the cellular level and postulates that neurons function suboptimally in people with ADHD because they cannot adequately recruit lactate from astrocytes [106]. The putative cause is altered noradrenaline and glutamate neurotransmission, which is needed to stimulate astrocytes to release the necessary lactate. Lactate is produced in astrocytes by glycolysis and, after uptake by neurons, is converted into pyruvate and glucose. The astrocyte–neuron lactate transfer shuttle system ensures a supply of substrates for brain metabolism. There is increasing evidence for lactate acting as a signalling molecule in the brain, to link metabolism, substrate availability, blood flow, and neuronal activity [107]. The suboptimal use of the shuttle system is proposed to result in lack of energy, which causes attention drifts, mental fatigue, and response variability, as observed in ADHD.

Future prospects for novel targets in ADHD

In the coming years, the hypothesis-generating data coming from genome-wide analyses can be expected to identify the mechanisms underlying the disorder; they may also contribute to developing treatment that goes beyond the current approach, which can only dampen the symptoms of the disorder. The first papers implicating novel biological processes and mechanisms in ADHD have now been published. This work has implicated the neurodevelopmental process of neurite outgrowth in the aetiology of the disorder [85]. More recently, integration of genome-wide association studies of common and rare genetic variants found several additional biological processes to be involved, including ligand-gated ion channel activity and oxidative stress-related pathways [108, 109]. Such processes are known to be druggable and thus may represent the first candidates for the development of novel therapeutic approaches. Since the field of genetics research is currently upscaling strongly, more interesting findings can be expected in the coming years. Ultimately, we will need interdisciplinary approaches integrating research across different levels of organismal complexity, including genetics, genomics, and cell- and/or animal-based model systems, as recently discussed in [50], to really understand the biology of ADHD and increase the chances of developing curative treatment options.

Epidemiology of attention-deficit/hyperactivity disorder and the implications for its prevention

Guilherme V. Polanczyk

Introduction

Since the publication of the third edition of the *Diagnostic and Statistical Manual of Mental Disorders*, third edition (DSM-III) in 1980, when the first reliable operational diagnostic criteria for attention-deficit/hyperactivity disorder (ADHD) appeared, the scientific literature on the various aspects of the disorder has been expanding significantly. Rigorous and informative epidemiological studies have been conducted to describe the distribution and natural course of the disorder. The familial nature of ADHD and the importance of genetic risk have also been recognized, as described in Chapter 34. Nevertheless, as for any complex disorder for which no single risk factor is either necessary or sufficient to cause the disorder, longitudinal—mainly retrospective—and case-control studies have suggested that certain environmental factors increase the risk for ADHD. As is usual in medicine, epidemiological findings have contributed to shed light on aetiological mechanisms and temporal and cultural effects, to plan services, and to monitor delivery of treatment, among other clinical and research advances. It has the potential to contribute to the next challenge of the field—to prevent the development of the disorder.

Prevalence

Studies investigating the prevalence of ADHD emerged soon after DSM-III was published in 1980. As the studies accumulated, the overall result was of a significant variability on reported rates, ranging from as low as 1% to as high as nearly 20% among school-age children. This variability raised debates of whether broad cultural and societal modifications, mediated by changes in family structure and habits and also by increasing academic expectations and failing educational models, were producing the disorder. As described in Chapter 31, these debates fuelled concerns about the validity of ADHD. However, it was important, and initially underestimated, that surveys adopted a variety of methods (in regard of sampling

strategy and study design), case definitions (for example, diagnostic criteria), and strategies to collect information (for example, instrument, informant), and several studies were of low or very low quality. The conclusion that prevalence rates varied across settings was, in fact, premature, because methodologies influence the findings and direct comparisons between individual results were not possible. Therefore, the appreciation of study methods and the empirical assessment of their effect are key to interpret prevalence rates of ADHD.

Study methods

Sampling is the process of selecting study participants. This is a fundamental process in an epidemiological study, because the sample must accurately represent the target population. If, for any reason, selected participants do not represent the specific population of interest, results cannot be generalized to that population and are valid only for the specific sample studied. A probabilistic sampling strategy, in which, by the principle of randomization, each eligible member of the population has a defined chance to be identified and included, is essential. Nevertheless, it is necessary to have an objective list of all of the units in the target population, that is, a sampling frame. Examples of sampling frames are telephone directories, census data, and schools. For studies investigating the prevalence of childhood mental disorders, including ADHD, schools are frequently used as the sampling frame. However, if virtually all children from the population of interest are not enrolled in ordinary schools, or if individuals are enrolled in schools but are not attending classes (which may be closely linked to the presence of mental disorders), this strategy is likely to produce biased results. Different probabilistic sampling strategies can be adopted to select the units within the frame such as simple random, stratified random, and systematic random. As the sampling frame and eligible participants are identified, it is possible to identify and study the individuals who refuse to participate. Among eligible individuals, the proportion who give consent to participate and are actually assessed (that is, the response rate of a study) is an important indicator of the success

of the sampling procedure. If a substantial proportion of eligible participants do not take part in a survey, or if refusal to participate is non-random (that is, associated with specific characteristics of participants), results may be biased and inferences about the whole population of interest may not be possible.

In one-stage design studies, diagnostic interviews are used to assess the whole sample. In two-stage design studies, a screening instrument is answered by the whole sample and individuals are selected for further assessment by diagnostic interviews based on its results. It is fundamental that not only individuals who are considered to have screened positive, but also a proportion of individuals who screen negative, are assessed with the diagnostic interview, so that rates of false and true positives (and negatives) at the screening phase can be determined and prevalence rates for the whole sample estimated.

In terms of case definition, the inconsistencies between diagnostic criteria presented by DSM and the International Classification of Diseases (ICD) may also have reduced the homogeneity of prevalence rates. The background to the overall approach to the diagnosis of ADHD has been described in detail in Chapter 31. Research diagnosis of hyperkinetic disorder requires symptoms of both inattention and hyperactivity-impulsivity, whereas DSM-III-R, DSM-IV, and DSM-5 require symptoms of only one of the symptom dimensions. Therefore, prevalence rates according to ICD are consistently lower than those according to DSM. Differences between DSM-III-R and DSM-IV were subtle. DSM-5 introduced three important modifications to DSM-IV criteria: extended the upper limit of the age of onset of symptoms from 7 to 12 years of age; decreased the symptom threshold for adults (18 years of age and older) from six to five symptoms; and indicated that ADHD could be diagnosed in comorbidity with autism spectrum disorder. The impact of the modification of the age of onset of symptoms on prevalence rates was investigated in a representative sample of the population prospectively followed during childhood. Results showed that extending the age of onset criterion to age 12 resulted in an increase in ADHD prevalence by age 12 of only 0.1% [1]. As for adult ADHD, uncertainties regarding the most valid definition of the disorder (for example, reflected by modifications of symptom threshold, developmental manifestations of symptoms such as hyperactivity) and the most appropriate strategy to assess the disorder (for example, reflected by the requirement, or not, of collateral informants) are very important for case definition in epidemiological studies. Reduction of the symptom threshold for diagnosing adults is expected to increase the expected prevalence rates by 27% [2].

Also in terms of case definition, diagnostic assessment, informant, and requirement for functional impairment for the diagnosis are all important. As for mental disorders generally, standardized assessment by using a diagnostic interview is a key component to guaranteeing consistency within and between studies (see Chapter 7). Interviews vary in the way questions are constructed, on the presence of gate/skip questions, and on the emphasis on the respondent's understanding and interpretation of the questions (structured interviews, usually administered by lay interviewers) or on the interviewers' interpretation of the responses (semi-structured interviews, usually administered by trained mental health professionals). Informants more frequently reporting ADHD symptoms are parents, children (usually older than 11 years), and teachers. The correlation between different informants is low to moderate, which suggests that symptoms are modulated by settings and/or different informants emphasize different aspects of behaviour. Thus, it is indicated to use multiple informants and integrate

information using different strategies such as the 'best estimate procedure', 'and rule', and 'or rule'. The best estimate procedure implies that data from different sources and instruments are integrated by clinicians, who define the presence of a diagnosis, based on their best judgement of available information. The 'and rule' implies that a symptom should be considered positive if both informants endorse the symptom. The 'or rule' implies that a symptom should be considered positive if one out of two informants endorses the symptom.

Requirement of functional impairment for the diagnosis is an important parameter for case definition, as individuals frequently meet symptomatic criteria but have minimal or no impairment criteria but have optimal functioning. This may be dependent upon the structure of the environment they are part of, the support they receive, the demands they are faced to, the expectations placed on their performance, and the very specific definition of impairment. Different definitions of functional impairment may be adopted such as measures of impairment specifically related to ADHD or global measures of impairment [such as the Child Global Assessment Scale (CGAS)]. The former has the advantage to be related specifically to the identified disorder, and the latter, although not specifying the source of impairment, is a good predictor of adaptive functioning and need of service.

Prevalence rates in childhood and adolescence

The first comprehensive literature review and meta-analysis on the prevalence rates of ADHD [3] was based on an extensive search strategy, and studies were included based on the following inclusion criteria: (1) original surveys on ADHD/hyperkinetic disorder prevalence (point prevalence); (2) diagnoses based on any DSM (III, III-R, or IV) or ICD (9 or 10) versions; (3) probabilistic sample from the general population or from schools; and (4) participants up to the age of 18 years. One hundred and two studies were included, which represented populations from North America ($k = 32$), Europe ($k = 32$), Asia ($k = 15$), South America ($k = 9$), Oceania ($k = 6$), Middle East ($k = 4$), and Africa ($k = 4$). Most studies had their samples ascertained from schools ($k = 60$), with a one-stage assessment ($k = 61$), adopting DSM-IV criteria ($k = 44$), with no impairment criterion ($k = 68$), and with parents as the most frequent source of information ($k = 33$). A meta-regression analysis was performed to empirically investigate the methodological approaches that impacted the detected rates. Multivariate meta-regression identified diagnostic criteria, source of information, and requirement of functional impairment for the diagnosis as methodological procedures significantly associated with variability of estimates. The analysis identified that study location was associated with heterogeneity only when estimates from Africa and the Middle East were compared to estimates from North America. Estimates from Europe, Oceania, South America, and Asia did not differ from estimates from North America. It is noteworthy that Africa and the Middle East were the continents with the fewest number of studies ($k = 4$ in each continent). A meta-analysis resulted in a pooled prevalence rate of 5.29% [95% confidence interval (CI) 5.01–5.56] (Fig. 33.1).

A second comprehensive review of the literature on the prevalence of ADHD and a meta-analysis including only studies that adopted DSM-IV diagnostic criteria were published in 2012 [4]. Eighty-six studies were included, and pooled estimates ranged from 5.9% to 7.1%, depending on the source of information for the diagnosis. Further results detected significant heterogeneity between estimates, but once again, the country or region where the study was

Fig. 33.1 ADHD/HD pooled prevalence according to demographic characteristics and geographic location.

conducted did not explain the variability, supporting the previous findings.

A third comprehensive review of the literature aggregated studies included in the first two meta-analyses [3, 4] and updated the search aiming to follow up the previous finding that estimates from Africa and the Middle East were different from those from North America [5]. As the influence of time on prevalence of ADHD was still a matter of controversy, this study also aimed to investigate time-effects on prevalence rates. The third review detected 154 studies, and 135 were included in the multivariate statistical models. The 25th, 50th, and 75th percentiles of distribution of studies, based on year of publication, corresponded, respectively, to years 1997, 2001, and 2005. The studies represented populations from North America ($k = 48$), Europe ($k = 42$), Asia ($k = 12$), South America ($k = 10$), Oceania ($k = 7$), the Middle East ($k = 11$), and Africa ($k = 5$). Univariate analysis revealed that diagnostic criteria, impairment criterion, source of information, and geographical location of studies (but not year of study publication) were significantly associated with heterogeneity of prevalence estimates. Multivariate analysis indicated that source of information, impairment criterion, and diagnostic criteria remained significantly associated with heterogeneity of results. Rates based on teacher reports were an estimated 5.47% higher than those based on best estimate procedure, and those rates with no requirement for impairment were an estimated 2.32% higher than when impairment was required. Regarding diagnostic criteria, rates based on DSM-III-R and ICD-10 were an estimated 2.42% and 4.09%, respectively, lower than rates based on DSM-IV. Study location was no longer significant when methodological variables were accounted for. Year of publication was not associated with heterogeneity, indicating the absence of time-effect on prevalence of ADHD (Fig. 33.2). No significant interaction was detected between year of publication and diagnostic criteria (Fig. 33.3), other methodological variables,

and geographic location (Fig. 33.4), ruling out a possible increase in prevalence estimates over time in specific geographic locations or for specific study methods [5].

The lack of time-effect on prevalence rates detected is in accordance with studies that have investigated rates of inattentive and/or hyperactive symptoms, using equivalent rating scales and parents or teachers as informants across time. They found no evidence for a systematic variation in prevalence of ADHD symptoms, with symptom levels and the proportion of children with clinical scores remaining stable or presenting small reductions over recent decades [6].

One important limitations of the existing epidemiological literature is the scarcity of studies outside Europe and North America. In this regard, the Global Burden of Disease Study 2010 (GBD 2010) and 2013 (GBD 2013) systematically reviewed the literature and employed an imputation method to derive prevalence estimates by age and sex in three time periods (1990, 2005, and 2010) for 21 world regions, including those with little or no data. For each of the time period, ADHD prevalence for boys was estimated in 2.2% (95% CI 2.0–2.3) and for girls in 0.7% (95% CI 0.6–0.7), indicating that prevalence remained stable over time [7]. Nevertheless, a very concerning scenario is the small proportion of the global population of children and adolescents represented in prevalence studies for any mental disorder. From the GBD data, it is estimated that only 5.47% of children and adolescents around the world are covered by ADHD surveys. This proportion is hugely discrepant between high-income and low-/middle-income regions—36.47% and 2%, respectively [8].

Other meta-analyses conducted on the prevalence of ADHD detected discrepant findings such as higher [9] or variable [10] rates across regions. Nevertheless, these analyses had different inclusion criteria that explained the contrasting findings, such as the inclusion of studies that relied on questionnaires for diagnosis and the

Fig. 33.2 ADHD prevalence rates as a function of the year of study publication. The point sizes are drawn proportional to the inverse of the standard errors. The predicted average prevalence estimate rate based on a mixed-effects model is added to the plot (with corresponding 95% confidence interval bounds).

exclusion of studies using ICD criteria [9] and the inclusion of studies using regional diagnostic criteria for mental disorders [10].

More recently, a systematic review of surveys estimating the prevalence of any mental disorder in the community across the world, including ADHD, was published [11]. The systematic search identified 23,191 abstracts; 198 studies were selected for review, 48 studies met inclusion criteria, and 41 studies were included. The studies were published from 1985 to 2012 and represented populations from North America ($k = 14$), Europe ($k = 14$), Asia ($k = 8$), South America

($k = 5$), Oceania ($k = 3$), the Middle East ($k = 2$), and Africa ($k = 2$). A pooled rate of prevalence of any mental disorder was estimated in 13.4% (95% CI 11.3–15.9). The final multivariate meta-regression model identified sample representativeness, sample frame, and diagnostic interview as significant moderators of prevalence estimates. Study geographic location and sample age range were not significant moderators. Secondary meta-analysis focusing on ADHD included 33 studies, representing a sample of 77,297 individuals, and resulted in a pooled prevalence of 3.4% (95% CI 2.6–4.5) [11].

Fig. 33.3 ADHD prevalence estimates over time as a function of diagnostic criteria.

Prevalence rates in adulthood

Prevalence studies of ADHD in adulthood emerged approximately a decade after studies in childhood, and significant fewer surveys have been conducted so far. A systematic review published in 2009 identified seven samples eligible for a meta-analysis, which yielded a prevalence rate of 2.5% (95% CI 2.1–3.1). Mean age of participants ranged from 19 to 45 years, but mostly up to 28 years, with only one sample with a mean age of 45 years [12]. Prevalence rates were detected to have a significant negative association with age, and this association was moderated by the gender composition of the sample. In a study investigating individuals from 60 to 94 years, the estimated prevalence rates of ADHD weighted back to the general population was 2.8% (95% CI 0.86–4.64) using a cut-off point of six symptoms, and 4.2% (95% CI 2.05–6.39) using a cut-off point of four symptoms [13].

Recently, the WHO's World Mental Health (WMH) Survey Initiative reported estimated prevalence rates for adults 18 to 44 years of age in 20 WMH surveys. These surveys were conducted in 11 high-income, 5 upper middle-income, and 4 low- and lower middle-income countries. Estimated rates were based on retrospective self-report of childhood ADHD, the presence of current symptoms and related impairment, and a multiple imputation method to assign clinical diagnoses of adult ADHD. Prevalence of

Fig. 33.4 (see Colour Plate section) ADHD prevalence estimates over time as a function of geographic location of the studies.

Reproduced from *International Journal of Epidemiology*, 43(2), Polanczyk G, Guilherme V, Willcutt, EG, ADHD prevalence estimates across three decades: an updated systematic review and meta-regression analysis, pp. 434–442, Copyright (2014) with permission from Oxford University Press.

DSM-IV ADHD in childhood averaged 2.2% across surveys (range 0.1–8.1%). Estimates had a positive correlation with country income. Current prevalence of adult ADHD averaged 2.8% across surveys (range 0.6–7.3%), a higher rate than childhood ADHD. Higher estimates in adulthood were also detected in high-income (3.6%) than in low- and lower middle-income (1.4%) countries [14].

Developmental changes

The first prospective longitudinal studies that investigated the natural course of ADHD across development included clinically referred children and clearly documented that symptoms declined over time. An early systematic review initially estimated an exponential decline during development, suggesting that virtually all children with ADHD would improve over time [15]. Subsequent studies have confirmed that remission of full diagnostic status was indeed common but that a substantial number of children remained symptomatic and most of them remained impaired as early adults [16]. Longitudinal studies documented that decline is more pronounced for hyperactive and impulsive symptoms, and less pronounced for inattention [16]. Indeed, cross-sectional studies assessing adults with ADHD indicated that inattention and executive dysfunction are the most common symptoms [17].

A meta-analysis of longitudinal studies confirmed that rates of ADHD persistence across development depended on its conceptual definition. The pooled rate for persistence at a mean age of 25 years according to full criteria (syndromic persistence) for DSM-III, DSM-III-R, or DSM-IV adult ADHD was approximately 15%, and according to partial remission (symptomatic persistence) approximately 65% [18]. The study with the longest prospective follow-up conducted until now evaluated adults at a mean age of 41 years who were clinically referred and diagnosed with ADHD as children, at a

mean age of 8 years [19]. Among them, 22% met adult ADHD criteria (vs 5% in the comparison group). Individuals with childhood ADHD had worse educational, occupational, economic, and social outcomes as adults, as well as increased rates of antisocial personality disorder and substance use disorders [19].

More recently, prospective longitudinal studies following representative community samples of children to adolescence and adulthood challenged the notion that ADHD always begins early in life. Moffitt *et al.* [20], studying the Dunedin Multidisciplinary Health and Development Study in New Zealand, documented ADHD cases prospectively from childhood to 38 years of age. The authors reported a follow-forward analysis of ADHD cases diagnosed in childhood and a follow-back analysis of ADHD cases diagnosed in adulthood. Follow-forward analysis revealed that only 5% of children with ADHD still met diagnostic criteria at the age of 38 but continued to experience difficulties in life adjustment. Follow-back analysis showed that only 10% of adults with ADHD had the diagnosis as children [20]. Surprisingly, these results were replicated in two other prospective longitudinal studies of community samples from the UK [21] and Brazil [22]. Analysis of the E-Risk Study (UK) demonstrated that 21.9% of children with ADHD met diagnostic criteria at the age of 18 years. At the age of 18 years, only 32.5% of those with ADHD met criteria for ADHD during childhood [21]. Analysis of the Pelotas Study (Brazil) demonstrated that 17.2% of children with ADHD met diagnostic criteria at the age of 18–19 years. At the age of 18 years, only 12.6% of those with ADHD met criteria for ADHD during childhood [22]. Adult ADHD cases without a history of childhood ADHD were not fully explained by comorbidities, subthreshold symptoms, and information bias. A possible explanation is that subthreshold cases in childhood emerge as cases in adulthood when demands exceed capacities [23]. Alternatively, child-onset and adult-onset ADHD may be distinct disorders, with possible distinct aetiologies. In this direction, polygenic risk score for ADHD (see Chapter 34) predicts childhood-, but not adult-, onset forms of ADHD [20]. Also, the likelihood of adult-onset ADHD arising in a monozygotic twin is not increased when the co-twin has childhood-onset ADHD [21]. The questions of whether adult-onset ADHD represents the late expression of early-onset neurogenetic risk factors or if it constitutes a distinct syndrome are yet to be answered [24].

Risk factors

Sociodemographic risk

ADHD affects predominantly males, with a male:female ratio of 3–4:1 in clinical samples [25] and 2.4:1 in community samples [26], suggesting a significant referral bias. Among adults, this sex difference is attenuated, probably also due to referral biases (in the opposite direction) or sex-specific developmental trajectories of ADHD. Cross-sectional studies and administrative data detected associations with ethnicity, which are not detected by community-based studies. Low socio-economic status in early childhood is associated with increased likelihood of ADHD, but it is not clear if it is a marker or risk, since there is a strong genetic risk and the disorder leads to low educational and occupational achievement, or if

there is a causal relationship [27], possibly interacting with other risk factors [28].

Genetics

Evidence from different approaches support the strong genetic influences on ADHD, which are mostly of small individual effect. Genetic variants underlie multiple molecular, neural, and cognitive trajectories, partially shared with other neurodevelopmental disorders, that lead to behavioural phenotypes currently defined as ADHD [29, 30]. A detailed description is given in Chapter 34.

Environmental risk

Twin studies indicate that shared environmental risks are not relevant to the aetiology of ADHD. Environmental risk factors seem to exert their effect in the non-shared familial environment, that is, parental influences that are specific to a child, peer, and school influences and exposure to individual risks. Exposure to environmental stressors may result in biological changes, such as brain structure and function, and also in modifications of gene expression. Environmental risk can also interact with genetic variants and, depending on them, can have different effects, that is, gene–environment interaction. Also, environmental risks can arise due to behaviours that are genetically influenced and may have partial or no effect on the outcome once the genetic effects are taken into account, that is, gene–environment correlation. Environmental risks have been investigated by different epidemiological methods, some of them suited to infer causality, but most of them not. Exposures to risk factors can be influenced by confounders, some of which are not identified and controlled for (for example, genetic effects), and also by the very presence of ADHD that can lead to the risk exposure (reverse causation). Selection bias is also an important methodological caveat that may lead to false positive associations.

Prenatal and perinatal factors

Low birthweight, prematurity, obstetric complications, *in utero* exposure to maternal stress, tobacco, and alcohol and substances (medications and illicit drugs) are risk factors associated with ADHD. There are no studies to date demonstrating their causal effect. Associations between maternal stress and smoking during pregnancy and ADHD have been demonstrated by genetically sensitive studies to be explained mainly by genetic or other shared risk factors [31].

Toxins

The association with prenatal exposure to toxins, such as organophosphate pesticides, polychlorinated biphenyls, and lead, has been studied in longitudinal studies, and also in cross-sectional studies which demonstrated higher levels in children affected by ADHD. Their causal association is biologically plausible, and animal studies have supported their negative effect over several domains of cognitive function. Nevertheless, their causal effect in humans has yet to be demonstrated.

Diet

Extreme nutritional deficits impair neurodevelopmental processes globally, but the effects of specific nutrients and how mild deficits at specific moments of development affect cognitive functions are

not yet clear [32]. The associations between zinc, magnesium, and polyunsaturated fatty acids and ADHD have been studied in cross-sectional studies, and there is no convincing evidence indicating that they are risk factors, and not correlates. Sugar and artificial food colourings have also been identified so far as correlates.

Other factors

Obesity [33], sleep disorders [34, 35], and television exposure [36] have been associated with attentional problems and ADHD by cross-sectional, prospective, and retrospective longitudinal studies, with insufficient data to characterize the temporal ordering; at the moment, they are also understood as correlates.

Family adversity

Family adversity and harsh or hostile parent–child interactions have been consistently associated with ADHD but may arise as consequences of the disorder, rather than increase the risk of it [37]. The English and Romanian Adoptees study has followed children exposed to early severe institutional deprivation in Romania who were subsequently adopted by English families and studied their long-term emotional and cognitive development. Deprivation had strong effects immediately after adoption, followed by substantial catch-up for some children at the age of 6 [38]. At the age of 15 years, children exposed to more than 6 months of deprivation were four times more likely to present with ADHD than those with less than 6 months of deprivation, and those children exposed to more than 6 months of deprivation had persistently higher rates of inattention and hyperactivity through to the ages of 23 to 25 [39]. These results point to a causal role of very severe early deprivation in the development of ADHD with particular characteristics. Deprivation-related ADHD was not as likely as non-deprivation-related ADHD to affect boys and to present with comorbid conduct problems; it presented with high levels of comorbid social disinhibition and autistic features and severe neuropsychological impairment [40].

Prevention

Conceptual and methodological issues

Preventive actions target causal risk factors to reduce incidence, that is, new cases of disorders. Therefore, by definition, preventive interventions are those implemented before the onset of the disorder. Those implemented after the onset are referred to as treatment or rehabilitation. There are three levels of preventive interventions: universal, selective, and indicated. Universal interventions target the general public or a whole population group that has not been identified on the basis of increased risk. Selective interventions target individuals or subgroups of the population whose risk of developing a disorder is significantly higher than average, as evidenced by biological, psychological, or social risk factors. Indicated interventions target high-risk people who are identified as having minimal, but detectable, signs or symptoms or biological markers, indicating a predisposition for a disorder, but who do not meet diagnostic criteria at that time. Also preceding the disease onset, measures to enhance well-being (by increasing protective factors such as supportive family, school, and community environments) may also function as preventive measures [41].

In the past decades, significant investment has been directed to the prevention science of mental, emotional, and behavioural disorders affecting youth. Researchers have successfully developed and tested interventions targeting depression, suicide, schizophrenia, and conduct disorder. These studies have begun to define the methodological challenges and strategies for the success of preventative interventions for mental disorders. Firstly, the causal mechanisms or origins of the disorder should be clear enough to be manipulated by strategies that are effective in reducing their occurrence or buffering their effects. Secondly, the disorder itself must be well characterized, together with the boundaries between the disorder and normalcy and its trajectory. Thirdly, methods to screen and identify individuals who are not affected by the disorder but are likely to develop it within a specific period of time should be available. Fourthly, the risks and costs related to the screening and intervention processes should be well balanced and not be higher than their potential benefits. Once all these challenges have been overcome, randomized controlled studies with adequate statistical power must demonstrate the benefits of the intervention. Statistical power reflects the necessary sample size to demonstrate reductions in incidence of the disorder, which may vary from hundreds to tens of thousands. It will depend on the base rate of new cases for the particular population studied and the magnitude of the effect of the intervention [42]. Preventive interventions are not necessarily ready to be used once their effectiveness has been demonstrated, but they must be implemented, sustained, and scaled up within clinical and community systems and offered to the target populations. At this stage, elements such as programme contents, delivery strategy, intensity and duration, personnel training and supervision, compliance, fidelity, and funding need to be addressed, so that they can be translated into real-world programmes [43–45].

Challenges of preventive interventions for ADHD

The development of preventive strategies for ADHD, such as for any neurodevelopmental disorder, is a challenging endeavour. ADHD arises as a consequence of multiple mechanistic causal processes, for which no component has been identified so far as sufficient or necessary. More importantly, as reviewed before, only a few environmental exposures—components that can be manipulated—have been identified so far as likely causal. Early severe institutional deprivation is likely to be causal but is mercifully uncommon in developed societies. Pre- and perinatal conditions and environmental toxins have been demonstrated to be risk factors with an unclear causal role. No other manipulable causal risk factor has been identified so far. In addition, genetic influences seem to be substantial, explaining a large proportion of heritability. The effects of genetic variants possibly interact with environmental exposures occurring early in life (some of them in the prenatal period) and lead to early emerging psychopathological processes. In addition, there are no current technologies to identify molecular and neural psychopathological processes at their early stages, before the manifestation of behavioural symptoms. Therefore, with obscure causal mechanisms and early arising psychopathological processes, at the present moment, ADHD becomes identifiable at a stage when strategies can no longer prevent its development. Early diagnosis and interventions have an important potential to prevent cumulative impairments and comorbidities over development but are not conceptually defined as preventive interventions.

Therefore, preventive interventions that might reduce the incidence of ADHD and that are readily available are universal or selective programmes to act on the initial stages of common multi-disease mechanisms. In fact, compartmentalized programmes that focus on specific aspects of behavioural, educational, or social problems are unlikely to be adopted as public policies, which is an argument in favour of universal and selective prevention programmes [46]. These interventions potentially produce multiple benefits, which increase their cost–benefit and consequently their implementation and scale. Several intervention programmes in early childhood have been developed and tested worldwide [47, 48]. Some of the most studied interventions focus on programmes for the development of parental competences [49], on the stimulation of infants during the first 3 years of life [50], or on school curricula for the development of social and emotional competencies of children from 4 years of age [51]. Important features of a successful early childhood intervention programme include integrated models that combine elements geared to physical health, cognitive, emotional, and social development, sufficient duration and intensity, modelling learning, structured curriculum, adequate material support for learning, systematic supervision, and clear incorporation of theories of change [52].

A number of issues arise from the experience to date [52, 53]. Firstly, is there a distinction between promotion and prevention strategies, and can the incidence of mental disorders be reduced with promotion strategies? It is hypothesized that the promotion of skills is one of the possible mechanisms through which mental disorders can be prevented [54]. Thus, as social–emotional skills are developed generally, there would be a secondary reduction in the occurrence of mental disorders. This is an example of the Rose prevention paradox and refers to the hypothesis that an intervention benefiting a large number of people at moderate risk may be of more value than an intervention benefiting only a small number of people at high risk [46]. However, it is a consensus that positive mental health and mental disorders are not just opposing poles of the same dimension, but two overlapping and interrelated components of the concept of mental health. Other important issues to be addressed are implementation characteristics, even for those programmes that have evidence of their effectiveness [43]. Among the main barriers are the limited description of the interventions, the overlap between elements of prevention and promotion in the same programmes, the limited theoretical conceptualization of the desired changes and how they can lead to the desired outcomes, and the external validity of the evidence. In addition, poor understanding of the mechanisms involved in the effect of interventions and the lack of evidence of sustained effects beyond their initial implementation constitute significant barriers to the success of prevention science.

Conclusions

ADHD is an impairing neurodevelopmental disorder that affects approximately 5% of children and adolescents worldwide, irrespective of their country of origin. In childhood, it affects predominantly males, although there is significant referral bias in their favour. In adulthood, sex differences are attenuated. ADHD is a long-lasting disorder, with symptoms or diagnosis persisting in approximately

70% of children as early adults. Cross-sectional studies estimate the adult ADHD prevalence in 2.5%.

Emerging evidence suggests that ADHD may arise in adulthood, challenging the notion that the disorder has always a neurodevelopmental origin. Currently, there are no definitive explanations for the so-called 'ADHD adult-onset cases', and hypotheses suggest that clinical cases in adulthood are preceded by childhood subclinical cases that emerge because of increasing demands or decreasing support or that child-onset and adult-onset ADHD are distinct disorders. In any case, no sufficient or necessary causal components (in terms of genetic risk, but also environmental influences and their interaction) have yet been implicated. Indeed, there are no environmental risks for ADHD identified so far of important magnitude and population-attributable fraction. In addition, molecular, neural, and cognitive psychopathological processes underlying the emergence of ADHD cannot yet be precisely identified, although, as explained in Chapters 32 and 34, the field is evolving rapidly.

Prevention is especially appealing for childhood mental disorders, which emerge temporally close to putative risk exposures. However, aetiological mechanisms probably operate during the perinatal period, are dominated by genetic risk, and have very few established environmental causal risk factors. Future elucidation of specific causal mechanisms will be required to inform the development of effective preventive interventions. Until then, the science of prevention of childhood mental disorders can be best further developed by accommodation with the growing interdisciplinary field of early childhood development.

Genetics of attention-deficit/hyperactivity disorder

Kate Langley and Anita Thapar

Overview

Attention-deficit/hyperactivity disorder (ADHD) is a phenotypically heterogeneous disorder and, like other psychiatric disorders, is multifactorial in origin; multiple genetic, as well as environmental, influences contribute risk. The multifactorial liability model is one useful approach to conceptualizing complex disorders such as ADHD. This considers disorders, including ADHD, as manifestations of an underlying continuously distributed liability, with the diagnosis lying above a certain threshold on this liability curve (Fig. 34.1). Multiple risk factors contribute to this liability, and the additive effects of genetic and environmental risk and protective factors shift individuals along this population liability. This chapter will look at the role of genetic factors in the aetiology of ADHD and those factors that have already been identified as being relevant, highlighting our current understanding regarding its genetic architecture. It will also discuss the methodological and phenotypic challenges that have influenced our current understanding. The heterogeneity of the ADHD phenotype has been discussed in more detail in Chapter 31.

Familial risk and heritability estimates from twin and family studies

Traditional genetic studies that infer, rather than directly assess, genetic contribution have overwhelmingly found ADHD to be a highly familial and heritable disorder. Family studies have shown that the risk of ADHD is increased in first-degree relatives of those with the disorder, with modest relative risks of between 4.0% and 5.4% [1]. Similarly, adoption studies of ADHD have suggested that adopted children have ADHD behaviour scores that are more similar to their biological than adoptive parents [2–5].

Numerous twin studies have also indicated the importance of genetic factors in the aetiology of ADHD, with meta-analyses reporting heritability estimates of between 70% and 80% [6]. The remainder of the variance is generally found to be due to unique environmental effects, with only a very small proportion attributable to shared environmental factors [6]. These studies suggest ADHD is one of the

more heritable of psychiatric disorders, on a par with autism spectrum disorder (ASD), bipolar disorder, and schizophrenia [7, 8].

These estimates are similar for the ADHD symptom dimensions of inattention and hyperactivity/impulsivity, with both common and separate genetic factors relevant to each dimension [6, 9–11]. There is also evidence from twin studies that genetic factors influencing ADHD act on a continuum, whereby heritability estimates are similar between those with a clinical diagnosis of the disorder and the traits seen within the general population (for example, [12, 13–15]). The informant utilized to ascertain ADHD symptoms appears to be important here and is an important consideration for genetic studies of ADHD. Twin studies using self-reported ADHD symptoms in adulthood have reported significantly lower heritability estimates of between 30% and 40% [16] than studies of children or adolescents that have generally utilized parent or teacher reports. The low self-report heritability estimates may reflect findings that affected individuals are less accurate than others at describing their own ADHD behaviours [17]. However, investigations have suggested that the drop-off in heritability estimates is likely due to the fact that (unlike with parent and, frequently, teacher reports) self-reported measures involve different individuals rating each twin. Studies where different parents or teachers reported on twins in childhood (for example, [18, 19]) have seen this same drop-off in heritability rates, while studies utilizing composite measures of parent and teacher reports and self-report in adulthood have observed high heritability rates of 60–70% [17]. While the initial findings of adult ADHD twin studies are no longer considered a challenge to the view that ADHD is highly heritable throughout the lifespan, they do highlight that methodological issues, such as the choice of informant, can impact upon our conclusions and understanding regarding the genetics of ADHD.

Rare genetic variants and copy number variants

While traditional twin and family studies are unable to identify which specific genetic factors might be involved in the disorder, they do indicate that molecular genetic studies should aid our

Fig. 34.1 Threshold liability model. Multiple risk factors, both genetic and environmental, are continuously distributed across the population. Individuals with a burden of risk factors above a certain threshold are considered to have a clinical diagnosis of the disorder.

understanding of the aetiology and pathogenesis of ADHD. To date, such studies have involved investigation of different classes of gene variants, both rare and common, across the whole genome and at specific candidate locations. It has been known for some time that some types of rare genetic syndromes are associated with ADHD phenotypes. For example, 22q11.2 deletion syndrome, as well as being a known risk factor for schizophrenia, is commonly associated with ADHD in childhood [20]. Other rare genetic syndromes associated with ADHD include fragile X syndrome [21] and tuberous sclerosis [22]. It is not inevitable that affected individuals show intellectual disability, but these syndromes are commonly characterized by additional phenotypic characteristics (for example, congenital heart defect, dysmorphic features, epilepsy). A number of studies have investigated the contribution of rare chromosomal deletions and duplications known as CNVs to ADHD risk. As observed for schizophrenia, ASD, and intellectual disability, a higher burden of large, rare CNVs has been identified in individuals with ADHD, compared to control individuals [23–26] (see Chapters 23, 28, and 59).

The burden of large, rare CNVs is especially elevated in those who have intellectual disability, as well as ADHD, but findings are not restricted to this IQ group [25]. Not all studies have individually observed an excess of CNVs in those with ADHD (for example, [27–29]). However, a pooled analysis of multiple data sets suggests overall there is an increased burden of CNVs in children with ADHD and a significant excess of duplications at chromosomes 15q13.3 and 16p13.11 [24, 25]. ADHD-associated CNVs show significant overlap with those implicated in ASD and schizophrenia [25, 27]. These findings highlight that even though these disorders are clinically very different, there are shared genetic risk factors. Genetic findings provide a window into biology that is otherwise difficult to directly access for psychiatric disorders, including ADHD. CNVs associated with ADHD have started to provide some clues on pathogenesis. These chromosomal duplications and deletions span genes that encode proteins involved in multiple biological pathways that also partially overlap with those implicated in autism and schizophrenia. Results to date from ADHD CNV studies [27, 30–32] suggest significant evidence of enrichment for genes involved in the brain (for example, neurite outgrowth, ion channel pathways). However, the

genes and biological mechanisms implicated in ADHD are not identical to those in other disorders. That is perhaps unsurprising, given their phenotypic manifestations are dissimilar and also medications that are effective in reducing ADHD symptoms do not benefit core symptoms of schizophrenia and autism.

Rare genetic mutations, including CNVs, can either be inherited from a parent with the same mutation (transmitted) or arise as the result of a spontaneous mutation in the individual (*de novo*). There have been some suggestions that spontaneous *de novo* CNVs may provide especially useful clues on genetic risk loci for disorders [33] and are associated with a larger effect size than transmitted CNVs [34]. While not all studies of ADHD have parental DNA to identify the origin of CNVs (for example, [32]), it seems that both transmitted and *de novo* CNVs have been identified in those with ADHD [25, 27–29]. Interestingly, some inherited CNVs seem to originate from parents who are also affected by ADHD [27–29] and involve regions previously implicated as risk loci for ADHD and other neurodevelopmental disorders [27, 28]. While further work is needed to replicate these findings and further elucidate their potential role in the aetiology of ADHD, they highlight the relevance of looking beyond the individual at the wider family to further understand the genetic aetiology of ADHD.

As one would expect for a multifactorial disorder, these rare genetic syndromes and CNVs are not observed in all affected individuals and CNV carriers do not necessarily show ADHD alone. CNVs are one class of rare genetic variant involving chromosomal alterations. To date, rare variations in DNA *sequence* have not been examined in ADHD. However, common gene variants have been investigated, and this will be discussed next.

Candidate gene studies

Initial molecular genetic studies were restricted to genotyping genetic variants at specific locations, rather than across the whole genome. In psychiatry, such candidate gene-based approaches are now regarded with scepticism, given the high likelihood of false positives. Also, the pathogenesis of psychiatric disorders is unknown, meaning that the selection of candidate genes is not based on a firm hypothesis. Nevertheless, for ADHD, some candidate gene variant findings were replicated and withstood meta-analysis. Meta-analyses have shown associations for variants within *DRD4*, *DAT1*, *DRD5*, *5HTT*, and *SNAP25* [35]. As the candidate gene methods have been replaced by newer hypothesis-free genome-wide association studies (GWAS), the relevance of these putative risk variants needs to be reconfirmed. While none of these findings have been upheld by GWAS to date, this might be observed in the future as sample sizes for such studies increase. This has been seen for schizophrenia; variants within the *DRD2* gene that had been associated with schizophrenia in candidate gene studies were not replicated in smaller GWAS, but *DRD2* has now been implicated by the largest schizophrenia GWAS to date [36].

Findings from ADHD GWAS

GWAS use case-control or similar types of design to investigate the association between a disorder and a large number of

single-nucleotide polymorphisms (SNPs), a type of common genetic variant, across the genome simultaneously. This method is advantageous, as it looks at multiple variants in a hypothesis-free (and therefore unbiased) manner, but requires stringent corrections for multiple testing as so many variants are tested for association [37]. This means that such studies require extremely large samples for associations to reach genome-wide significance [38].

GWAS of ADHD have generally been undertaken on small, underpowered samples. In the first nine reported studies [23, 39–45], sample sizes for ADHD cases ranged from 343 to 1013, with a meta-analysis of four separate studies [46], including just over 3000 individuals with ADHD. None of these studies reported any genome-wide significant findings, and there was little overlap in the top hits across studies. Although the small sample sizes were acknowledged to be an issue (for example, [47, 48]), as for similarly sized samples investigating schizophrenia or bipolar disorder [46], the lack of findings initially led some to question the relevance of common gene variants in the aetiology of ADHD [49].

However, recently, the ADHD sample size assembled by the Psychiatric Genetics Consortium (PGC) ADHD subgroup has risen to over 20,000 ADHD cases and 35,000 controls. Initial reports suggest twelve genome-wide significant loci (PGC-ADHD subgroup report, International Society of Psychiatric Genetics meeting, Toronto, October 2015) [49a]. This is an exciting development and, given the increased sample size in comparison to previous studies of ADHD, demonstrates the frequently cited need for large samples to find genome-wide significant risk loci [38, 50]. It is too early to understand the implications of these findings. Each of these variants will need to be looked at in more detail to identify the specific causal variant, as has been undertaken in other complex disorders (for example, [51]). It will also be important to ascertain whether the genes implicated by the associated SNPs highlight specific biological functions or pathways [36]. Furthermore, it is clear that these putative risk loci are only the ‘tip of the iceberg’ in understanding the aetiology of ADHD, as a multifactorial disorder influenced by multiple genetic *and* non-genetic risk factors. Also, a much larger number of common and rare genetic loci remain to be identified. Although the latest ADHD GWAS includes a much larger sample size, it is still small in comparison to those utilized for studies of other medical and some psychiatric disorders. Indeed, in the study of schizophrenia, where the largest GWAS study has identified 128 genome-wide significant hits [36], it is recognized that this is not the full extent of the common genetic variance accountable for the disorder [50].

However, because these studies were sufficiently powered to identify genetic loci with an effect size of 1.3 [37], we can conclude that there are no ADHD common genetic risk variants with a large effect size. This suggests that, as with other disorders such as schizophrenia (for example, [36]), the genetic architecture of ADHD is explained by a large number of common gene variants, each of small effect size, as well as rare mutations that have larger effect size. Environmental risks may also make an important contribution.

Composite measures of common genetic risk

While the recent GWAS findings are promising, any single SNP has a small effect size on its own. This has led to methods that involve

generating composite measures of multiple common genetic risk variants [37, 52]. One such method is genomic relationship–matrix restricted maximum likelihood (GRML), which is often referred to by the software programme used to implement it—GCTA. Using genome-wide SNP data, this method estimates the genetic similarity between unrelated individuals. This makes it possible to identify SNP heritability, which ranges between 17% and 45% [45, 53–55] (although not all are in agreement [56]). Schizophrenia polygenic risk scores derived from much larger studies account for only 7% of the variance [36]. Common gene variants appear to account for only a proportion of the heritability identified by twin studies, and this will, in part, be due to the role of additional risks, including rare variants such as CNVs.

A further method used to obtain a composite measure of common genetic risk is polygenic risk score analysis, which involves summing multiple risk alleles (SNPs) identified by a ‘discovery’ GWAS, including those at a very nominal level of significance. Putative risk alleles in individuals in an independent sample are then combined to give an individual polygenic risk score. ADHD polygenic risk scores have been shown to predict ADHD caseness [57], which highlighted, prior to the PGC genome-wide significant findings, that common gene variants contribute to risk.

ADHD is a multifactorial liability disorder whereby genetic and other risks are on a continuum throughout the population, with clinical diagnosis as one extreme (for example, [12–15]). Polygenic risk scores derived from the general population’s ADHD trait scores predict ADHD diagnosis in a case-control sample [58], while the opposite is also observed; ADHD polygenic risk scores derived from patients with the diagnosis (case-control samples) predict ADHD trait levels in the general population [30, 59].

Polygenic risk scores (across all disorders) currently account for a very small proportion of the phenotype variance—0.1–2.0% in the current studies of ADHD (for example, [49a, 57, 59]). Therefore, while polygenic risk score analyses can give some insight into the genetic architecture of ADHD, they only provide one indicator of genetic risk and alone cannot be used as diagnostic prediction tools. As sample sizes increase and our ability to identify loci more accurately from GWAS increases, measurement of genetic risk should improve, and when coupled with other measures of genetic risk (for example, family history), predictive ability should also improve [60].

Gene–environment interplay

Environmental exposures often believed to be risk factors for ADHD are described in Chapter 34. It will be explained in more detail here why the epidemiological findings may be a further expression of genetic, rather than simply environmental, risk. Environmental exposure in ADHD is not independent of an individual’s genes—a phenomenon known as gene–environment correlation. Gene–environment correlation arises for environmental exposures (for example, quality of relationships) that are shaped by individuals’ behaviours or dispositions (active and evocative gene–environment correlation) or through their parents’ attributes (passive gene–environment correlation). Further explanations and examples of gene–environment correlation can be seen in [Table 34.1](#). Even if an environmental risk has genetic origins, the impact on ADHD could still be environmental, although designs that go beyond observation

Table 34.1 Types of gene–environment correlations: descriptions and examples

Type of gene–environment correlation	Description	Example
Passive	An individual inherits genotypes from their parents who also provide the rearing environment	A disorganized parent may provide a more chaotic home environment, which reinforces the child's own disorganized tendencies
Active (niche picking)	Individuals seek environments that are compatible with, and reinforce, their genetic propensities	An impulsive child may seek out more risky situations or choose friends who engage in risky behaviour
Evocative	An individual's genetic tendencies elicit reactions from others which reinforce these tendencies	An irritable child will elicit more negative interactions from those around them

(for example, genetically informative twin studies) are required to test this. For example, cigarette smoking is an environmental risk that is strongly genetically influenced (that is, has genetic origins), but it is an exposure that still has environmentally ‘mediated’ causal risk effects on lung cancer.

There is evidence to suggest that some of the environmental risks thought to contribute to ADHD (for example, maternal lifestyle during pregnancy) do have partly genetic origins. The next question is whether the genetic factors that impact on ADHD environmental exposures (for example, maternal lifestyle) overlap with the ones that contribute to offspring ADHD. If that is the case, it would mean these environmental exposures, rather than being true causal risk factors for ADHD, represent expressions of the same genetic liability. Maternal smoking in pregnancy is a risk factor that is robustly associated with ADHD [61] but that is also under strong genetic influence. Multiple genetically informative studies, including discordant sibling pair designs (where the mother smokes in one pregnancy, and not in the other) [62], children of twins [63], and a design based on children born by assisted production [64], suggest that while the links between maternal smoking in pregnancy and offspring low birthweight are ‘environmentally mediated’, as one would expect, for ADHD, the association appears to be entirely, or mainly, explained by shared genetic liability in mother and child (manifest as smoking in pregnancy and offspring ADHD) [64a]. Clearly, smoking cessation is advisable for offspring and maternal health, but these findings suggest that this policy is unlikely to reduce the numbers affected by ADHD.

Mother–child hostility is another apparent environmental risk factor for ADHD. However, a number of genetically informative [65, 66] and treatment designs [67] suggest that it again is a consequence of ADHD symptoms and child genetic liability. Nevertheless, parent–child hostility has environmentally mediated links with conduct disorder [68] so might be important in terms of modifying ADHD outcomes. In contrast to these findings, very extreme early privation, as experienced by a group of children initially reared in Romanian orphanages and then adopted away, is an exposure that impacts on ADHD-like symptoms [69]. The links cannot be explained by shared genetic liabilities because the environmental exposure was imposed, rather than selected or evoked.

Gene–environment interaction provides another example of how genes and the environment work together. This has been demonstrated most clearly in animal models where the observable manifestation (phenotype) of a gene depends on the environmental context (for example, diet, exposure to a pathogen). Interaction extends to the molecular level; DNA codes for proteins, and there are multiple complex molecular mechanisms, including epigenetic ones, that

modify the biological function of the same DNA sequence. Gene–environment interaction in humans is much more challenging to assess robustly at a molecular level. Traditional behavioural genetic designs that involve separation of G and E and capture all genetic liability via design (for example, children adopted away at birth) have shown repeatedly that the clinical manifestations of genetic liability (for example, for criminal behaviour, schizophrenia) are modified by the rearing environment and/or adoptive context (for example, [70, 71]). However, ADHD has not been studied in this way. Although there are published reports of interaction between specific candidate gene variants and environmental exposures (for example, [72, 73]), convincing findings on ADHD have yet to emerge. Similar methodological issues apply to the concept of ‘differential susceptibility’ whereby some individuals are more susceptible to the benefits of positive enriched environments, as well as more vulnerable to environmental risks.

Another example of gene–environment interaction comes from pharmacogenetics when the effects of medication (the environmental exposure) vary according to genotype, for example, slow and ultra-rapid metabolizers of drugs metabolized by the enzyme CYP2D6 [74]. So far, there have been no consistent and robust pharmacogenetic findings in relation to ADHD medications that would have clinical practice implications. Despite the research challenges, it remains important at a conceptual level to appreciate the interplay of genes and the environment in understanding the aetiology of ADHD.

Phenotype heterogeneity and ADHD

As described in detail in Chapter 31, ADHD is a highly heterogeneous clinical disorder, with individuals frequently presenting with comorbid ASD, conduct disorder, anxiety, or depression.

Heterogeneity is very likely to be influenced by the underlying genetic architecture of the disorder. For example, the degree of genetic risk loading appears to vary for different subgroups of individuals with ADHD. Family and twin studies of ADHD suggest that individuals with comorbid conduct disorder have an increased genetic load, in comparison to those with ADHD alone [75, 76]. The relative risk (RR) of ADHD in biological relatives of those with ADHD plus conduct disorder is almost twice as high (RR 9.5) as that among first-degree relatives of individuals with ADHD alone (RR 5.4) [75]. At a molecular level, ADHD polygenic risk scores have also been observed to be higher in those individuals who have ADHD with comorbid conduct disorder, when compared to those with ADHD alone [57].

Previous candidate gene studies have suggested that there may be additional genetic variants which are specifically related to the subgroup of individuals with ADHD and conduct disorder, rather than all individuals with ADHD (for example, associations with the *COMT val158met* variant which have been identified in numerous replicated studies and a pooled analysis) (for example, [77, 78–80]). Time will tell whether or not this pattern of different genetic risks contributing to ADHD subtypes (and these specific associations) is confirmed, but such studies highlight the potential association of clinical heterogeneity to the genetic architecture of ADHD and the need to take this into account in the future.

While initially considered to be a childhood disorder, it is now recognized that ADHD persists into later adolescence and adulthood in a substantial number of individuals [81, 82]. Twin studies suggest that heritability estimates for ADHD are relatively stable throughout the lifespan (for example, [17–19]). Indeed, longitudinal studies following individuals throughout childhood to early adulthood suggest that heritability rates for ADHD remain stable, although the influence of specific genetic factors may change over time [83]. This change in the specific genetic factors potentially relevant at different ages may introduce a further element of heterogeneity in studies attempting to identify specific ADHD loci and may need to be considered. This is especially because, as larger samples are sought for GWAS, samples of children and adults with ADHD may be pooled. However, family and twin studies suggest that persistence of ADHD into adult life is more strongly familial [84] and highly heritable than childhood ADHD alone. To date, genome-wide gene discovery studies of adult ADHD have not yielded unique findings. Recent reports have suggested a further source of heterogeneity in adult ADHD; three population cohorts have shown that new cases of ADHD can present for the first time in late adolescence or adulthood [85–87]; future studies may consider the extent to which genetic factors are relevant to this group and how this may be the same or different to those for childhood-onset ADHD. The first of these studies [86] found that ADHD polygenic risk score did not significantly predict this later-onset group, although the sample size was small and an older discovery GWAS was used to generate risk alleles. Replication will be required.

Shared genetic risks across disorders

Given that ADHD is known frequently to co-occur with other disorders, there has been interest in whether or not there is an overlap between the genetic risk for different psychiatric disorders. Twin studies suggest that there is considerable overlap of ADHD genetic risk factors with those that contribute to ASD [9], conduct disorder [76], and other neurodevelopmental disorders [88], although the extent of this overlap may vary somewhat, depending upon whether age or hyperactive/impulsive or inattentive symptoms are considered [9]. Although there are some shared genetic effects, twin studies also demonstrate genetic risks that are unique to each disorder. ADHD polygenic risk score studies have shown some overlap with other disorders (schizophrenia, bipolar disorder, and depression [54, 57]) and with other neurodevelopmental traits, including cognitive and language ability in the general population [89].

The large PGC Cross Disorder Group investigates the overlap between eight psychiatric disorders: ADHD, ASD, schizophrenia,

bipolar disorder, major depressive disorder, anorexia nervosa, obsessive compulsive disorder, and Tourette syndrome. Using GWAS data, this group has found four genome-wide significant genetic loci appearing to be in common across disorders [54]. Interestingly, ADHD genetic overlap was strongest between ADHD and major depressive disorder [90, 90a].

Summary and clinical implications

While it has been known for some time that ADHD is highly heritable, progress to date in identifying specific gene variants has been slow until recently. However, now is an exciting time. The findings of the first twelve genome-wide significant loci from the largest GWAS study to date give a glimpse of the specific common genetic risk variants that might be involved in the disorder and provide future insights into biology. Genetic findings confirm what clinicians have long supposed—that ADHD lies at the end of a population continuum. However, individual genetic loci have very small effect sizes, and at present, even composite measures cannot be used to predict who has or will get ADHD [90b].

CNV studies have demonstrated the relevance of rare variants to ADHD that have much greater effect size than individual common variants. These CNV findings have further highlighted the neurodevelopmental origins of ADHD and overlap between different neurodevelopmental traits as well as disorders. Overall genetics research findings are strongly supportive of the DSM-5 approach whereby ADHD is classified under the group of neurodevelopmental disorders, along with autism. Major efforts will be required to move research on ADHD genetic discoveries into clinically meaningful findings. This includes investigating the biological impacts of gene mutations, especially rare, highly penetrant ones. This can be achieved using a variety of approaches, including animal studies and cellular models (see Chapter 32). Other research will involve assessing the impact of gene variants (composite measures of common gene variants or rare, highly penetrant mutations) on brain/cognitive function (for example, [91]) and population health (for example, [92]).

Finally, genetic testing will become an issue. At present, although rare mutations are associated with ADHD, routine genetic testing for CNVs in those with ADHD alone is not indicated in any country, unless the affected individual also has intellectual disability. While genetic understanding cannot currently influence clinical practice, it is likely that as rare genetic subforms of ADHD are identified, policies for genetic investigation in practice might alter. Increased understanding will enable researchers to investigate the pathogenesis of ADHD in more detail, with positive benefits for the treatment of ADHD.

Insights from neuroanatomical imaging into attention-deficit/hyperactivity disorder throughout the lifespan¹

Philip Shaw and Eszter Szekely

Introduction

Early models of attention-deficit/hyperactivity disorder (ADHD) sometimes viewed the disorder as a result of ‘minimal’ damage to brain structure and function [1]. This was partly based on a comparison with the effects of lesions of certain brain structures. For example, damage to the prefrontal cortex (PFC) is linked to deficits in motor and impulse control [2, 3]. The advent of magnetic resonance imaging (MRI), a non-invasive imaging tool that is free of ionizing radiation, accelerated the study of brain-behaviour relationships. It provided direct access into the developing brain. Here we review the literature, exploring the insights into ADHD throughout the lifespan provided by neuroanatomical imaging.

To outline this chapter, firstly, models of ADHD are briefly reviewed to aid in the interpretation of the neuroanatomical findings. Secondly, the literature on structural brain differences found in ADHD is summarized, adopting a developmental perspective, as childhood, adolescent, and adult ADHD are considered. Finally, looking to the future, we consider possible clinical applications of this work and likely research directions.

Neurocognitive models of ADHD

There is a near consensus that there are multiple neuropsychological pathways to ADHD [4–7]. These are discussed in greater depth elsewhere (see Chapters 32 and 33). Here, we sketch these models to aid with the interpretation of the major neuroanatomical findings. The models are illustrated in Fig. 35.1. Firstly, ADHD has long been associated with anomalies in the *fronto-striato-thalamic*

circuitry, that is, the rich, sometimes bidirectional, interconnections between the prefrontal/parietal cortices, basal ganglia, and thalamic nuclei [8]. These circuits mediate a host of cognitive functions that are disrupted in ADHD such as working memory, response inhibition, and sustained attention. Secondly, children with ADHD also often show deficits in processing information about the temporal structure of the environment, making errors in time estimation, perception, and temporal foresight [9, 10]. In turn, this implicates the *corticocerebellar circuitry* spanning the cerebellum and its projections to the PFC, cingulate, and some parietal regions.

Thirdly, an aversion to delayed reinforcement, expressed as atypical processing of rewards, has been found in ADHD [6, 11]. This feature, along with anomalies in brain activation during anticipation of rewards, has spurred interest in connections between the *ventral striatum* and the *ventromedial cortex/orbitofrontal cortex (OFC)* in ADHD [12]. Fourthly, emotion dysregulation is increasingly recognized as a common, if not core, problem in ADHD [13]. It implicates the paralimbic circuitry, particularly interactions between the *amygdala*, *medial PFC*, and *OFC*. Finally, it has been argued that children with ADHD are not so much consistently worse at certain cognitive functions as they are more variable in performance, perhaps due to anomalies in vigilance or motivation [14–16]. This model has been linked most closely with atypical neurophysiology, specifically anomalies in the patterns of synchronized brain activity that arise during periods free from task demands [17]. However, there are also some possible neuroanatomical correlates, with increased within-subject variability associated with decreased white matter and prefrontal grey matter anomalies.

Most cognitive models of ADHD derive from research in children. However, it is increasingly clear that we need to consider the neural and cognitive anomalies that underpin ADHD throughout the lifespan. This is because, while some children ‘grow out’ of ADHD, many do not. Recent prospective studies find that 20–45% of children with ADHD will have the full syndrome into adulthood

and a further 25–48% have impairing symptoms [18, 19] (see also Chapter 34).

A review of the neuroanatomy of ADHD throughout the lifespan

This is a selective, but comprehensive, review of the structural neuroimaging literature of ADHD, highlighting some landmark studies and key concepts. Systematic reviews and meta-analyses are referenced throughout, where appropriate. We first review childhood ADHD, summarizing findings for the three main compartments of the brain: deep brain structures, the cerebral cortex, and the cerebellum. We then review the literature on adolescent and adult ADHD.

Childhood ADHD: the basal ganglia and other deep structures

The basal ganglia are perhaps the most widely studied brain structures in ADHD. This reflects their status as pivotal components in nearly all of the circuitry implicated in the disorder. Neuroimaging studies in the 1990s focused mainly on the caudate, often using manual tracing to chart volumetric alterations. The findings were mixed, with reports of increase [20], decrease [21, 22], and no difference [23]. The next wave of imaging studies has employed methods unconstrained by a priori regions of interest. These include voxel-based morphometry, which allows change in grey matter volume and density to be measured at thousands of points (or voxels) throughout the entire brain. In a landmark quantitative meta-analysis, Nakao and colleagues found that 14 such studies converged to find reduction in the dimensions of the right putamen and globus pallidus extending to the head of the caudate [24]. This effect was more pronounced in childhood and could not be attributed

to psychostimulant medication (which attenuated diagnostic group differences). The findings lend support to the ‘classic’ models of ADHD as stemming from anomalies in the fronto-striatal circuitry which mediates many executive functions.

Conventional MRI, at the currently used field strength of 1.5 and 3 T, has great difficulty in resolving the individual subnuclei of deep brain structures such as the striatum and thalamus. Thus, localized compromise of subnuclei could be missed. One strategy to circumvent this limitation is to examine the surface morphology of these deep structures. This is defined by the degree to which an individual’s basal ganglia (or thalamic) surface contours have to be ‘deformed’ (stretched or shrunk) to fit a template [25, 26]. Surface expansions are generally interpreted as reflecting volume increase in underlying nuclei, and surface contractions as indicative of volume loss. The identity of the underlying nuclei is inferred through reference to surface maps of the structures, created by expert neuroanatomists.

One of the first studies to use this approach found that smaller basal ganglia volumes in boys with ADHD were driven by compression bilaterally in the head of the caudate and the anterior putamen, with relative sparing of more posterior regions [27]. A somewhat similar pattern was reported by a separate group [28].

The basal ganglia are richly interconnected with the thalamus, and here too localized surface anomalies have been delineated using this surface mapping technique [29]. Specifically, marked surface contraction in the region of the pulvinar nuclei bilaterally was noted in a group of 105 children with ADHD and controls. The pulvinar nuclei link action and vision, and the pulvinar’s lateral portions, where the morphological anomalies were most prominent, support circuitry that detects salient somatosensory stimuli. Such morphological disruption of the pulvinar could contribute to the inefficient allocation of attentional resources seen in ADHD [30]. Notably, these complex surface changes and associated underlying volumetric perturbations did not lead to a change in the overall volume of the thalamus in

youths with ADHD, relative to typically developing youths. Thus, a traditional region-of-interest study examining the volume of the thalamus would have missed these subtle, but important, diagnostic signals.

Others have looked beyond striatothalamic regions and delineated similarly localized changes that can inform cognitive models of ADHD. One study of 114 children delineated components of the limbic system, specifically the amygdala and the interconnected OFC [31]. It detected anomalies in amygdala shape—but not volume—and a disruption of the typical correlation between the amygdala and orbitofrontal volumes, suggesting a breakdown in the connectivity between components of the limbic system. The limbic system underlies affective processes such as emotion perception and emotion regulation. Thus, these findings lend support to the emotion regulation difficulties often seen in the disorder.

The basal ganglia develop throughout childhood [32]. This raises the question of whether the growth trajectories of the basal ganglia are altered in childhood ADHD. While cross-sectional data can be used to define trajectories, longitudinal data are better suited for capturing dynamic processes. In part, this is because longitudinal data focus on within-subject variation over time (which is of central interest) and remove much between-subject variance (which can confound). Indeed, theoretically, the only situation in which individual trajectories can be correctly inferred from cross-sectionally derived curves of mean values is when all entrances or exits from the study are random and the trajectories of the ADHD and control groups are parallel [33]. Neither requirement is likely to be met in ADHD.

One study used a mix of longitudinal and cross-sectional data to chart the development of the basal ganglia, comparing 270 children with ADHD against 270 well-matched typically developing controls [34]. Age-related change was mapped using surface-based morphological methods. The study confirmed prior findings of a general increase in surface area of the basal ganglia throughout childhood into mid adolescence. Children with ADHD similarly showed an increase in surface area but started from a 'lower' point, as they had a decreased surface area at study entry in the head of the caudate and the body of the putamen. Only one region showed a diagnostic difference in trajectories—the ventral striatum. Here, the typically developing group showed surface area expansion with age, whereas the ADHD group showed progressive contraction. In cognitive terms, the atypical development of the ventral striatum supports cognitive models implicating anomalous reward processing as a key contributor to childhood ADHD.

Childhood ADHD and the cerebral cortex

Different areas of the cerebral cortex have also been implicated in most neurocognitive models of ADHD, partly through their rich interactions with striatal, thalamic, and cerebellar regions. An early landmark study of 152 children with ADHD and 139 well-matched typically developing controls established that there was a 4–6% reduction in the volume of the cerebral cortex, affecting all the major lobes [35]. Advances in analytical techniques provide more precise localization of change, allowing a closer alignment of neuroanatomical findings with cognitive models. Many studies have used methods that extract the cortical mantle and then measure the thickness, surface area, and curvature at thousands of points across the cerebrum [36, 37]. In childhood ADHD, ten studies have converged

to find a predominantly thinner cortex with reduced surface area, albeit with less agreement on the precise location of change [38–47]. Thus, widespread reduction of cortical dimensions in children with ADHD have been reported in the PFC, superior parietal cortex, and medial and anterior temporal regions. One study has reported increased dimensions confined to the primary somatosensory cortex [48]. Direct links between this compromised cortical substrate and cognitive deficits have been found. Thus, one study reported that at a group (but not individual) level, deficits in inhibitory control found in ADHD were accompanied by a thinner inferior frontal cortex [44]. A separate study using voxel-based morphometry found that age-related deficits in response inhibition in children with ADHD improved in tandem with increasing volumes in a network comprising the anterior cingulate cortex, striatum, and medial temporal lobes [49].

The cerebral cortex also develops during childhood, again prompting us to ask if trajectories differ in ADHD. Using data from over 500 children, many with repeated observations, the velocity of cortical development of both cortical thickness and surface area was defined [42, 50]. The key finding was a slower rate of cortical change in childhood ADHD. This altered velocity entailed a 'delay' in some prefrontal regions, as defined by the age at which each cortical vertex attained its peak dimensions. More recent work suggests that these differential trajectories may be moderated by intelligence, with slower rates of cortical development being more prominent in ADHD children with lower intelligence [51].

Childhood ADHD and the cerebellum

Although the cerebellum has traditionally been considered a site of motor control, lesion studies and functional imaging studies in healthy subjects have demonstrated a wide range of cognitive and affective functions in cerebellar structures, particularly temporal information processing (but also attention shifting, verbal working memory, and emotional regulation [52, 53]). Dysfunction in each of these cognitive domains has, in turn, been implicated in the aetiology of ADHD. Anatomically, there are reciprocal loops that interconnect cerebral cortical areas, including the PFC, with the cerebellum by way of the pons, dentate nucleus, and thalamus. Structural anomalies of the cerebellum are among the most consistently reported features of ADHD [54–57]. A recent meta-analysis found that the regions most reduced in ADHD—lobule IX and VIIIB, Crus 1—were entirely distinct from those compromised among children with autism or developmental dyslexia [58]. These ADHD-related cerebellar regions interact richly with prefrontal and striatal regions to form networks involved not only in temporal information processing, but also in the effortful allocation of attention.

Dividing a literature overview into sections on different brain regions should not be taken to diminish the importance of discerning the coherent patterns of change that occur across the entire brain [5]. Large-scale brain networks in ADHD have largely (and appropriately) been mainly delineated using imaging modalities that more directly measure structural (for example, diffusion tensor imaging) and functional connections (for example, resting state fMRI) [59]. Nonetheless, the ways in which different brain structures co-vary in their dimensions can provide a more indirect index of anatomical networks [60]. One study adopting this approach found anomalous anatomical network structures in children with ADHD, centred on

the OFC and insula [61]. Future work will usefully integrate such approaches with other modalities of imaging.

Adolescent and adult ADHD

Most studies have focused on childhood or adult ADHD, with a relative neglect of adolescence. This gap has been filled by a recent large study of 307 adolescents with ADHD, 169 of their unaffected siblings, and 196 typically developing controls [62]. Two major neuroanatomical findings have emerged. Firstly, during adolescence, there is a fixed, non-progressive reduction in total brain volume in ADHD, echoing earlier childhood studies [63]. By contrast, there was progressive volume loss in adolescence in the right caudate and putamen (unlike childhood studies). Many of these changes were present in an attenuated form in the unaffected siblings, suggesting that they represent shared familial, perhaps genetic, risk factors. Cortical dimensions were also examined, and the ADHD group showed global thinning, compared to controls, with the medial temporal cortex being particularly compromised [45]. This effect was found throughout the adolescent to the adult age range and held even when psychostimulant medication was considered. This finding might suggest a developmental shift from the fronto-parietal anomalies that are prominent in early childhood ADHD towards more medial temporal/limbic anomalies in adolescents and adults.

In addition, the medial temporal anomalies are consonant with the prominent emotional dysregulation seen in young adults with ADHD (although direct evidence of a link was not found).

Studies into adults with ADHD have addressed two central issues. Firstly, are the neuroanatomical changes seen in childhood ADHD fixed and thus carried forward into adulthood, or do novel neuroanatomical changes emerge in adult ADHD? Secondly, is the variable clinical course of ADHD reflected in neuroanatomical change?

Most adult studies have focused on cortical structure and reported decreased volumes of predominantly prefrontal regions (dorsolateral, anterior cingulate, and OFC) [64, 65]. Cortical thinning in adult ADHD has also been found in the right inferior prefrontal, cingulate, and medial frontal cortices, in keeping with childhood findings [66, 67]. This would suggest that many of the anomalies of childhood are carried forward to adulthood. However, a more complex picture emerges, particularly when we consider the highly variable clinical course of ADHD.

One study clinically followed a large group of males with childhood ADHD into late adulthood (mean age 41 years) [68]. By this stage, 17 individuals had ADHD persisting into adulthood and 26 had remitted ADHD; contrasts were drawn against 57 never-affected controls. Neuroimaging was added at the adult assessment to allow an examination of the cerebral cortical structure and grey matter density. The study found a globally thinner cortex in both the persistent and remitted ADHD groups, compared to controls, particularly in the parietal, temporal, and frontopolar regions and the precuneus. The ADHD outcome groups mostly did not differ significantly from one another, compatible with fixed 'trait' deficits possibly carried forward from childhood. However, some changes did reflect outcome. The right middle frontal and limbic cortices were thinner, and the right cerebellum and thalamus had lower grey matter density in the persistent, compared to the remitted and never-affected, groups.

A separate study of clinical course used a fully longitudinal design and acquired neuroanatomical data in tandem with clinical

assessments, both in childhood (mean age 10 years) and in early adulthood (mean age 24 years) [69]. Such longitudinal data provided the ideal tool for delineating the neuroanatomical trajectories that are tied to the variable clinical course. By adulthood, 55 of the 92 members of the ADHD group had remitted and the remainder still met diagnostic criteria. Contrasts were made against 184 never-affected controls. Regions were identified where change in cortical structure—specifically cortical thickness—was tied to this variable outcome. A link emerged in the cingulate cortex bilaterally, the right inferior parietal cortex and dorsolateral PFC, and the left sensorimotor region. Here, increasing severity of adult inattention, but not hyperactivity-impulsivity, was linked with higher rates of cortical thinning. The net effect of these differences was that those whose ADHD symptoms improved showed a significant convergence during adolescence towards typical cortical dimensions, rectifying early anomalies. By contrast, those with persisting symptoms had childhood cortical anomalies that persisted into adulthood. Importantly, these outcome-related differences in trajectories held when psychostimulant treatment history was entered as a covariate. These regions where the trajectory was tied to outcome span several of the brain networks most closely linked with ADHD. For example, outcome was linked with trajectories of the fronto-parietal cortical regions that guide much goal-directed behaviour through cortico-striato-thalamic circuits.

Do the trajectories of other brain regions also mirror the clinical course? Such a link was found for the developmental trajectories of some, but not all, cerebellar regions [70]. Studying 72 participants from the study just discussed, the trajectories of cerebellar development were defined from at least three scans. Outcome was assessed in adolescence. Some cerebellar trajectories were sensitive to outcome. There was atypical progressive volume loss in the inferior-posterior cerebellar lobes in those with worse clinical outcome, and a convergence to typical dimensions in the anterior hemisphere in those who improved. Not all cerebellar change reflected outcome—a reduced volume of the superior vermis persisted, regardless of outcome.

In summary, there is regional heterogeneity in the neuroanatomical trajectories of variable adult outcome. While different prefrontal cortical and cerebellar hemispheric development may be tied to different clinical outcome, more posterior cortical regions and the cerebellar vermis may show more fixed, trait-like deficits.

To summarize this section, meta-analyses and some of the larger individual studies converge to find anomalies in the basal ganglia in ADHD, some of which appear developmentally fixed while others may be progressive. Compromise of the cerebral cortex is commonly found, albeit with less consensus on the exact regions affected. Again, some of these anomalies may vary with age in ADHD and may be tied to the clinical course of the disorder. Finally, while the morphology of the cerebellum is relatively understudied, it may also show a mix of fixed and dynamic anomalies, some of which show diagnostic specificity.

Towards future clinical application

Clinicians are often interested in two questions. Firstly, can neuroimaging aid with the diagnosis or prognosis of ADHD? Secondly, what are the effects, if any, of psychostimulants given as treatment for ADHD on brain structure?

At present, neuroimaging remains a research tool and the diagnosis of ADHD remains a clinical skill. Neuroimaging can define robust differences at the group level and provides rich insights into neurobiological mechanisms. However, to realize clinical utility, the next wave of studies will need to be able to detect changes at the individual level with high sensitivity and specificity. It seems unlikely that ‘one-shot’, one-modality imaging will suffice for this purpose, and multimodal imaging may be required. Biomarkers are not only needed to inform diagnosis, but also prognosis. We currently cannot accurately predict an individual child’s likely outcome using clinical, sociodemographic, and neuropsychological data. For example, while baseline symptom severity and multiple comorbidities are significantly associated with long-term course, one study found these factors combined account for only 15–20% of the variance in outcome [71–73]. There are mixed findings on whether or not socio-economic status, general intelligence, family environment, and cognitive skills are associated with adult outcome [71, 73–79]. In this context, future studies will increasingly turn to objective measures of the brain and the genome to inform diagnosis and prognosis.

Psychostimulants appear to normalize brain activity in ADHD during the performance of tasks and while the subject is at rest [80, 81]. What about neuroanatomy? Nearly all studies found that either there is no clear association between anatomy and psychostimulant treatment or treatment is associated with more normative dimensions (reviewed in [82]). One report found psychostimulant treatment to be associated with a smaller hippocampus, although this was not found in a larger study [63, 83]. However, it is critical to remember that all of the neuroanatomical studies discussed here are observational and causality cannot be inferred. For example, other factors, such as socio-economic status, access to care, or comorbidities, could influence the likelihood of receiving psychostimulant medication and brain structure. Statements about causality await imaging within the context of randomized medical trials.

Future research directions

What does the future hold for neuroanatomical imaging in ADHD? Four major shifts are already discernible: (1) a shift from diagnostic categories towards considering underlying dimensions; (2) a move to ‘big data’ partly attained through collaborative efforts; (3) the rise of novel imaging modalities and their integration; and (4) the use of brain structure as a phenotype in genetic studies into ADHD and related disorders.

The shift from categorical approaches to dimensionality

The National Institute of Mental Health has recently proposed a shift in research focus away from the use of DSM-5 diagnostic categories towards objectively defined constructs that are continuously distributed throughout the population [84]. In line with this concept, epidemiological and neuropsychological evidence suggests that ADHD can be considered dimensionally, lying at the extreme end of a continuous distribution of symptoms and underlying cognitive processes [85, 86]. Thus, it becomes pressing to ask if such dimensionality is also present in the brain changes associated with the categorical disorders.

To date, studies have only asked if the symptom dimensions of ADHD are tied to neuroanatomical change. Three studies have found such links. The first built on the earlier finding of a slower

rate of cortical change in those with a diagnosis of ADHD. It found that this slower rate of cortical thinning during late childhood and adolescence was also associated with the severity of symptoms of hyperactivity and impulsivity in typically developing children [87]. As symptoms of hyperactivity–impulsivity increased in 193 typical children (with 389 neuroanatomical scans), the rate of cortical thinning decreased, approaching that seen in a group of 197 children with the clinical syndrome. Thus, similar, but attenuated, disruptions to trajectories are found in children who exhibit behavioural problems characteristic of ADHD, even when these do not pass the threshold for making a diagnosis. This finding was replicated in a separate cohort of 357 typically developing children among whom higher-attention problems were associated with a thinner cortex at baseline and slower cortical thinning with ageing in multiple areas involved in attention processes [88]. Finally, a population-based imaging study of 444 children found that greater problems with hyperactivity and impulsivity were associated with a thinner post-central cortex bilaterally [89]. The next stage is to define how cognitive domains pertinent to ADHD and related diagnostic entities might also impact on the brain and its development.

Big data

Several meta-analytic studies have already demonstrated the power of quantitative summaries of several smaller studies. Such meta-analyses are being facilitated by international collaborative efforts such as the Enhancing Neuroimaging in Genetics through Meta-Analyses initiative (<http://enigma.ini.usc.edu>). This collaboration has already provided initial reports on subcortical compromise in ADHD in over 3200 participants [90]. Such meta-analyses are not without their limitations. Foremost is the integration of data acquired using different scanners, with different sequences, and with often slight, but important, variations in image processing. This includes consensus protocols on how to assess the quality of images for motion and other imaging artefacts. The requisite methods are being developed to allow the integration of diverse data collected on different platforms.

Novel imaging modalities and their integration

We are already seeing a shift towards imaging at field strengths (7 T and above) that can distinguish, for the first time, the layers of the cortex, the subfields of the hippocampus, and the subnuclei of deep structures. These data will quickly surpass existing data, extending and refining our current conclusions. Integration of these multimodal images is under way, often using multivariate methods that detect patterns or ‘motifs’ across multiple data sets that characterize ADHD [91].

Brain structure and genomics

While ADHD is highly heritable ($h^2 > 0.7$), there has been limited progress in understanding the mode of action of susceptibility genes [92, 93] (see Chapter 35). It has been argued that the phenotype for genetic studies should not always be the diagnostic category of ADHD per se but should also include quantitative brain-based traits that are pertinent to the disorder [94, 95]. Such quantitative traits have the advantage of containing more information about inter-individual trait variability than a dichotomous diagnostic category. The brain also lies closer to gene action and may be genetically less complex than the more distal clinical phenotypes of outcome.

Finally, progress in genetics might also be aided by parsing ADHD according to its highly variable clinical outcome. Developmental phenotypes that capture the dynamic nature of ADHD might better reflect its biology and provide better targets for genetic understanding. This developmental perspective is particularly important, given that a longitudinal study of 8395 twin pairs found that over half of the genetic contributors to variance in clinical course were distinct to those genetic factors driving the onset of ADHD [96].

What is the evidence that the brain alterations associated with ADHD are genetically determined? Comparing monozygotic and dizygotic twins is the ideal design for parsing the relative contribution to aetiology of genetics and unique and shared environmental factors. While no study has yet adopted this design in ADHD per se, one group used a variant of this design [97]. It found that volumes of the PFC were likely under genetic control (through a contrast of concordantly affected against concordantly unaffected monozygotic twins), whereas striatal volumes were more likely under environmental control (differing within discordant twin pairs). Several studies have also reported that some of the brain changes seen in children with ADHD, such as decreased prefrontal grey volume, are also found in their unaffected siblings in an attenuated form [63, 98]. Similarly, a study of 169 unaffected siblings found they had reduced volumes of total and cerebral grey, but not white, matter that lay between their siblings with ADHD and unaffected controls [63]. Interestingly, the finding of compromise in unaffected siblings does not extend to the cerebellum, one of the least heritable brain structures [99]. These unaffected sibling studies point to familial factors—either genetic or shared environment—as pivotal in determining some, but not all, brain dimensions pertinent to ADHD.

The next step is to identify the specific genes driving this heritability. To date, candidate genes implicated by a priori knowledge have been studied. Among structural studies, most have focused on common polymorphisms of the dopaminergic system. Risk-conferring variants of the dopamine transporter gene and the dopamine D4 receptor were associated, respectively, with decreased volume of the caudate nucleus and volumes and thickness of the prefrontal and parietal regions [100–102], with some studies finding this effect was confined to those with ADHD [102]. However, several studies do not report associations. A notable negative finding came from a population-based study of 1871 children, of whom 344 had neuroimaging [103]. It tested for additive effects of genetic variation in dopamine, serotonin, and neurite outgrowth pathways on both the severity of ADHD-related problems and the volume of the basal ganglia. While a modest association between ADHD symptom severity and putamen volume was found, none of the genetic pathways were related to clinical or brain features.

The future lies in studying the impact of common and rare genetic variants across the entire genome on the brain in ADHD. Given the large numbers that are needed for such studies (usually tens of thousands), it is likely that the primary phenotypes used for gene discovery will have to be relatively cheap and quick to ascertain, and entail minimal inconvenience—such as online questionnaires and testing. The deep phenotyping provided by multimodal imaging may prove prohibitively expensive when focused on just one disorder. Thus, the neural phenotyping of ADHD might be most usefully employed to characterize the most promising signals to emerge from larger studies using more readily available clinical and behavioural phenotypes.

Understanding the impact of DNA sequence variation on the brain in ADHD is only the first step. Interactions between the environment and genes are critical to consider, not least as the high heritability estimates include not only the main effect of genes, but also gene–environment interactions. There are a handful of pertinent studies. One of the most studied and controversial gene–environment interactions is between variants of the serotonin transporter gene (a variable number tandem repeat polymorphism in the promoter region) and early life adversity in producing vulnerability to depression [104, 105]. A study of 701 youths found that this interaction between the serotonin transporter gene variants and chronic life stressors was also associated with the severity of ADHD symptoms [106]. Using mediation analyses, the study further found that decreased volume of the OFC and anterior cingulate cortex could be the mechanism underlying this interaction.

The environment can also alter gene expression through epigenetic modifications such as methylation of DNA sequences. A recent study found that high levels of methylation of the serotonin transporter gene in 102 children with ADHD were associated with more severe symptoms and decreased thickness of the right occipitotemporal cortex [107]. Clearly, such preliminary findings require replication, but the studies illustrate how we can take well-characterized gene–environment interactions into the brain in an effort to map out the pathways to ADHD.

Conclusions

Structural neuroimaging in ADHD is surprisingly young; large-scale research applications of MRI only started in the 1990s. Imaging has already moved beyond delineating morphometric change in entire lobes or deep structures, to consider how the disorder might be characterized by highly localized alterations in volume, shape, and surface complexity. The future holds challenges. Group-level differences can richly inform our models of ADHD, which could, in turn, impact on treatment approaches. However, direct clinical application of imaging to diagnosis or prognosis awaits the delineation of specific and sensitive alterations among individuals with ADHD. Chances of attaining this goal may be boosted by integrating neuroanatomical imaging with other imaging modalities and neuropsychological, clinical, and environmental data. Multimodal imaging will also prove vital if we are to define the neural mechanisms through which genetic variants confer risk for ADHD. While many challenges lie ahead, given the advances already made, it appears that the future of neuroanatomical imaging in ADHD is shaping up well.

Management and treatment of attention-deficit/hyperactivity disorder

Alessandro Zuddas and Sara Carucci

Assessment

As explained at length in Chapter 32, attention-deficit/hyperactivity disorder (ADHD) assessment involves the integration of information from different sources and an appropriate clinical decision-making process able to resolve conflicting observations and information. The full assessment includes information collected by validated instruments documenting present problems, health and developmental history, comorbid psychiatric conditions, and global functioning; instruments and procedures include questionnaires, interviews, and, when appropriate, direct observation and neuropsychological testing. Assessment of cardiac risk factors needs to be recorded at assessment before prescribing medications and routinely thereafter. At the end of the assessment process, the clinician will determine a principal and differential diagnosis and the presence of any comorbidity, and will develop a formulation that places these diagnoses in context.

ADHD treatment guidelines and algorithms have been developed in Europe [1–4] and North America [5–7], proposing evidence-based approaches for ADHD assessment and management. Model templates for planning services for ADHD assessment and intervention, such as the Dundee ADHD Clinical Care Pathway (DACCP) [8], have also been tested and are currently used in many countries; it includes specific stages for: (1) referral and pre-assessment; (2) assessment, diagnosis, and treatment planning; (3) initiating treatment; and (4) monitoring and continuing care.

Clinical management

Treatment for ADHD is based on a multimodal approach combining behavioural and pharmacological treatment [2, 9]. European guidelines highly recommend a stepwise approach, with psychobehavioural interventions as first-line treatments, especially for pre-school children and subjects affected by a mild form of the disorder. American guidelines do not preclude pharmacotherapy as a first therapeutic approach, even in the youngest and mildest cases.

If pharmacological treatment is prescribed first line, it should be combined with behavioural interventions in any case. However, it is

largely accepted that pharmacological treatment for ADHD is highly effective, either alone or in combination with behavioural interventions, that it has greater benefits than behavioural intervention alone, and that outcomes are much improved when a structured approach to medication management is adopted [10]. There is not a unique strategy for management; individual circumstances, comorbidities, and medical history have to be considered as an integral part of the treatment plan [11]; after appropriate information, parents' and patients' preference should always be taken into account.

When concomitant medical or psychiatric conditions such as conduct disorders, specific learning disorder, and social difficulties are present, psychosocial, psychoeducational, and environmental interventions centred on the family and school are often required.

The main objectives of any comprehensive treatment are:

- To improve *core* ADHD symptoms.
- To improve interpersonal relationships with parents, siblings, teachers, and peers.
- To decrease disruptive behaviours.
- To improve school learning abilities.
- To increase personal autonomy and self-esteem.
- To improve social acceptability of the disorders and the quality of life of children/adolescents suffering from the disorder.

Non-pharmacological interventions

The most common non-pharmacological treatments are behavioural interventions both for children and carers [that is, parent training (PT), educator/teacher training, cognitive behavioural therapy (CBT), support groups, and social skills training], cognitive training, neurofeedback, and nutraceuticals. The objective is to improve global functioning and reduce ADHD symptoms.

Parent training

PT programmes are psychoeducational interventions providing parents with information about ADHD and adequate strategies to target and monitor problematic behaviours, in order to better manage their children. The intervention is typically delivered to

groups of parents and covers positive reinforcement skills, reward systems, the use of 'time out', liaison with teachers, and planning ahead to anticipate problems.

According to recent studies, PT has positive effects on the behaviour of ADHD children by increasing parents' behaviour management skills, as well as reducing stress and improving parents' sense of efficacy [12].

Cognitive behavioural therapy

CBT is a structured psychotherapeutic approach to help subjects in recognizing their dysfunctional patterns of thought and behaviour. It aims to help subjects to learn new skills and strategies to achieve their objectives, improve self-esteem, and deal with their emotions and social difficulties.

Objective evidence for the efficacy of psychosocial interventions is problematic. A recent meta-analysis by the European ADHD Guideline Group (EAGG) showed good effect sizes when outcome measures were based on ADHD assessments by raters closest to the therapeutic setting. There was an overall standardized mean difference (SMD) of 0.40 (95% CI 0.20, 0.60). However, when only ratings by assessors *blind to treatment allocation* were considered, treatment effects almost disappeared (SMD 0.02, 95% CI -0.30, 0.34) [13].

In contrast with the lack of sufficient evidence on ADHD core symptoms, a more recent meta-analysis showed a significant positive effect of behavioural interventions on parenting skills and conduct problems in ADHD children [14, 15].

Cognitive training

In recent years, also cognitive training aimed at targeting specific deficits (for example, attention, working memory, inhibitory control) has been investigated as potential ADHD treatment [16]. The effects of cognitive training on ADHD, as addressed in a recent meta-analysis performed by the same EAGG, were significant when calculated using unblinded ratings (SMD 0.64, 95% CI 0.33–0.95) but, as reported for psychoeducational interventions, became statistically non-significant (SMD 0.24, 95% CI 0.24–0.72) when measures generated by probably blinded observers were used [17].

A more recent meta-analysis, including a larger number of trials, showed a more reliable estimate of the effects of cognitive training on specific functions (working memory, sustained attention, and inhibition); when measured by blinded raters, cognitive training mainly improved working memory, with limited effects on ADHD core symptoms [17].

Neurofeedback

Neurofeedback is based on the training of self-regulation of brain activity; it has been considered a promising ADHD treatment by targeting aberrant patterns of brain activity putatively underpinning the disorder. The results of a recent meta-analysis on 13 controlled trials did not show neurofeedback to be an effective treatment for ADHD when evaluated by probably blinded raters [18]. A recent study in adults confirmed these results [19], although some more promising preliminary results have been reported with innovative techniques [20, 21].

Behavioural interventions have also been provided as useful treatments for managing comorbid disorders in ADHD subjects. Recently, a multi-centre RCT conducted in 159 adolescents, investigating two new individual, short-term cognitive behavioural

therapies (one including skills teaching, while the other was solution-focused), showed significant improvements in comorbid depression, anxiety, and disruptive disorder symptoms with both approaches [22]. Weaker evidence is available for the efficacy of behavioural sleep interventions in children with ADHD, although about 70% of ADHD subjects display mild to severe sleep problems. Behavioural treatments for insomnia are clearly effective in children in general [23], and ADHD should be considered not only a day-time disorder, but also better as a 24-hour ongoing process including sleep difficulties. Given the well-known consequences of poor sleep on memory and cognition, behavioural approaches to improve sleep may represent an important resource needing more specific research [24]. Some clinicians already recommend initiating behavioural treatment for poor sleep early in management, since it is a non-contentious symptom, carrying none of the stigma of a psychiatric diagnosis.

Nutraceuticals
