Major changes have taken place since 2000 in prescription patterns for bipolar disorder in mental care in Western countries in general [38]. Nation-wide and other population-based longitudinal pharmaco-epidemiological studies on prescription patterns have shown that lithium is prescribed less and anti-epileptics and dopamine antagonists are prescribed substantially more in recent years. In particular, the prescription of lamotrigine and quetiapine has increased substantially (from 0–3% in 2000 to approximately 40% of all patients in 2011 [38]). In many areas of the world, lithium has gone from being the first drug prescribed as maintenance therapy for bipolar disorder to being replaced by dopamine antagonists or anti-epileptics. The use of drugs for depression has been constantly high in Western countries, approximating 70–80% of all patients since 2000 [38, 39]. Combination therapy of lithium, anti-epileptics, drugs for psychosis (see Chapter 140), and also antidepressants has increased substantially during the last decade.

Overall, the development in prescription patterns during the last decade has not been in accordance with the evidence and recommendations in international guidelines in relation to the use of lithium [40–44] and antidepressants [43–47] in bipolar disorder. Changes in study populations do not seem to explain the changes in prescription pattern and use [38]. The high rates of combination therapy reflect that, in real life, patient response and remission rates are low with monotherapy for acute episodes and relapse rates are high during maintenance monotherapy therapy [48].

Adherence to treatment

Pharmaco-epidemiological studies have consistently shown that adherence to medication is a major clinical challenge in the treatment of bipolar disorder. As much as half of the patients do not take medication or take it in other durations and doses than prescribed, although randomized trials show that group-based psychoeducation can substantially add to improve adherence.

Risk factors for affective episodes in patients with bipolar disorder

A range of other biological factors are risk factors particularly relevant to the onset of episodes of illness, but they may contribute a relatively small part to lifetime vulnerability. Many women have their first episode of depression or mania in the post-partum period. There is substantial evidence that seasonal patterns influence the onset of manic and depressive episodes. There are consistent findings of an excess of manic episodes in late spring and early summer. To date, however, the nature of the environmental factors that influence this late spring, early summer peak of manic episodes is less clear.

There is also substantial evidence that disruptions of normal biological rhythms may precipitate the onset of manic or depressive episodes. This has been documented in relation to international travel involving east–west or west–east travel with disruption of circadian rhythms. Disruption of circadian rhythms through shift work or other factors which disrupt the normal sleep cycles may also be important triggers to the onset of episodes of mania.

Adverse life events have been well documented to be precipitants of manic episodes, as well as depression. It appears that life events are more likely prior to the first or second episode of mania and are less likely later in the course of illness.

Life expectancy, mortality, and causes of death

Standardized mortality rates (SMRs) among patients with bipolar disorder have been found consistently to be increased 2–3 times, compared to the general population [49–51], and life expectancy has been reported to be decreased 8–12 years for patients with bipolar disorder, compared to the general population [52]. The increased mortality is related to increased mortality due to suicide [51, 53], unintentional injuries [49, 51], and comorbid general medical illnesses, including cardiovascular disease [49–51, 54], diabetes [51, 55, 56], and chronic obstructive pulmonary disease [51, 57].

The SMR for completed suicide is estimated to be between 10 and 15 [58]. The lifetime risk of suicide may have been overestimated in some prior studies, due to incomplete follow-up in selected samples or rather short-term follow-up of patients with first-time treated mental disorders [59]. The absolute risk of committing suicide within 36 years after the first psychiatric contact has been estimated to be 8% for men and 5% for women [59]. Suicide is a prevalent reason for lost life years specifically during adolescence and early and mid adulthood, and that risk clearly decreases with age [60]. Among 15-year-old patients with bipolar disorder, suicide accounted for 23–24% of all lost life years, decreasing to 0–5% for patients aged 75 years [60]. However, rather surprisingly, natural causes of death is the most prevalent reason for lost life years already from adolescence and increased substantially during early and mid adulthood, that is, from age of 15 years and during the twenties, thirties, and forties [60]. For 15-year-old boys with bipolar disorder, natural causes of death have been found to account for 58% of 12 lost life years, and for 15-year-old girls, natural causes account for 67% of 9 lost life years, increasing to 74% and 80% for 45-year-old men and women, respectively [60].

Reasons for increased mortality due to comorbid general medical illness in bipolar disorder may include unhealthy lifestyle, decreased health care, adverse pharmacological effects, and biological factors [61]. In relation to biological factors, accelerated ageing has recently been proposed as a mechanism explaining the increased prevalence of comorbid medical illness due to disparate pathophysiological changes observed in bipolar disorder such as brain structural alterations, cognitive deficits, oxidative stress imbalance, amyloid metabolism, immunological deregulation, immunosenescence, neurotrophic deficiencies, and telomere shortening [62]. It is well established that, in addition to being differentially affected by chronic medical disorders, the age of onset of medical chronic disorders is much earlier, when compared to individuals in the general population [63].

Depressive disorders

Diagnostic issues

A key issue for the epidemiology of depressive disorders is defining the boundaries of major depression and dysthymia. Depressive symptoms in the community are common, and defining both the symptom count and the duration at which depressive symptoms

count as part of a clinical disorder is arbitrary. Provided that one accepts the arbitrary definition of major depression, then determining the rates of current depressive disorders is not especially problematic. However, there are major methodological issues involved in determining whether an individual has ever had a lifetime episode of major depression. Lifetime prevalence rates vary from 4.4% in the United States ECA study to 17.1% in the NCS and to over 30% in the Kendler's Virginia twin sample of women. In part, subjects in the community may forget or fail to report past episodes of major depression (recall bias), and the manner in which the questions are asked may importantly influence lifetime rates of depression. In the diagnostic interview schedule, which was used in the ECA, respondents were asked about lifetime symptoms, a lifetime diagnosis was made, and then recency of the lifetime diagnosis was determined. Diagnostic interview schedules, such as the Composite International Diagnostic Interview, first ask about current depressive symptoms and then, having 'primed' individuals about depressive symptoms, go on to enquire about past depressive episodes. Interviews that follow the schedule of 'priming' before asking about past episodes appear to obtain considerably higher rates of lifetime major depression. Determining lifetime rates of depression with greater precision is an important task, as the vulnerability to depression conferred by risk factors such as genetic factors and childhood experiences may be wrongly estimated if lifetime rates of major depression are imprecise.

DSM-5 allows major depression to be further sub-classified into subtypes, such as melancholia, atypical, psychotic, and by severity and recurrence. Most of the traditional epidemiology studies have tended to ignore the issue of subtyping major depression.

Prevalence

In the ECA, the 6-month prevalence of major depression across five sites was 2.2 per 100. In the NCS, the 1-month prevalence of a major depressive episode was 6.1 per 100 [64]. In the National Psychiatric Morbidity Surveys of Great Britain, the 1-week rate of a depressive episode was 2.1 per 100 [65], and in the European Study of the Epidemiology of Mental Disorders, the 1-year prevalence of major depressive disorder was 3.9% [66]. Together, these studies would suggest that the current rate of major depression is in the realm of 2–5%.

Estimates of the lifetime rate of major depression are much more variable. The lowest rate reported is 4.4 per 100 from the ECA study, while in the study of Virginia twins, the lifetime rate of major depression is over 30%. It is reasonable to believe that the true lifetime rate of major depression is probably in the realm of 10–20 per 100, but caution should be exercised in expressing lifetime rates of depression with undue precision.

Over the past decade, one of the controversial findings in the epidemiology of major depression has been whether the rates of depression are increasing and whether it is occurring at a younger age. Despite methodological concerns about the reliability of lifetime major depression, studies across countries have reasonably consistently documented an increasing rate of major depression with an earlier age of onset [67, 68]. As mood disorders are the single largest risk factor for suicide, it is also of note that, in most Western countries, the rate of suicide, especially in young adults, increased considerably from the 1970s to the 1990s, although the suicide rate is now declining in many countries. This could, however, reflect better recognition and treatment of depression.

Comorbidity

Comorbidity is prevalent in depressive disorder. Not surprisingly, the most common comorbid disorders are anxiety disorders and substance abuse disorders. In the NCS, the anxiety disorders with the highest odds ratios indicating comorbidity were generalized anxiety disorder, panic disorder, and post-traumatic stress disorder. It is also important to note that for most anxiety disorders, with the exception of panic disorder, the anxiety disorder usually predates the onset of the depressive disorder. This is of considerable importance, as the risk factors for pure major depression differed from the risk factors for comorbid major depression. Furthermore, the cohort effects of increasing rates of major depression were largely attributable to increasing rates of comorbid major depression, rather than to increasing rates of pure major depression. These results raise important issues for prevention, as it may well be that targeting young people with anxiety disorders could be a major step towards prevention of the development of later major depressive disorders.

The second key area of comorbidity with major depression is with alcohol dependence. Data from the Virginia Twin Register suggest that part of this comorbidity is due to shared genetic factors, although there is also a smaller common environmental risk factor to both disorders.

Another area of considerable comorbidity with depressive disorder is the personality disorders. Comorbidity between depression and these disorders is receiving considerable attention in clinical samples, but to date, there are only limited data from epidemiological samples on the importance of these patterns of comorbidity.

Risk factors

Genetics

There is substantial evidence that genetic factors are of major importance as risk factors for vulnerability to major depression, with a heritability at about 40%. Genes for major depression do not appear to be unique for depression but overlap with genes for anxiety and genes for neuroticism. The greater prevalence of depression in women may be due to the strong association of anxiety and neuroticism with depression and the fact that higher rates of anxiety and neuroticism in women lead to higher rates of depression.

Stressful life events and childhood adversities

Although the experience of a stressful life event is a well-known risk factor for developing depression, the associations are complicated. Firstly, causation may be unclear, as life events may cause depression and depression may result in stressful life events. Further, the type and timing of stressful life events play a role, including the experience of acute vs more chronic stressors and the experience during childhood and the adolescent period or during different age spans in adulthood. Secondly, the impact of life events differs in relation to the onset of the first depressive episode and to subsequent depressive episodes. Approximately 60–80% of patients with a first and single depressive episode have experienced stressful life events in a 6-month period prior to the onset of depression, whereas the prevalence of life events is decreased to 20–40% or less in relation to subsequent depressive episodes. Finally, the experience of life events is highly individual and may be stressful for one person or life situation but positive for another. Overall, assessment of life events based on

self-report may be influenced by recall bias and those based on interviews may be influenced by observer bias and interpretation.

Gene–environment interaction

In 2003, Caspi *et al.* showed that risk for depression was related to an interaction between the serotonin transporter-linked polymorphic region (5-HTTLPR) and stressful life events, with persons carrying the short, less transcriptionally active 5-HTTLPR allele more vulnerable to depression after stressful life events [69]. The study sparked research into interactions between candidate genes and environmental exposures on risk for psychiatric disorders, but although this field of research has now persisted for more than a decade, it has been characterized by much controversy. Nevertheless, studies identifying stress using objective measures, such as specific medical conditions, or observer-based measures, such as in-person interviews, seem to have found stronger evidence for a gene–environment interaction than studies measuring stress by self-report [70].

Gender

One of the most consistent findings in the epidemiology of major depression is that the ratio of women to men is approximately 2:1. This increased rate of major depression in women arises during puberty, as in childhood, there is a slightly higher prevalence of depression in boys than girls. The timing of this transition in rates by gender is related to biological puberty, rather than just to age. Intriguingly, a new population-based cohort study found that use of hormonal contraception among adolescent women is associated with an increased risk of subsequent development of depression, suggesting depression as a potential side effect to hormonal contraceptive use on a population level [71].

Personality

There has been a long history of interest in the likelihood that people with certain personality traits are more vulnerable to depression than others. It is likely that those individuals who are unduly anxious, impulsive, and obsessional may have increased rates of later major depression. The best data exist for neuroticism, which emerges as a clear risk factor for the later development of depressive and anxiety disorders. However, as already mentioned, the same genes seem to contribute to the development of neuroticism and to later anxiety and depressive disorders.

Physical illness

Having a chronic or severe physical illness is associated with an increased risk for depression. The mechanisms behind this increased risk may vary, depending upon the physical disorder. In disorders such as Parkinson's disease, it is possible that there are shared neurotransmitter abnormalities between Parkinson's disease and depression. In post-stroke depression, there is good evidence that the location of the lesion, at least in part, contributes to the rate of depression, which suggests a neuroanatomical/neurotransmitter connection between the physical illness and the likelihood of depression. For non-central nervous system disorders, such as acute myocardial infarction, diabetes, and cancers, the mechanism for this association is less clear. Further, stress associated with a serious or chronic physical illness may act by bringing out an individual's lifetime vulnerability to depression.

An integrated aetiological model

The ultimate purpose of studying risk factors for depressive disorders is to contribute to the development of an integrated aetiological model. The most promising research in this area has been performed by Kendler and colleagues on twins from the Virginia Twin Register [72] who developed a model that predicted over 50% of the variance in the liability to develop major depression in the next 12 months. The strongest predictors to depression were as follows:

- Stressful life events.
- Genetic factors.
- Previous history of major depression.
- Neuroticism.

Approximately 60% of the effect of genetic factors on the liability to depression was direct, but the remaining 40% was indirect and largely mediated by past episodes of depression, stressful life events, and neuroticism.

Use of health services and untreated depression

One of the major challenges for psychiatry presented by epidemiological studies of depression has been the consistent finding that the majority of cases of depression in the community are not recognized, diagnosed, or treated. In the ECA study, it was found that 65–70% of people with depression had visited a health professional in the last 6 months, but only 15–20% had had a visit for a mental health reason and only about 10% had seen a mental health specialist. Among individuals with a 12-month diagnosis of pure major depression in the European Study of the Epidemiology of Mental Disorders, only 21.2% had received any antidepressant treatment within the same period; the exclusive use of approved drugs for depression was even lower (4.6%), while more individuals took only drugs for anxiety (18.4%) [73].

Patients with depression who present with largely somatic, rather than psychological, symptoms are unlikely to be recognized by general practitioners. Even if major depression is recognized in the primary care setting, it is often not adequately treated.

The duration of untreated illness (DUI), defined as the time interval between first onset of the illness and initiation of (pharmacological) treatment, has increasingly been considered to influence the clinical course of different psychiatric disorders. Knowledge of the potential consequences of postponing medical treatment of depression is of crucial importance, when the choice stands between a drug for depression, other therapies, or watchful waiting. Unfortunately, the effects of DUI have been investigated only scarcely in first-episode depression. The largest study found that initiation of appropriate drug treatment more than 6 months after the onset of first-episode depression reduces the chance of obtaining remission to 50% [74].

Use of pharmacotherapy

Non-adherence to medication is a major challenge concerning up to 50% of patients and is associated with an increased risk of relapse and hospitalization.

Age of onset and course of illness

Age of onset is later for depressive disorder than for bipolar disorder, with a mean age of around 30 years—however, with a substantial

proportion of patients having age at onset of below 21 years. The distribution of age of onset is bimodal, with peaks in the thirties and fifties.

Length of episodes is typically 3–12 months (median duration of 5 months), but 10–20% of patients experience depressive periods of longer than 2 years (that is, a chronic depressive episode). Results from up to 25 years of follow-up studies show that approximately 30–50% of patients remain symptom-free after a depressive episode, while the remaining 50–70% develop new episodes or chronic depression. In a recent 5-year follow-up of patients with psychiatric hospital contact for the first lifetime episode of depression, 83% obtained remission and among these, 32% experienced recurrence of depression and 9% converted to bipolar disorder [6].

Approximately 1% convert from unipolar depressive disorder to bipolar disorder per year [5, 6], approximating 20–40% during the lifetime course.

Social and cognitive outcomes

Dysfunctions in social interactions remain persistent several years after recovery from depressive symptoms and are correlated with unemployment, disability, and decreased work performance. Within 5 years, 20% of psychiatric inpatients and outpatients with major depression and belonging to the labour force at baseline in Finland were granted a disability pension [75].

Cognitive dysfunction in attention, memory, and executive function is less prevalent in the remitted state of depressive disorder than in bipolar disorder and schizophrenia. However, self-reported attention and concentration difficulties mediate as much as 25% of the impact of depression on patients' psychosocial impairment. Long-term studies rather consistently show that depressive disorder is associated with a 2–3 times increased risk of developing dementia eventually [28–30, 32, 76].

Life expectancy and mortality

The SMR for completed suicide is estimated to be increased 20-fold [58]. In the longest population-based follow-up study, a 36-year study after the first psychiatric hospital contact, the absolute risk of committing suicide was 7% for men and 4% for women [59].

Life expectancy is decreased approximately 12 years and 10 years in men and women, respectively [77]. SMR is highest for death due to suicide and accidents, but the absolute number of deaths is highest for natural causes.

As bipolar and depressive disorders are associated with long-term deficits in social, functional, and cognitive outcomes and a substantially decreased life expectancy, there is a need for future studies on early and lifestyle interventions. A recent randomized trial has shown that early intervention, combining optimized pharmacological treatment and psychoeducation, following the onset of bipolar disorder substantially improves the outcome of the bipolar illness [78] and specifically so among young adults below 25 years of age [79].

Primary prevention of mood disorders: building a target for prevention strategies

Gin S. Malhi

Introduction

Mood disorders, both depressive and bipolar, are seemingly ubiquitous in modern-day society and, once established, cannot be cured. Research efforts in the latter half of the last century focused largely on diagnosis and optimal treatment of mood disorders, with the implicit aim of illness containment, rather than its complete removal. But even symptomatic management of mood disorders has been less than optimal. Part of the reason for this is that there has been a widespread lack of consensus regarding whether psychiatric disorders are discrete entities or lie on a continuum defined by dimensional constructs, and though the key features that characterize the disorders have been reliably identified, the construction of a meaningful hierarchy has eluded both researchers and clinicians alike. Apart from creating difficulties in diagnosis, this has meant that defining targets for treatment, clinically and for research purposes, has proven to be challenging. It remains unclear, for example, which symptoms or clusters of symptoms are most closely coupled with functional recovery and which symptoms are most likely to herald a recurrence or re-emergence of the illness. Therefore, treatment has generally been symptom-focused and its main goal has been to limit acute episodes of illness and to return the individual to wellness. Only relatively recently has there been a shift towards longer-term prophylaxis and maintenance of well-being, with a growing emphasis on prevention. Clearly, prevention is the ultimate and ideal goal, namely, to intercept the illness before it takes hold by stopping processes that lead to the emergence of mood disorders. But to achieve this, a deeper understanding of the pathophysiology of mood disorders is necessary. Sadly, our current knowledge of how mood disorders evolve is incomplete and insufficient for this purpose. Nevertheless, attempts at prevention have begun in earnest, and emerging evidence suggests that, when such efforts are suitably targeted, reasonable benefits can be achieved, in the short term at least. Whether these outcomes can be sustained, and for how long, is the key question—the answer to which remains elusive. Therefore, this chapter briefly discusses some models of prevention, the types

of interventions and treatments that are currently being trialled, and where future insights in this field might lead us.

The burden of mood disorders

By their very nature, mood disorders distress the affected individual, but they also impact their families, friends, peers, colleagues, and the broader community. This makes mood disorders a tremendous burden to bear. Among mental disorders, the highest global burden, as explained by disability-adjusted life years (DALYs), that is, the cumulative number of years of productive life lost to disability, ill health, or early death, occurs in adolescents and the young to middle-aged and is associated with depressive and anxiety disorders, while the burden from bipolar disorders is ranked fourth overall [1, 2]. This ‘quantitative’ evidence underscores the need to avert or reduce the qualitatively palpable burden exerted by these disorders at an earlier stage, and it has been suggested that evidence-based interventions may be capable of doing just this [3]. But presently, and somewhat alarmingly, based on the WHO projections for 2030, this burden is not being diminished [4]. So what are the impediments to reducing this burden, and how can these barriers be overcome?

Barriers to reducing the burden

Although gaps in the scientific knowledge base regarding prevention and treatment of mood disorders are gradually narrowing, puzzlingly, the actual burden is not diminishing at a commensurate rate. This is attributable to a number of factors, including the conflicting and disparate priorities of diverse stakeholders who collectively shoulder the burden of mood disorders. Consequently, barriers exist at all levels—from individuals and families to communities, societies, and organizations. To overcome this, an integrated approach is needed, one that targets modifiable barriers by

Table 68.1 Modifiable barriers that hinder efforts to reduce the burden of mood disorders, and potential strategies to overcome them

Barriers	Strategies
Delayed diagnosis [*]	1. Early identification of risk and protective factors 2. Early detection and diagnosis
Delayed initiation of treatment ^{**}	Use of early intervention strategies (mainly those that have the potential to cause little harm)
Stigmatization (constrains uptake of services)	1. Psychoeducation (factual information regarding the nature, causes, risks, and protective factors of mood disorders) 2. Awareness campaigns to enhance attitude and behaviour change 3. Supportive community engagement campaigns
Uneven distribution of funding	1. Clarity of policies governing resource allocation 2. Availability of resources for training needs
Paucity of evidence-based interventions and treatments	Translating research from the laboratory to the real world

^{*} Especially likely with bipolar disorder where the illness usually manifests with depression and is therefore misdiagnosed [41].

^{**} A tentative approach to intervention (especially the prescription of medications) is understandable where the diagnosis may be speculative.

taking into consideration contributions from the various stakeholders (Table 68.1) [5–7].

It is estimated that primary care interventions have the potential to reduce the burden of mood disorders by 10–30%, but because of a *delay in diagnosis* and the subsequent *initiation of treatment*, this reduction may not be sufficient [8]. Another barrier—*stigmatization*—which is largely based on fear, embarrassment, little or insufficient knowledge, and restrictive policies for those with mood disorders, further limits access to services and their uptake. Therefore, to provide sustainable and effective evidence-based interventions, it is necessary to identify changes in mental health policies and research services and to address inefficiencies in the distribution of funding and training needs [7]. At the same time, it is also important to understand the causes and underlying mechanisms involved in the development of mood disorders, to enable timely identification of the factors that contribute to their development. With early identification of risk and protective factors, it may be possible to intervene sooner to either prevent onset or delay progression to full-blown mood disorders.

Causes of mood disorders

To be able to intervene in an effective way so as to prevent and treat mood disorders, a deeper understanding of the *risk factors* that predispose young people to developing mood disorders and the *protective factors* that may increase resilience and adequately buffer

them from the development of mood disorders, or at least their consequences, is critical. Understanding these factors may reveal targets for preventative and early interventions, as well as measurable outcomes that allow assessment of their efficacy and effectiveness.

But despite extensive research in recent years, it has become increasingly evident that the causes of mood disorders are multifactorial and that numerous variables contribute to the myriad of manifestations encountered clinically. For example, mood disorders are often preceded or triggered by life events—implicating a set of interactions between environmental and intrinsic risk factors that presumably converge on any number of neural systems and pathways. Identification of such intrinsic and extrinsic risk factors that increase the probability of developing mood disorders may assist in predicting onset and serve to focus prevention endeavours. This is exciting because some of these factors may be discernible from a relatively early age [9–12], and while many are seemingly irreversible, others are modifiable and may potentially serve as targets for prevention strategies.

At the same time, enhancing protective factors may also serve to delay or prevent the deterioration of mental health. Thus, to maintain an optimal level of well-being, any imbalance between risk and protection needs to shift so as to favour resilience. However, while exposure to risks and protective factors is inherent in the course of everyone's life, critically, it is the extent of exposure and the individual's response to this that varies. Interestingly, despite individual differences, there seems to be a developmental trajectory to exposure, that is, some risks and protective factors seem to be phase (stage of life)-dependent while others are more stable and present throughout the course of life.

In the context of mood disorders, there seems to be a cumulative effect of risk and protective factors, wherein as the number of risk factors and the duration of exposure to these increases, so do the odds of developing a depressive or bipolar disorder, whereas a greater number of protective factors decreases these odds [13–16]. Specifically, emerging evidence suggests that through cumulative damage over time or disruptions during particularly sensitive developmental periods (phase-dependent), the emergence of enduring mood disorders can be traced to exposure to adversity in the early years of life, from birth and infancy throughout childhood and adolescence into young adulthood (Fig. 68.1) [11, 14, 17–24]. At the same time, throughout these periods of growth and development, protective factors (intrinsic and extrinsic) act as buffers to minimize the deleterious effects of such adversity, and from the standpoint of prevention, these may also serve as targets that can be potentially enhanced as part of preventative strategies.

For instance, from birth, there is a genetic predisposition, via parental transmission, that interacts with environmental risk factors to increase the likelihood of developing mood disorders, but there is no particular time period during which this interaction is destined to exert an effect. As such, through the interaction between the cumulative effects of, or exposure to, adversity at 'critical' time points and the individual's genetic disposition, a somewhat delayed, but chronic, expression of mood disorders may ensue years, or even decades, after the adverse event. These cumulative effects are thought to arise as a result of the 'wear and tear' or allostatic load of the body and the brain due to persistent exposure to adversity at multiple time points [16, 25, 26]. On the other hand, latent, but enduring, effects of exposure to adversity during sensitive periods

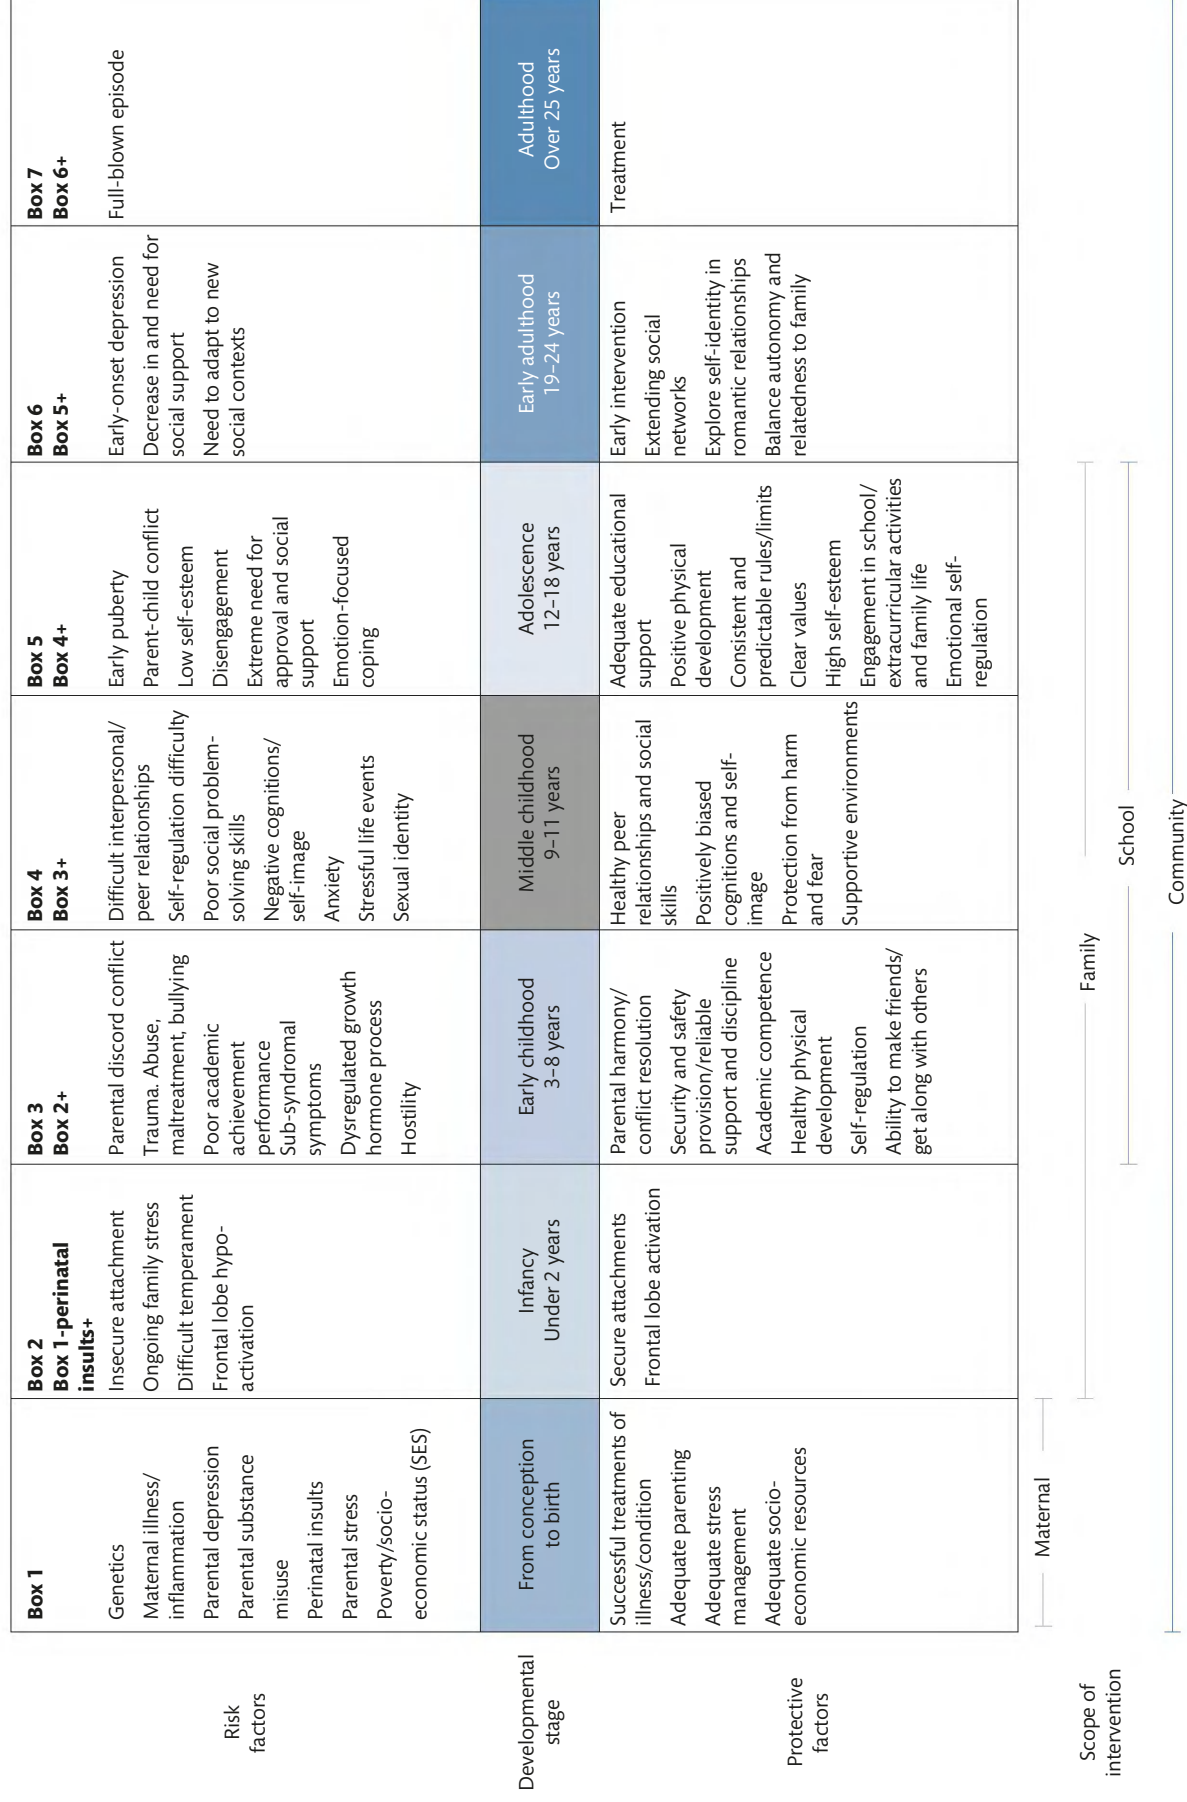

Fig. 68.1 Risk and protective factors by developmental stage, reflecting the cumulative and latent effects of stressful life events, culminating in the development of mood disorders or resilience. These factors also span the affected individual's lifetime. Maternal health is important, especially during pregnancy. Similarly, early childhood milieu is critical in defining secure attachment to the 'world' and understanding interpersonal interactions. Family, peer groups, and school provide evolving and iterative environments that shape aspects of personality and lay down the foundation for later stages of development. Puberty and adolescence mark a period of rapid social, emotional, and cognitive development that culminates in a sophisticated understanding of oneself and the world, and as such, it is this phase of life during which most psychiatric disorders first appear. Throughout, the balance between risks and protective factors oscillates, eventuating, over time, in the development of vulnerabilities and resilience.

when the brain is presumed to be more responsive to positive and negative environmental triggers may become intricately embedded in underlying neurobiological processes [16, 18]. However, though it is likely that there are sensitive or ‘critical’ periods during which vulnerability to mood disorders is increased, the difference is probably modest, and evidence for such epochs of heightened susceptibility has thus far proven to be relatively weak and largely circumstantial [16, 18, 19].

Nevertheless, as a general rule, the earlier the intervention, the better the long-term outcomes are likely to be, and thus far, the evidence for this also seems to hold [27–30]. Most important, however, is to target the risk and protective factors that have a demonstrable causal link with mood disorders, and doing so earlier in development, as this has the greatest potential to produce the most robust, and possibly long-term positive outcomes [28, 29, 31].

Nature of mood disorders

The major psychiatric taxonomies—the Diagnostic and Statistical Manual of Mental Disorders (DSM) and the International Classification of Diseases (ICD)—define mood disorders cross-sectionally, and they give relatively little consideration to their longitudinal course (while they acknowledge that they are chronic lifelong illnesses—often with an early age of onset) [24, 32–39]. This myopic view is, in part, pragmatic—because the trajectory of mood disorders is difficult to predict and the illnesses are intrinsically capricious. But, because the propensity for recurrence binds all mood disorders, a longitudinal and longer-term perspective is essential. In this context, recurrence refers to the repeated occurrence of episodes of depression and mania, but in reality, the underlying pathophysiology of the illness, once established, is always present; it is merely its clinical expression that ebbs and flows. This concept is not fully captured in classification systems, which instead emphasize the impact of acute exacerbations and infer that in between episodes of illness, patients recover as the illness remits. But when considering

prevention, it is the underlying processes, that is, the subsyndromal pathological activity, that need to be targeted (Fig. 68.2).

Prevention strategies

When to intervene for maximum benefit is a crucial question that requires an understanding of the developmental trajectory of mood disorders. For instance, Howes and Falkenberg [40] have identified potential points for prevention in the developmental trajectory of bipolar disorder (BD). The earliest point in this schema is when there is fluctuation of mood that represents an underlying cyclothymia or a mental state of ‘being at risk’ of developing BD. The second stage is when precipitating life events accumulate to the extent they cross a threshold and transition the illness into the ‘prodromal phase’—in other words, the last stage where prevention is possible. However, as BD is often initially diagnosed as MDD, and the transition from MDD to BD can take up to 5 years, and even then, only a small proportion of cases make the transition, waiting for the prodromal phase before intervening risks altogether missing the window for prevention [41–43]. One advance could be to regard the developmental trajectory of some depressive disorders as the prelude to that of BD, and in such instances, by focusing on the prevention of depression, it may be possible, in fact, to prevent the development of BD. Similarly, a step further (backwards) builds on the observation that anxiety (and anxiety disorders) often precedes major depression and is a common ‘comorbidity’ of both depression and BD [44–48]. Therefore, anticipating and targeting anxiety may aid the prevention of mood disorders. With this developmental and chronological perspective in mind, it is important to note that while vulnerabilities for anxiety and mood disorders may be established in adulthood, it is adolescence that seems to be the critical period for their clinical emergence and that this is set against a background of considerable neurobiological and psychosocial change that begins post-puberty [34, 49, 50]. The impact of these changes can be protective or detrimental to long-term health outcomes, and so in either case, targeting

Fig. 68.2 The clinical trajectory of mood disorders and their underlying components. The shaded blue zones represent periods of pathological activity that drive the core pathological processes underpinning the illness. This leads to damage which then accumulates. Cumulative damage is shown as a blue line, and this indicates how, as the illness progresses, it scars brain functioning—impacting reserve and resilience. The underlying pathological processes and cumulative damage lead to clinical symptoms. The dashed line depicts clinical symptomatology upon which diagnoses are dependent. This transitions from being subsyndromal to eventuating in illness. The troughs and peaks illustrate the seemingly episodic nature of the illness, as it traverses the threshold for clinical diagnosis.

this stage could hold potential to benefit long-term outcomes [50]. Therefore, targeting the developmental trajectory of anxiety and depression may be a productive prevention strategy, with a particular focus on early vulnerability markers.

'Prevention' vs treatment

Prevention is the reduction of risk factors and enhancement of protective factors prior to the onset of disease. Prevention interventions occur before the onset of a clinical episode and precede treatment interventions, and therefore, they lie intermediate on a continuum between health promotion and treatment [51, 52]. Effectiveness of prevention strategies appears to depend on the identification of risk factors for mood disorders and protective factors that produce resilience and defend against the development of mood disorders—even in extreme adversity. Treatment, on the other hand, is the reduction of disease-related symptoms and the enhancement of protective factors and is usually only prescribed once an illness has formed and a clinical diagnosis has been made.

However, the distinction between prevention and treatment is somewhat blurred. Some time ago, the Institute of Medicine recommended prevention should target only those with early symptoms that are not sufficiently severe to warrant a diagnosis of a mental disorder [53]. But this somewhat narrow definition overlooks a large pre-symptomatic group that may be at increased risk of mental disorders, and given our current understanding of the aetiology of mood disorders, waiting until symptoms emerge, apart from being less effective, may primarily be regarded as unethical—especially if timely interventions can be shown to have a substantial impact. An alternative perspective on the prevention of depression stipulates that for an intervention to be preventive, it has to show a post-intervention increase in depressive symptoms in the control group and either no increase or an attenuated increase in depressive symptoms in the intervention group [54]. This suggests that post-intervention, a reduction in depressive symptoms, in the absence of an increase or no change in depressive symptoms in the control group, may be indicative of a treatment effect, rather than a prevention effect (Fig. 68.3).

Rationale for prevention

The difficulty of diagnosing mood disorders in children and adolescents is widely acknowledged, and as a consequence, diagnostic criteria originally created for adults have been modified to capture mood disorders as they evolve in young people. But a lack of specificity and the variability in presentation mean that depression is often misdiagnosed and likely overlooked. Naturally, this impacts treatment decisions. The efficacy of drugs, in combination with psychotherapy, for the treatment of unipolar depression is well established, and medications are a key component of any treatment regimen for bipolar disorders. However, the long-term consequences of pharmacotherapy are yet to be fully determined, especially if commenced early in life [55–57]. For example, in the treatment of paediatric BD, pharmacological agents and cognitive behavioural, as well as interpersonal, therapies produce some benefit [intermediate effect sizes (ES)], but these are thought to be unsustainable over time [56]. Interestingly, randomized controlled studies of psychosocial treatments suggest they may be effective in delaying the time to relapse, facilitating mood stabilization, reducing the severity of symptoms of depression, and improving psychosocial functioning [58]. Intriguingly, such evidence points to the possibility that treatments, while ameliorating indicated symptoms, do not necessarily prevent the onset of mood disorders and the recurrence of future episodes, but instead may limit negative consequences. Therefore, while treatment is often regarded as having a preventive component, in actuality, true prevention is rarely achieved with treatment alone.

Evidence suggests that in primary care patients, prevention is more cost-effective than care as usual [59]. This is because the earlier the onset of mood disorders, the poorer the long-term prognosis—as demonstrated by a poorer overall quality of life, significantly dysfunctional interpersonal relationships, a greater number of recurrences, with shorter euthymic periods in between, greater comorbidity, and an increased likelihood of suicide attempts [60, 61]. Thus, it is no surprise that the most effective strategies to reduce the health burden of mood disorders are those most likely to prevent the onset of mood disorders, particularly in vulnerable young people [14, 60, 62–64].

Fig. 68.3 A comparison of the effects of prevention and treatment interventions in depressed patients vs healthy subjects. Vertical bars represent implementation of either a prevention or treatment strategy. Horizontal lines represent risk of depression during prevention, and clinical change in response to treatment. An intervention that is an effective treatment decreases depression in depressed patients but has no tangible effect on controls. An intervention that is preventive does not impact those that have already established illness (patients) but moderates the risk, and therefore reduces the likelihood, of depression in healthy controls.

Intended target of prevention strategies

The main aim of mood disorders prevention strategies is to reduce the likelihood of developing the disorders and, as discussed, the benefits should readily outweigh any potential risks [14]. When considering prevention strategies, it is important to understand for whom they are intended and how they would be implemented, but most critical is to identify the target for which they are aiming. In this respect, according to the Institute of Medicine report [53], prevention strategies can be grouped into three categories: *universal*, *selective*, and *indicated* programmes (Table 68.2).

Impact of prevention strategies

The success of a prevention strategy is determined by its outcome, but measuring this is a complex task. Gauging the efficacy or effectiveness of prevention approaches requires establishing clear outcomes, and unfortunately these are not easily defined. For instance, using a change in mood state as an outcome is not particularly useful in assessing universal and selective prevention strategies, whereas it is ideal for indicated prevention. This is because universal and selective approaches target intervention groups that may include those with low mood state levels from the outset and whose mood state changes are unlikely to be sufficiently large and clinically meaningful in comparison to other groups. This is because subthreshold depressive symptoms and syndromes seem to be prevalent (ranging from 10% to 50%) in community samples of youth who are the focus of universal and selective interventions [65–67]. On the other hand, the indicated approach will reveal clinically significant mood changes due to initial subsyndromal mood elevations in the intervention group, compared to other groups. Conversely, quality of life is an outcome measure that can be applied broadly across

different types of strategies, but because it is a very general measure that is only loosely coupled with the intervention itself, its utility, particularly in differentiating different prevention approaches, is limited. Therefore, the selection of outcome measures is critical. Furthermore, in the absence of clearly defined causal mechanisms, it is difficult to identify not only reliable and measurable outcomes, but especially the ones that have clinical salience. Another pertinent issue regarding prevention approaches is the number of people needed to show the benefits of an intervention, in other words, its ES. Across the various prevention strategies, the numbers vary, with universal strategies usually requiring much larger numbers and indicated prevention strategies generally requiring smaller numbers to demonstrate an effect [51].

Professional responsibility

Globally, mental health services (MHS) are often multi-disciplinary, and a number of different disciplines and professionals can assume responsibility for the prevention of mood disorders and the promotion of well-being. For instance, a social worker from child services may be in a position to monitor interactions within families and identify problematic interactions that may be addressed with specific strategies to prevent the escalation of maladaptive behaviours. Indeed, ideally, the delivery of interventions has to be multi-disciplinary but integrated [68]. However, careful justification is needed when considering prevention because there are significant financial implications that affect funding policies governing the distribution of resources and training needs across disciplines. However, the prevention of mood disorders has been positioned as a global priority, and its goals extend beyond the narrow strictures of interdisciplinary MHS [69]. For instance, the Australian

Table 68.2 Intervention programmes aimed at preventing or reducing mood disorders

Features	Universal	Selective	Indicated
Target	Intended for the general public or community, regardless of risk status	Target a subgroup that is at higher risk, based on biological, psychological, or social/environmental risk factors, for example offspring of depressed parents, those with traumatic or life events such as divorce, bereavement, those experiencing marital or family conflict	Target people who display subthreshold signs and symptoms of a given disorder. For example: For bipolar disorder—those in the prodromal phase exhibiting mood dysregulation, fluctuation of energy levels, and anxiety symptoms For depression—those with subclinical depressive symptoms (that do not fulfil the criteria of a diagnosis) Proximal to first onset/case identification and treatment
Impact	If successful, have a greater public health impact	If successful, have the potential to block the transgenerational transfer of mood disorders	If successful, can reduce the incidence of mood disorder onset and recurrences
Risk	Degree of individual risk is not taken into account	Risk may not always be imminent; it could be a lifetime risk	Risk is often imminent, needing swift attention
Risk/cost benefit	Ideal when their risk and cost are minimal	Preferred when the risk of the intervention is minimal or non-existent while the cost is not too high	Intervention would be deemed necessary, even if the risk and cost of the intervention are high
Examples	School-based and community/primary interventions, for example PRP [93, 94], mindfulness-based interventions [115, 116], beyondblue [123], PSL [95], PRP [143], CB and IP interventions [144]	Parenting focused and family-based interventions, for example ROSE programme [72], Preparation for Parenthood/Surviving Parenthood [145], FOCUS [76], EFFEKTE-E [77], FGCB [78], Family Options [79], KFS [80], FTI [81, 82]	** School- and family-based CBT interventions, for example [87, 96, 113]; Effective Child and Family programme [83, 105, 106], ** STERK [142]

** This is an ongoing intervention evaluation protocol.

Government National Standards for Mental Health Services [70] recommended that MHS should identify individuals who are ‘*accountable for developing, implementing and evaluating prevention activities*’, while ensuring adequate training in the principles of prevention for the workforce, with appropriate support provided for the implementation of prevention activities. However, it is not clear how these individuals can be identified. Likewise, the EU Compass for Action on Mental Health and Well-being—Prevention of Depression and Promotion of Resilience, in its consensus paper, has promoted intersectorial collaborations between the health, educational, labour sector, informational technology, and economic stakeholders and the building of capacity through training in order to tackle and alleviate the burden of depression in Europe. But in practice, it is possible that any number of individuals can be identified for such roles, and those need to be determined on the basis of implementation requirements [31] (Fig. 68.4).

Lastly, prevention has to be targeting specific individuals or groups, and in that case, the contexts under which the prevention will be implemented, for the individual/parents/extended family members/peers/colleagues/schools/communities, have to be well understood. In this regard, the developmental and contextual framework that determines when and how interventions are implemented has to be taken into account. For instance, the National Research Council [14] recommended that besides multiple contexts, age-related patterns of

competency and disorders and developmental tasks, as well as the interactions between biological, psychological, and social risk factors, have to be taken into consideration when designing prevention interventions.

The section on Preventative interventions, p. 706, illustrates the complexity of difficulties faced when making these considerations, with a summary of interventions implemented to date that directly or indirectly target the earliest developmental stage, that is, youth, and the setting under which they were implemented.

Preventative interventions

Parenting and family-based interventions

Parenting and family-based interventions target parents or the family as a unit in order to reduce risk factors and enhance protective factors in the offspring. This encourages changes in maladaptive parenting skills, attitudes to parenting, and interactions between the parent and the child. Therefore, adaptive parenting skills and functional parent–child interactions are crucial at very early stages of child development and can be commenced perhaps during pregnancy and early infancy, so that parents can be prepared emotionally and feel capable of nurturing their offspring and providing an environment that fosters secure attachment. Thus, early childhood

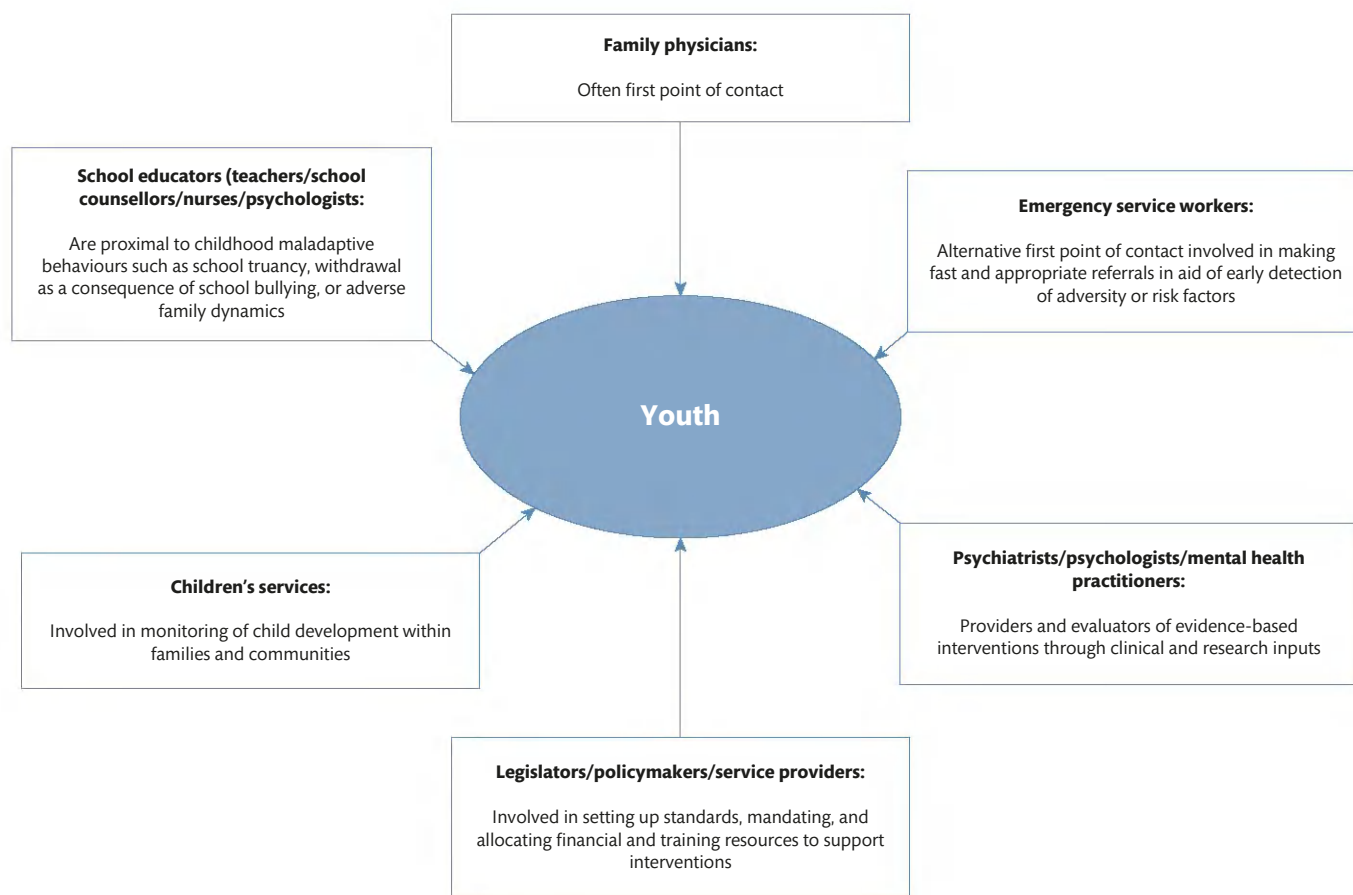

Fig. 68.4 Professionals that have the potential to contribute to the prevention of mood disorders. Six groups of professionals, among others, have the potential to directly contribute to the prevention of mood disorders. Where possible, those involved should be working collaboratively and ideally targeting youth populations.

environments and social networks have been identified as critical in shaping emotional development because strong social supportive relationships and networks determine positive and enduring mental well-being that extends to adulthood [27]. The ultimate aim of these interventions is to limit the transgenerational transmission of mood disorders, and several interesting strategies have been developed to achieve this goal.

Core features of parenting and family-based interventions include enhancing resilience, building of interpersonal relationships and supportive networks, parental skill enhancement, and problem-solving, as well as raising awareness of the impact of mental disorders on the individual and the family, particularly the offspring. In this regard, it is encouraging to note that prevention interventions can be implemented at very early stages of development, that is, during prenatal and perinatal stages, and can restrict maladaptive or enhance adaptive parenting skills so as to modify neurocognitive development in offspring [71]. Indeed, an example of such an intervention is the Reach Out, Stand Strong, Essentials for new mothers (ROSE) programme that targets disadvantaged pregnant women deemed to be at risk of post-partum depression [72]. The ROSE programme intervention is an interpersonal therapy (IPT)-based intervention that puts emphasis on building supportive interpersonal relationships. While limited by a very small sample size, the larger reduction (20%) in parental incidence of depression in the intervention group, compared to the smaller reduction in the comparison antenatal-only group (4%), is supportive of the potential utility of such interventions. Furthermore, psychosocial and interpersonal postnatal depression prevention strategies focusing on the perinatal phase may at least reduce the incidence of postnatal depression, a promising finding for infant well-being and development. Indeed, recent evidence for a direct and sustained effect of perinatal maternal mood on the offspring's neuropsychological development is strong and has prompted for calls for *in utero* programming and activation of the stress-immune systems [19, 21, 73]. Although promising, the specific effects of such interventions on offspring mood states are not known, as the follow-up periods in most studies have thus far tended to be relatively brief—lasting typically no more than 6 months. Therefore, longer-term follow-up of offspring cohorts is urgently needed to initially verify and then quantify these effects.

Fostering adaptive interactions between parents and their adolescent offspring requires different parenting approaches to those employed in rearing infants and children. To identify parenting strategies that could potentially prevent depressive and anxiety symptoms in adolescent offspring, a poll of experts was undertaken using the Delphi Consensus method [74, 75]. This identified parenting strategies, such as establishing clear ground rules and consequences, establishing and maintaining a good relationship with the adolescent, and showing affection, as important. These strategies could be used in a manualized format, targeting parents as a checklist that they employ to help monitor their own behaviours in the implementation of interventions.

Families at risk interventions

Evidence from other parenting and family-based interventions of families at risk because of the presence of parental depression seem to show short-term benefits on the functioning of the family as a unit. These interventions do not target the offspring but instead target parents with children aged 18 months to 18 years, for

example the Families OverComing Under Stress (FOCUS) intervention for youth aged 3–17 years [76]; *Entwicklungsförderung in Familien: Eltern- und Kinder-Training* in emotional belasteten Familien (EFFEKT-E) intervention for children aged 4–6 years [77]; Family Group Cognitive-Behavioural (FGCB) for youth aged 9–15 years [78]; Family Options for children and adolescents aged 18 months to 18 years [79]; and Keeping Families Strong (KFS) intervention for youth aged 9–16 years [80]. The core features of these interventions are problem-solving and skill building, mainly parenting and coping skills, as well as providing psychoeducation on various issues related to depression and its impact on the affected individual and the rest of the family, particularly the offspring. This, in turn, raises awareness and possibly tolerance, thus enhancing resilience and minimizing maladaptive stress responses.

Generally, these interventions show short-term benefits for both the children and their parents, with reductions in parental depressive symptoms and an increase in the offspring's prosocial behaviours and emotional expression that are mediated by ameliorating parental depression. However, one intervention evaluation did not have child-specific outcomes [79], and another showed improvements in child behaviour within the family that could not be transferred to the school environment where an increase in school maladjustment was seen [80]. The FGCB intervention, based on clinician ratings of mood changes, showed sustained benefits lasting 24 months, while the Youth Self-Report (YSR) measure showed intermittent and inconsistent benefits that could not be explained [78]. It could be that the sensitivity of the outcome measure might be crucial in the detection of changes.

Family therapeutic interventions (FTIs) target both mentally ill parents and their offspring aged 8–17 years [81–83]. These interventions employ CBT and psychoeducation components. Generally, these interventions have been shown to produce variable effects on mood state. For instance, FTIs produced inconsistent improvements in mood that were short term [83]. Interestingly, it is possible that these were mediated by improvements in anxiety, which often precedes depression and is thought to increase its likelihood and advance its onset to an earlier age [84]. Therefore, perhaps measures of anxiety should be routinely included when evaluating outcomes of prevention interventions [85]. However, FTIs also seem to have widespread effects in reducing risk and increasing protective factors of mood disorders through facilitation of a stronger child–parent relationship. Such improvements in family functioning have been shown to be sustained for up to 5 years, but this effect is not specific to FTIs and can also be achieved through brief parental psychoeducation [81–82].

CBT-based interventions have also been shown to have sustained reductions in the incidence of depression that is detectable for up to 75 months post-intervention and is moderated by baseline parental depression [86]. This means that, for maximum benefit, it might be prudent to treat parental depression prior to the initiation of prevention intervention programmes. Perhaps the successful treatment of parental depression fosters an environment that facilitates the preventative effects of interventions on depression. Interestingly, this series of evaluations [86–88] also seem to suggest that overall a smaller number of adolescents need to undergo an intervention to prevent the onset of depression (NNT = 9 at 9 months to NNT = 6 at 33 months). However, these findings have to be interpreted with caution because the inclusion of adolescents with a prior history of

depression might, to some extent, be responsible for the observed intervention effects—obfuscating whether the intervention is truly preventative or simply therapeutic.

School-based interventions

There have been an increasing number of school-based interventions in the last two decades, with similar overarching principles. Primarily, they are aimed at preventing the development of mood disorders, particularly depressive disorders in children and adolescents. School-based interventions offer advantages over other intervention settings because they provide ready access to large groups of young people and also remove some of the physical and economic barriers to access of services that usually limit their uptake [89]. School-based interventions, such as the CBT-based Penn Resilience Program (PRP) intervention, beyondblue, Problem Solving for Life, Resourceful Adolescent program, Positive Thoughts and Actions, and mindfulness-based programmes, have been implemented with varying degrees of success (Table 68.3). Each of these interventions has a number of core characteristic features, with some modest variations, involving mostly universal or targeted (selective and indicated) approaches. A selection of some recent interventions illustrates these similarities and differences.

Penn Resiliency Program

The PRP [90] is the most evaluated CBT- and strength-based prevention programme designed for children and adolescents aged 10–14. It is aimed at increasing resilience, reducing depressive

symptoms, and preventing the development of depressive disorders. Typically, it is a 12-week programme focused on changing cognitions, linking these to emotions, challenging negative explanations for events, handling and resolving conflict, problem-solving, and coping strategies, with weekly homework assignments between sessions. It is primarily a school-based intervention but has been evaluated in other settings such as primary care clinics. Its effectiveness seems to be independent of the expertise of the personnel leading its implementation, although the effects are slightly larger when implemented by research leaders than trained community leaders. It has been evaluated both as a targeted and as a universal intervention programme, and the former seems to be more beneficial [91–94].

Problem Solving for Life

The Problem Solving for Life (PSFL) [95] intervention is a universal intervention that is teacher-led and incorporated into the school-term schedule. It is offered in weekly sessions over an 8-week period during a term, with each session lasting for 40–50 minutes. All sessions use various teaching methods, including interactive exercises, diary keeping, homework assignments, and the use of cartoons and class discussions. The intervention focuses on integrating cognitive restructuring and problem-solving. Targeted core skills include the identification of cognitive styles and challenging maladaptive problem-solving tendencies by teaching life problem-solving skills, enhancing the development of a positive problem-solving orientation, and optimistic thinking styles [95].

Table 68.3 Examples of school-based programmes

Programme	Prevention type	Age range	Programme content	Comparison programme	Number of sessions	Evaluation duration	Author
Penn Resiliency Program (PRP)	Selective (high risk based on low socio-economic status)	10–13 years	CBT-based manualized group intervention	No intervention	12	Up to 12 and 24 months	[91, 92]
PRP	Universal (girls only and co-ed)	11–14 years	CBT-based	Co-ed no intervention	12	Up to 12 months	[93]
PRP	Universal	11–14 years	CBT-based	Penn Enhancement Program (identification of depression-related stressor) or no intervention	12	Every 6 months up to 3 years	[94]
Problem Solving for Life (PSFL)	Universal	12–14 years	CBT-based	Monitoring control	8	Up to 1 year	[95]
Resourceful Adolescent Program (RAP)	Universal (RAP-Adolescent or RAP-Parent)	12–15 years	CBT	Adolescent Watch (no intervention)	RAP-A: 11 RAP-P: 3	Up to 10 months	[97]
RAP-Kiwi	Universal	13–14 years	CBT and IPT	IPT only	11	Up to 18 months	[96]
beyondblue	Universal	13–14 years	Multicomponent	Community focus	10	Annually for 3 years and up to 5 years	[122, 123]
	Selective (attributional styles) Indicated (subthreshold depressive symptoms)	14–15 years	Adaptive coping skills training, enhancement of self-esteem and personal development	Assessment only conducted at beginning and end of active intervention	14	6 and 12 months	[105, 106]
Positive Thoughts and Action (PTA)	Indicated (subthreshold depressive symptoms)	12–14 years	CBT	Individual Support Program	12	6 and 12 months	[99, 100]

The Resourceful Adolescent Program

The Resourceful Adolescent Program (RAP) [96–98] is a universal school-based intervention designed for adolescents (RAP-A) and their parents (RAP-P). The RAP-A component is fully manualized and implemented by school personnel at baseline during classes to groups of adolescents, aged 14–15, in Year 9. It is implemented in 11-weekly sessions per term, with each session lasting for 40–50 minutes. It is strength-based to enhance resilience through implementation of CBT and interpersonal therapy techniques. The focus is on stress management, cognitive restructuring, problem-solving, managing and resolving conflict, and building supportive networks. The RAP-P component is offered to parents of a cohort of adolescents and is usually delivered as a series of two separate 2- to 3-hour long workshops. The focus is on building parent's strengths, stress management, examination of parental roles in the development of their adolescent children while promoting positive family relationships, and conflict management and resolution.

Positive Thoughts and Action Program

The Positive Thoughts and Action Program (PTA) [99–100] is a manualized indicated prevention programme that is developmentally sensitive, targeting early adolescents. It is a CBT-based group intervention, focusing on cognitive style, problem-solving, coping skills, and the application of learnt skills in social functioning and behaviours. It is implemented in weekly sessions lasting 50 minutes in groups of 4–6 adolescents. Parental involvement is encouraged via two home visits with the child and parents, as well as parent workshops. Parent workshops involve psychoeducation regarding adolescent development and skills training.

Beyondblue intervention

The beyondblue intervention [101] is a flexible universal intervention established as part of the national depression initiative in Australia that fosters a stronger partnership between health and education services. It is implemented to Year 8 adolescents aged 13–14 years and follows them up for the next 3 years, in each year building on skills that have been previously taught and learnt. Each year, adolescents participate in 10-weekly classroom sessions lasting for 30–40 minutes. The intervention has four core features. It is a curriculum intervention, which is focused on building supportive environments, while building pathways for care and education and the use of community forums. As a curriculum intervention, it promotes well-being and enhances core skills and resilience. During the classroom sessions, core skills are taught in an interactive manner with the use of role plays, videos, quizzes, group exercises, and discussions. Core skills include problem-solving, conflict resolution, assertiveness, stress reduction, social skills, emotional education, self-efficacy and awareness, building of positive expectations of self in relation to the world and the future, greater understanding of mental health problems, and capacity to seek help.

Summary

The PRP intervention effects have been variable, with some evaluations revealing short-term benefits that are not sustainable in the long term, while others have shown longer-term benefits for up to 2 years. Interestingly, the longer duration of benefits seems to depend on the presence of subthreshold symptoms at baseline and their severity. This raises the question of whether the PRP was preventative

or merely a treatment of mild depressive symptoms, which, in turn, raises issues regarding conceptualization as a determining factor in prevention vs treatment. Furthermore, the strength of intervention effects seems to be dependent on symptoms at baseline, with stronger effects in those with subthreshold symptoms at baseline and only trend effects in those who are asymptomatic. It has also been suggested that the most reliable PRP effects are produced in research settings when the intervention is implemented by the developers and their expert colleagues. This means that while it is efficacious, its effectiveness is questionable. However, it does seem to have potential for those with mild to moderate depressive symptoms.

The PSFL intervention has also been shown to be superior to monitoring in the short term, with reductions in depressive symptoms that are clinically equivalent to the normative sample. The use of the Beck Depression Inventory (BDI) as an outcome measure in non-clinical populations has not been promoted due to questionable sensitivity in this population group [102, 103], but there is a possibility that booster sessions might have been helpful in maintaining benefits from the initial intervention.

Although, conceptually, the beyondblue intervention has multiple components, each of which is evidence-based, it failed to show effectiveness in reducing adolescent depressive symptoms or improving their well-being. It could be that, while the efficacy of the cognitive and IPT-based components of the intervention is somewhat established, efficacy of the building pathways for care and education and community focus components is largely unknown. Therefore, the effects of these components, separately and combined, have not been well tested and estimated. However, a meta-analytic review has suggested that the programme content does not moderate intervention effects [104]. Perhaps, with so many components to address, ten sessions per term is too conservative and does not allow for an in-depth exploration and analyses of all the issues raised by participants to their satisfaction. Another challenge brought to the fore is the need for adequate and in-depth training of teachers to implement the intervention with fidelity, which requires significant resources. This further highlights the difficulty of incorporating and integrating such complex multicomponent interventions within the school setting.

Contrary to this, a selective (based on the presence of a cognitive risk factor—attributional style) and indicated (based on the presence of subthreshold depressive symptoms) prevention programme targeting adolescents aged 14–15 years was successfully implemented in a school setting in Iceland [105, 106]. The intervention was aimed at enhancing adaptive coping, self-esteem, and personal development, while the comparison was only an assessment conducted at the beginning and at the end of the active programme, although participants in this intervention were allowed to seek treatment elsewhere at any time, if needed. It was implemented by school psychologists and regular school staff trained in its implementation and assessment procedures. This intervention showed no new episodes of depression/dysthymia in the intervention group, compared to a 2.5% increase in the usual treatment group, and at 6 and 12 months' follow-up, there was a 1.6% and 3.92% increase, respectively, in new episodes of depression/dysthymia for the intervention group, compared to a 13.3% and 20.97% increase, respectively, in the treatment as usual group. This increase was twice and three times as large in females, compared to males, at 6 and 12 months. This evidence suggests that sustained gains in the prevention of the onset

of depression/dysthymia can be achieved with an intervention that enhances adaptive coping and personal development. The authors also identified the age of 14 years as potentially a good age to commence preventive intervention in those at high risk. Interestingly, this tallies with neurobiological research that shows the biggest changes occurring in 15-year-old girls with emotional symptoms—thought to be antecedents [107]. By using school personnel for the implementation of the programme, the authors point to its potential for real-world utility and effectiveness in significantly reducing the onset of depression, further bolstering the potential of targeted interventions in preventing or possibly delaying the onset of depression/dysthymia by at least a year.

The universal implementation of the RAP intervention is considered to have the potential to either shift about 13% adolescents out of depression or prevent them from developing subclinical or clinical depression, at least within 10 months of receiving the intervention. However, although well tolerated by adolescents, teachers were less optimistic about the programme, stating the manual was restrictive and inflexible for addressing the unique needs of individual classes. Furthermore, the intervention effects seem to vary, depending on the outcome measure used. For instance, although both the self-report Reynolds Adolescent Depression (RAD) scale and the Beck Depression Inventory-II (BDI-II) revealed initial intervention benefits, only the RAD revealed sustained effects to 18 months post-intervention. This again perhaps points to a lack of sensitivity of BDI measures in non-clinical populations. However, the results have to be interpreted with some caution because the analysis was performed based on the assumption that the intervention would be more beneficial than placebo. The presence of some deterioration in mood state for both interventions over time may suggest that such an assumption was premature. Statistical analysis should have taken this possibility into account but has likely compromised the detection of intervention effects.

A recent systematic review and meta-analysis of school-based interventions for depression only and depression and anxiety, respectively, have revealed very small and short-term intervention effects that are seemingly influenced by the type of prevention and the proficiency of the personnel delivering them [89]. In terms of how long the effects last for, on average, they tend not to last for more than 24 months; indeed, the effects are stronger immediately following the intervention ($ES, g = 0.23$), reducing to $g = 0.20, 0.12$, and 0.11 in the first 6 months, 6–12 months, and over 12 months, respectively. It is not clear whether it is loss of power to detect long-term effects or a natural process of decline that explains the loss of benefit over time. If it is the latter, then perhaps booster sessions may be necessary to maintain improvements long term. However, if the issue is simply that of the studies being underpowered, then there is a need for further evaluations that are suitably powered to gauge long-term effects involving larger numbers of subjects. Alternatively, other measures that can perhaps detect more subtle changes over time with relatively smaller numbers may be trialled. Interestingly, a recent Cochrane review of CBT- and IPT-based interventions has revealed short-term benefits lasting no more than 12 months, and an estimated number to treat of 11, which is comparable to other public health interventions [108].

Internet-based interventions

Emerging evidence from the few Internet-based interventions reveal moderate to large effects of the intervention on reducing depressive

symptoms that are sustainable for 2.5 years. For instance, the targeted Competent Adulthood Transition with Cognitive Behavioural and Interpersonal Training (CATCH-IT) intervention for adolescents and young adults aged 14–21 years was developed to establish strategies physicians could use to actively engage young people at risk of depression [109–112]. As a behaviour change and resiliency-building Internet-based intervention, it was implemented by physicians offering motivational interviewing (MI) or brief advice (BA). Both interventions elicited prevention and treatment effects, with an increasing percentage of symptom-free individuals from baseline to 12 months and reductions in clinically significant depressive symptoms over the 2.5-year follow-up. Furthermore, when comparing the CATCH-IT to reported face-to-face cognitive behavioural-based interventions, it was revealed that they produced larger effects, with a lower NNT for depressive episode (Internet NNT = 4.79 vs face-to-face NNT = 11.4) [113]. Also, CATCH-IT produced large effects ($ES\ 0.96$), compared to face-to-face interventions ($ES\ 0.51$) [113]. These ES are comparable to BDI-measured treatment effects in adults [114].

Mindfulness-based interventions

Mindfulness interventions are based on adult mindfulness-based stress reduction (MBSR)/mindfulness-based cognitive therapy (MBCT) principles and were implemented in a cluster of 50 schools in Belgium [115] and in Australian schools [116]. During sessions, guided and unguided mindfulness practices and relaxation were taught, followed by manualized homework exercises. Practices included breath counting, stopping and being present, mindfulness of daily activities, for example walking or watching thought traffic, two guided audio (9 minutes long) of seated and lying body scans, and breath awareness. The control arm involved normal curricular activities.

Interestingly, mindfulness has significant and sustained beneficial effects on self-report depressive symptoms, at least in the short term of 6 months' duration, suggestive of preventative and treatment features in Belgium studies, whereas none of these effects were seen in Australian studies. It could be because the Belgian cohort was slightly older than the Australian cohort (14–17 years vs 12–14 years) [115, 116]. The developmental trajectory of mindfulness is not fully understood, and it could be that younger participants are at a different developmental stage and are not ready, or able, to process and use the concepts of mindfulness. Furthermore, in the Australian study, mindfulness seemed to produce anxiety [116]. The increase in anxiety in the mindfulness intervention group might be associated with, or driven by, an increase in ruminative processes where attention is perhaps drawn to issues that would normally be ignored or avoided.

Universal vs targeted interventions

In general, universal interventions produce smaller effects ($g = 0.19$), compared to targeted interventions ($g = 0.32$), and indeed a systematic review revealed that targeted CBT-based interventions produce moderate to large ES (ranging from 0.21 to 1.40) [117]. Interestingly, these effects were achieved only when the intervention was delivered by mental health professionals, while teacher-led interventions produced significantly smaller effects, suggesting that the personnel delivering the intervention and, in particular, the extent of their training contribute to the effects. Specifically, school-based

personnel achieved the smallest effects ($g = 0.17$) and their experience was variable. This is potentially problematic because it could encourage reluctance to incorporate and embed such interventions within regular school schedules where teachers and school counsellors have to invest a lot of time in class preparation, training, and supervision for relatively small gains. It has also been suggested that the magnitude of these effects may be influenced by the gender composition of participants, along with their age, and the duration of intervention. Thus far, larger effects have been seen with interventions involving more females, older adolescents, and shorter-duration programmes with homework assignments.

At the same time, it has been argued that regardless of the fact that the effects are small, they can potentially translate to meaningful improvements at a population level, with enormous implications for preventing the onset of mood disorders. Indeed, it has been shown that up to 9 months, implementing preventative interventions reduces the risk of developing depression, with RR 0.45, 0.61, and 0.79 for universal, selective, and indicated interventions, respectively, although the indicated intervention maintains reductions up to 18 months (RR = 0.23) [118]. This therefore supports the notion that, despite the smaller ES of universal interventions in reducing depressive symptoms, they may have greater utility in preventing the onset of depression. Hence, a combination of both universal and targeted interventions is needed.

Evaluation duration

There is a growing need for long-term evaluations not only because the long-term sustained effects of prevention interventions have been variable, but because the initial effects of interventions have been shown to surface years later, during subsequent developmental phases, possibly because of having been missed earlier at times of greater 'noise' [119]. Perhaps initial intervention effects are masked by other processes or events occurring simultaneously, such that when emotional stability and maturity have been achieved, they re-emerge. Indeed, in one series of studies, intervention effects on risky behaviour seen at age 13, were no longer discernible for 4 years and then resurfaced at age 18 [28, 29]. This poses the quandary of whether initial intervention benefits need to be demonstrated before one can have some confidence in their likely downstream effects. Naturally, in the absence of initial benefits, one would assume that the intervention was not successful. The other point to consider regarding duration is the possibility that prevention interventions may not necessarily prevent the onset of mood disorders but may merely delay their onset [120]. If so, it remains to be seen how long this delay is in reality, and thus intervention evaluations may provide evidence for this alternate hypothesis. Furthermore, longer-duration evaluations may also reveal whether intervention effects decay after a while, and the potential of interim booster sessions to reignite intervention effects that may well be on their way to decay, and whether the strength of initial benefits determines the rate of decay.

Age effects on interventions

The question of when to intervene or which age to target is a separate question that seems to be dependent on the content of the intervention. For instance, evidence from mindfulness-based interventions seems to suggest intervention efficacy in later adolescence (14–17 years), compared to early adolescence (12–14 years) [115, 116]. This is most likely because the concepts of mindfulness are too

complicated for younger adolescents to comprehend and process. On the other hand, other school-based interventions that are largely based on cognitive behavioural techniques reveal stronger effects among children ($g = 0.50$), compared to early adolescents ($g = 0.23$) and older adolescents ($g = 0.22$), although the sample of interventions targeting younger children is relatively small [89]. Together, it suggests that each type of intervention is likely to be age-specific.

Conclusions

The evidence from school-based interventions does not seem to be as strong as initially envisaged. Indeed, numerous null findings and non-significant trend effects have been reported [94, 121–123]. Factors contributing to the inconsistencies need clarification to help improve future prevention endeavours.

At the same time, while universal interventions produce the smallest short-term or intermittent effects, targeted interventions seem to produce the largest ES. Furthermore, it seems that ES are dependent on the type of intervention, and also, there may be an issue with the reliability and sensitivity of outcome measures that fail to detect significant effects but tend to reveal non-significant trend effects. Furthermore, intervention effects tend to be short term, and those showing sustained effects tend to be indicated, rather than selective and universal interventions. Only a few have revealed truly prevention vs treatment effects; only targeted interventions show small numbers needed to treat. When to intervene and the possible need for booster sessions to sustain long-term benefits need further clarification.

Future directions

It is clear that the potential for prevention interventions is largely untapped. This is due to several reasons. Firstly, the issue of whether to intervene universally or to target specific populations remains unclear, despite superior gains from targeted interventions, as compared to universal interventions. This is because the nature of mood disorders is unpredictable. For example, although it can be predicted, with some confidence, that those who have parents with depression or have been themselves exposed to childhood adversity are more likely to develop mood disorders at some point in their lives, not everyone with these risk factors will go on to do so. On the other hand, there are many who develop mood disorders but have not been seemingly exposed to these risk factors. But prevention should aim to benefit both sets of individuals—those at high risk who go on to develop mood disorders and those at low risk who happen to develop mood disorders because of factors that are as yet unknown. Clearly, both groups should benefit from intervention, and hence the need for both targeted and universal interventions.

Specifically, in order to target only those who need the intervention, it has been suggested that a multi-level, integrated approach to prevention is needed—one that takes into account the multitude of key risk and protective factors [31, 88]. But this approach, aimed at enhancing resilience, needs to be dynamic and contextual, because each developmental stage is characterized by the emergence of new risks that may override or negate earlier protective factors, necessitating ongoing adaptation [119, 124]. Indeed, although exposure to regular and controlled stress is necessary for adaptation, the development of effective coping strategies, and maintenance of

allostasis, it is when the stress is uncontrollable, irregular, and unpredictable that allostatic overload and ensuing problems arise, and are qualitatively compounded by environmental factors and individual differences such as genetic disposition and personality traits [23]. This is particularly relevant to children and adolescents who have to be taught the best ways of dealing and coping with stress in different contexts. For instance, when taught strategies that are maladaptive or that become maladaptive in a particular context, a flexible and integrated approach is needed for countering elicited stress. This is because prolonged exposure to stress potentially results in cumulative damage that is undetectable at first but causes subliminal pathological activity that eventuates in mood disorders. Therefore, neurobiological and psychosocial processes provide important substrates that underpin the integrated approach to prevention [119, 124]. Remarkably, to date, prevention approaches have focused largely on psychosocial aspects of mood disorders.

There is also an incentive to target the prodrome of mood disorders, because the benefits of intervention reductions in subclinical symptoms may be easier to measure. This reduction is presumed to reflect a slowing of any underlying process, thereby delaying the onset of the disorder or instigating the expression of a full-blown episode. However, a reduction in symptoms is perhaps more of a therapeutic than a preventive effect. Furthermore, delaying to intervene until prodromal symptoms present might also be too late to enact, 'true prevention'—that is, preventing the initiation of underlying pathological processes. Such subtle underlying pathological activity is undetectable using current tools and measures. However, recent technological advances bode well for the prevention of mood disorders, and perhaps it is time to shift towards more sensitive and specific measures that are able to target the underlying pathological activity before it escalates and leads to a mood disorder [23]. Lastly, there are ongoing protocols that address some of the limitations in previous intervention protocols such as the inclusion of quality of life and cost-effectiveness measures as outcomes. Also, the computation of a high risk index (HRI) as a measure of risk loading might be a useful tool to use for stratification.

Contributions from genetic studies

A potential avenue that is yet to be fully understood is the genetic contribution to the risk of mood disorders. The evidence accumulated from studies of candidate genes and single-nucleotide polymorphisms (SNPs) provided no clear answers, largely because of the clinical heterogeneity of mood disorders and the large numbers of data points required for such investigations.

However, in recent times, with the use of much more powerful genome-wide association studies (GWAS), genetic risk prediction scores for individuals can be obtained that may well lead to new strategies for understanding and preventing mood disorders [125, 126]. For example, the polygenic risk score (PGRS) is a 'measure' that can be obtained by aggregating effects of SNPs (alleles) associated with disease status present in each individual, and this can be robustly applied to small samples [126–128]. Using this approach, PGRS has been applied prospectively to predict the risk of BD where the PGRS was found to be higher in high-risk young individuals (offspring and siblings of individuals with BD), compared to controls, and to provide a useful means of identifying traits linked to the genetic risk of mood disorders [20, 129–132]. The potential

to apply the PGRS as an outcome measure in prevention interventions has already been demonstrated in medical conditions. For example, in a 10-year coronary heart disease risk study, those receiving statins had a significant (3%) reduction in relevant PGRS, compared to controls. Similarly, in a 30-year risk of cancer, a lifestyle change (stopping smoking) had a significant (5.4%) reduction in PGRS. Importantly, these reductions were seen in those with a high PGRS score, compared to those with a moderate score. Furthermore, the risk threshold for screening for breast and colon cancer has been found to be reached much earlier by those with a high PGRS and family history of the disease [133]. Therefore, primary prevention strategies could potentially be facilitated by incorporating PGRS and other biological factors to identify those at different levels of risk of developing mood disorders. In other words, interventions could be tailored according to risk [133]. Furthermore, modification of the PGRS and, in turn, gene expression through psychosocial interventions serves as demonstration of the impact and importance of epigenetic processes. However, ethical, legal, and organizational considerations affecting the perception of genetic testing would have to be explored and addressed in order for polygenic predictions to be widely adopted in clinical practice.

Filling in the gaps

The missing link in prevention programmes that may contribute to the less than robust effects of interventions on measured outcomes could also be the use of more sensitive and possibly reliable outcome measures targeting individual biology. While social processes are fluid and changing practically on a daily basis and self-reported functioning may be biased, other measures targeting biomarkers may be more subtle and stable. It has been suggested that identification of blood biomarkers for mood disorders may provide more specific and sensitive outcomes measures, while other potentially promising biomarkers of both resilience and vulnerability include measures of hypothalamic–pituitary–adrenal (HPA) axis dysregulation, oxidative stress, inflammation, autonomic responses, telomere length, and epigenetic profiles [15, 16, 23, 134]. Indeed, the course of stress exposure may not always be current or traumatic in its intensity but often can be traced to the prenatal period which seems to prime future neural and physiological responses, and these effects may persist throughout life [23]. The use of such measures in conjunction with the PGRS may eliminate the inherent problems of deciding who to target, irrespective of the risk status, whether at increased or low risk at the time of testing. Thus, in this context, the ultimate aim of prevention is not just to prevent the behavioural and clinical manifestations of mood disorders, but also to go deeper and redress or modify imbalances at cellular, neural, psychological, and behavioural levels. Indeed, there is potential utility in targeting significant mediating biomarkers for depression such as oxidative stress and inflammation, for instance with lifestyle changes and increasing the consumption of antioxidant-rich foods and omega-3 fatty acids and engaging in regular, but moderate, physical activity, along with ensuring adequate production of melatonin through sufficient sleep, but there are several problems that need to be solved to make these measures viable. Research in this area is still in its infancy and possibilities for the prevention of mood disorders are emerging; therefore, these investigations are crucial [135–137].

When to intervene

At the same time as considering what to intervene with, the timing of any preventative measures is a key decision—for which there is no clear answer. Should preventative measures be instituted in early or middle childhood, or later still in adolescence, or are there specific critical periods that yield the most beneficial outcomes? Perhaps a standard cannot be developed and instead it is necessary to tailor interventions to individual needs based on specific risk markers. This would also mean that monitoring and follow-up adopt a personalized approach. Driving the need for prevention/early intervention is the fact that the cumulative effects of stress exposure are increasingly damaging, the longer they are present; and the earlier an intervention is instituted, the greater the potential long-term benefits [15, 16]. Prevention strategies that have been used so far, with variable success, include mindfulness- and CBT-based interventions, IPT interventions, psychoeducation, and skill training (parenting, coping, and problem-solving skills). Mindfulness prevention techniques have produced less than robust effects with respect to depression, and research thus far suggests that late adolescents may benefit more than early adolescents [115, 116]. However, understanding the mechanism of action and targeting those mechanisms may be more efficacious than self-reported mood changes. It has recently been revealed that mindfulness exerts effects on enhancing self-regulation through neuroplasticity changes in several brain regions implicated in mood disorders and their development, including the anterior cingulate cortex (ACC), the insula, the temporo-parietal junction, fronto-limbic connectivity, the default mode networks (DMNs), and grey matter volume (GMV) increases in neural structures involved in emotion regulation, learning, and memory [88, 138–140]. This burgeoning body of research provides further evidence for the need to incorporate biological consequences of interventions in the evaluation of such prevention strategies, and their potential to identify when responsiveness to interventions occurs in the developmental trajectory.

Model generation

While our understanding remains incomplete, working models of the emotional mind are important but need to be constantly reviewed as new knowledge comes to light. It is therefore necessary to refine the models underpinning prevention interventions, so as to integrate neurobiology, neuropsychology, and social aspects of depression/mood disorders. For instance, if there are intervention gains in depression but not a significant mediator on which the intervention is based, for example cognition, or there is a change in cognition but not depression, then the accuracy of the original model and the sensitivity, reliability, and validity of the outcome measures need to be modified [104]. In this vein, it has also been posited that ‘*identification of genetic variants and understanding the molecular mechanisms may lead to prevention strategies aimed at correcting molecular disturbances in the pathways that lead from genes to behaviour, including the molecular pathways that underlie the effects of known risk factors for the disorder*’ [14]. However, scrutiny of recent systematic reviews and meta-analyses of various approaches for the prevention of depression in children and adolescents published in the decade since this proposal was made reveal a huge gap that has not even begun to be narrowed [63, 89, 108,

117, 118]. Fundamentally, integration of our knowledge is lacking, and common and consistent approaches are yet to be developed and agreed upon. It may be that such endeavours are under way, but based on the few published protocols of ongoing evaluations, this seems unlikely [141, 142]. Therefore, renewed efforts are needed that integrate the use of biomarkers and epigenetic processes, with a view to developing a robust and testable model that traces the developmental trajectory of mood disorders within a meaningful ecological framework. Ultimately, our focus and energies to such an approach is long overdue—especially given that success in preventing mood disorders is too great an opportunity to ignore.

Basic mechanisms of and treatment targets for bipolar disorder

Grant C. Churchill, Nisha Singh, and Michael J. Berridge

Introduction

In our coverage of this area, we emphasize depth, rather than breadth, and focus on current leads in the basic mechanisms underlying bipolar disorder and its treatment targets, suggested by recent advances, and place these against a background of historical concepts. For more encyclopaedic accounts, we point readers in the direction of the excellent reviews available [1–3]. We take as our starting point the mechanism of action of a drug (lithium) of known efficacy and translate this information into a biologically meaningful and unifying working hypothesis, in which all molecular defects and treatment targets for bipolar disorder are directly or indirectly linked to calcium signalling. We will illustrate the utility of this conceptual framework by providing examples of how these pathways encompass current, and how they could be used to great advantage in the future for, drug discovery.

Bipolar disorder is related to intracellular signalling pathways

Other neuropsychiatric disorders have basic mechanisms and treatment targets that directly implicate neurotransmitter systems. For example, schizophrenia has strong ties to overactive dopamine and D2 receptor activation, with D2 receptor antagonists being effective antipsychotics. Depression is also empirically linked to the serotonergic system as selective serotonin reuptake inhibitors (SSRIs) that increase the availability of serotonin in the synaptic cleft. In contrast, bipolar disorder does not implicate preferentially one neurotransmitter system, but rather is linked to several [2, 4]. Moreover, studies have demonstrated that there are changes in almost all the major neurotransmitters in studies using blood samples and post-mortem tissues [2]. Therefore, the gold standard treatment for bipolar disorder remains lithium (see Chapter 72).

Lithium and its possible targets

Lithium arguably exerts the most specific clinical effect in psychiatry and is highly effective in reducing the risk of relapse [3]. Only lithium

meets the stringent criteria of a true mood stabilizer [5]. Lithium works in acute mania and depression and as maintenance therapy, and is the only proven anti-suicidal drug [6]. However, monotherapy is rare [4], and though lithium remains the gold standard [7], it is often combined with other pharmacological agents such as the anticonvulsants valproate, carbamazepine, and lamotrigine, as well as dopamine antagonists such as olanzapine and quetiapine [4].

The treatment targets of lithium and, by extrapolation, the pathological targets of bipolar disorder have been the Holy Grail in the field ever since lithium's discovery in 1949. Despite its toxic side effects, lithium revolutionized the treatment of bipolar disorder and its success has been impossible to replicate with other drugs because we do not understand exactly how lithium works at the molecular and cellular levels. Lithium's simplicity—the third lightest element—obscures its action on multiple targets and pathways. In the past, potential drug targets for lithium have come and gone in response to scientific fashion, rather than experimental evidence. This is nicely outlined by Belmaker [8] who noted that the suggested targets varied through the decades according to the latest knowledge of brain function.

The early years of lithium research focused on neurotransmitter systems, and although lithium has definite effects on these, it is now becoming increasingly evident that the targets of all mood stabilization lie not at the receptor level, but downstream of it [2].

The most effective drugs for treating bipolar disorder share a complex pharmacology that modulates second messenger pathways. Evidence for second messenger modulation comes not only from lithium, but also from the efficacy of certain anticonvulsants. Valproate and carbamazepine both show efficacy towards bipolar disorder and affect second messenger systems; in contrast, the anticonvulsants topiramate and gabapentin do not show efficacy and do not affect second messenger systems, based on current evidence [9]. Historically, drugs used to treat bipolar disorder have been suggested to act at many intracellular targets within: the adenylyl cyclase (AC)/cyclic adenosine monophosphate (cAMP)/cAMP response element binding protein (CREB) pathway; the extracellular regulated kinase (ERK)/mitogen-activated protein kinase (MAPK) pathway; the phosphoinositide (PI)/inositol-1,4,5-triphosphate (IP₃)/protein kinase C (PKC)/diacylglycerol kinase (DAGK) pathway; and the Wnt/frizzled (Fz)/dishevelled (Dvl)/glycogen synthase kinase-3 beta (GSK-3β) pathway. Because of the intertwined

nature of these signalling networks, with much crosstalk through feedback loops, dysfunction in unrelated gene products can give rise to similar cellular and neural network dysfunction; similarly, drugs with distinct mechanisms of action can all affect a similar cellular signalling pathway and yield the same effect on neural activity. Lithium is exceptionally promiscuous because it competes for magnesium at binding sites, due to a similar atomic radius, and can inhibit all magnesium-dependent processes, depending on its concentration. Lithium's large number of potential targets can be reduced by comparing the concentration of lithium required to inhibit a putative therapeutic target with the concentration that is therapeutically relevant (0.6–1.2 mM) [10] and by considering the likely biological relevance of a given target.

Guanine nucleotide-binding proteins (G proteins)

Substantial evidence implicates G proteins in bipolar disorder [2, 3, 11]. G proteins are a large ubiquitous family of proteins that transduce signals from the cell surface into the cell (Fig. 69.1). The heterotrimeric class of G proteins are made up of three subunits (alpha, beta, and gamma) and couple signals from activated G protein-coupled receptors (GPCRs) to enzymes (effectors) that generate second messengers. The effector enzyme and second messenger pathway is largely dictated by the alpha subunit. The alpha subunits G_s (stimulatory) and G_i (inhibitory) control the activity of adenylyl cyclase, which makes cAMP. Conversely, the alpha subunit G_q activates phospholipase C (PLC) beta. The pathways have numerous points where they can interact to increase or decrease the

function of the other. In this manner, cAMP can amplify or inhibit calcium signals, and vice versa.

When a GPCR is activated, it causes a conformational change that results in guanosine diphosphate (GDP) being exchanged for guanosyl triphosphate (GTP), causing dissociation of the G_α and $G_{\beta\gamma}$ subunits, which then activate a variety of signalling pathways, depending on the location and coupling to second messengers and effectors (Fig. 69.1). Eventually, GTP is hydrolysed to GDP by the intrinsic enzymatic activity of the G_α subunit or the presence of other enzymes that hydrolyse GTP, and it re-joins the $G_{\beta\gamma}$ subunit to revert to the inactive trimer. This 'off-mechanism' is governed by different regulatory enzymes such as GTPase activating proteins which facilitate the G_α subunit's intrinsic GTPase activity. For more detailed information, see a review [12]. Additionally, there is a family of G protein receptor kinases (GRKs) which work to phosphorylate the activated receptors directly and prevent the binding of G proteins [12] (Fig. 69.1). Evidence suggests that lithium does not act directly on G proteins but, after chronic treatment, leads to the stabilization of the inactive heterotrimeric state [3, 13].

Based on the hypothesis that overactive GPCR signalling is causal in bipolar disorder, lithium could dampen overactivation by stabilizing the inactive heterotrimeric G protein, leading to a reduction in G protein–effector coupling. Neural hyperactivity in bipolar disorder is based on several lines of evidence. Post-mortem, as well as genetic, studies have shown that there exist regulatory differences in GRKs in affective disorders [14]. More specifically, a single nucleotide polymorphism of the *GRK-3* gene has been associated with bipolar disorder [2]. Other findings show hyperfunctional G protein function in leucocytes [14] and increased G_α subtypes in post-mortem brain tissue, platelets, and leucocytes [2]. This is suggestive of an overall amplification of signalling, as the receptors are less likely to be phosphorylated and therefore inactivated. Hence, it is feasible that lithium's therapeutic effects may be related to its ability to reduce the increased signalling as a virtue of a polymorphism in *GRK-3*. When tested *in vitro* in platelets from bipolar manic patients, valproate also showed evidence of reducing G protein coupling, and thereby attenuating signalling [15].

AC/cAMP/CREB pathway

The initiation of the cAMP signalling pathway occurs when a hormone or neurotransmitter binds to the receptor and induces either an increase (G_s coupled) or a decrease (G_i coupled) in AC activity. The latter is a dimeric enzyme which catalyses the conversion of adenosine triphosphate (ATP) to cAMP, which further amplifies the signalling by acting on numerous effector proteins (Fig. 69.2), the most well characterized of which is protein kinase A (PKA). Many physiological effects of cAMP are mediated by PKA (Fig. 69.2), which phosphorylates its targets to increase or decrease cell signalling-related physiological effects. Overall, PKA activation increases cytosolic calcium via entry through L-type Cav1.1 and L-type Cav1.2 channels. Another important action of PKA is its ability to induce gene transcription via the transcription factor CREB. The catalytic subunit of PKA translocates to the nucleus and phosphorylates CREB, which, in turn, binds to the DNA promoter region and turns on or off the transcription of certain genes. Some genes regulated by CREB relevant to bipolar disorder include the ones

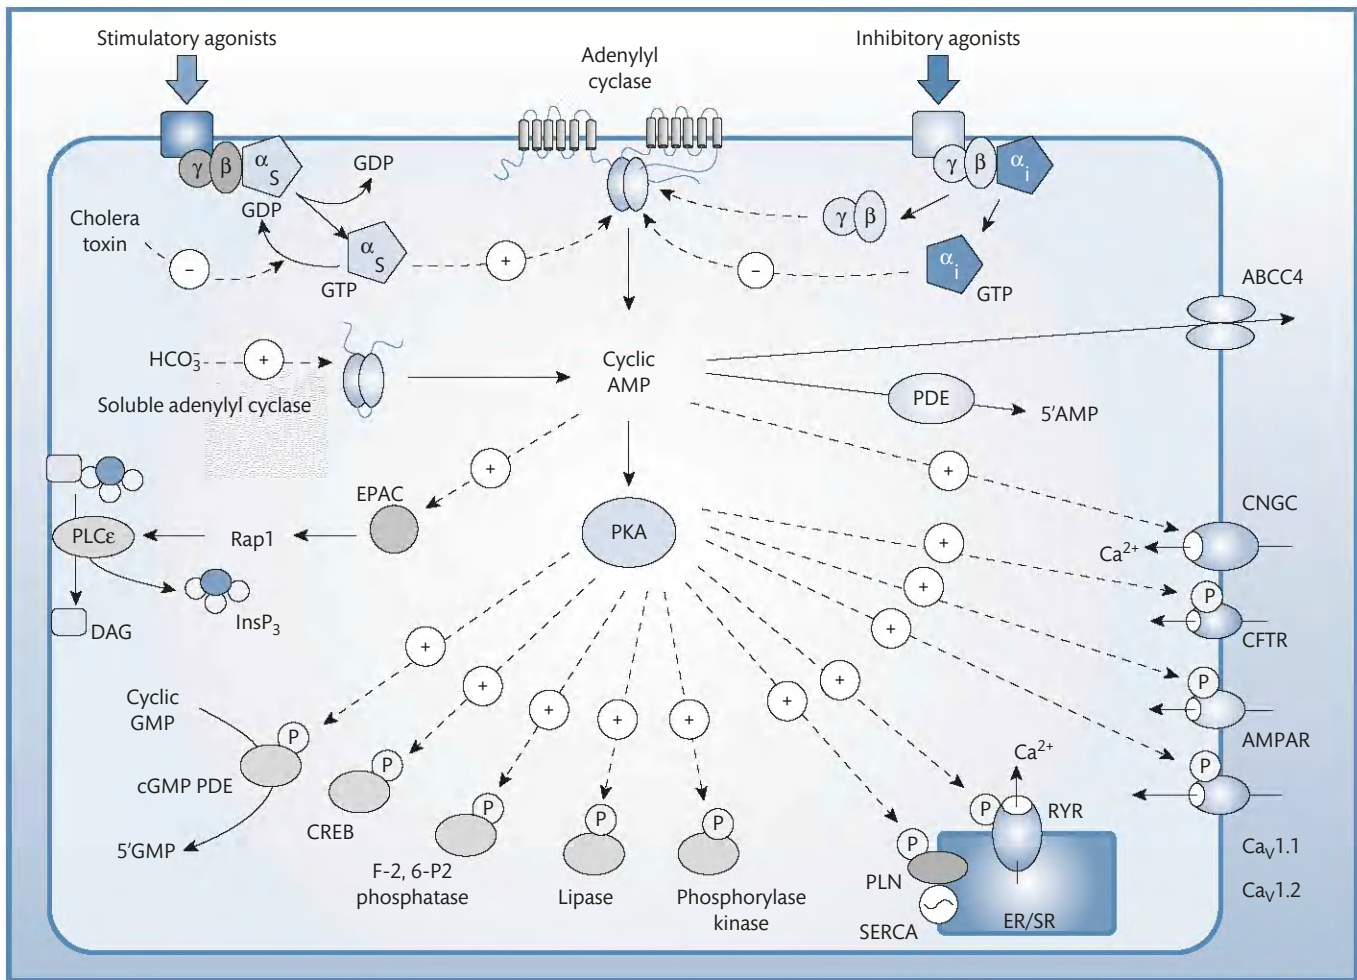

Fig. 69.2 Summary of the control of cyclic AMP levels and its cellular targets.

that code for brain-derived neurotrophic factor (BDNF), tyrosine hydroxylase, and circadian regulators.

Lithium produces complex effects on this cAMP signalling pathway [2, 3]. It inhibits cAMP accumulation in response to stimulation; however, paradoxically, it increases basal, and in some cases stimulated, AC activity, resulting therefore in an increase in basal cAMP [16]. Moreover, lithium's effects on cAMP and AC are tissue-specific [16, 17]. It has also been suggested that chronic lithium treatment might be producing these effects on G proteins, rather than on AC directly, as these effects were reversible *in vitro* only when increasing concentrations of GTP [18] were added, and not by increasing magnesium. If the effect of lithium were mediated by inhibition of AC, increasing magnesium would reverse the effect, as it does during acute treatment. Overall, chronic treatment with lithium showed reduced CREB phosphorylation in rat brains [2], indicative of an attenuation of this pathway, at least with respect to CREB activity. By comparison, valproate also decreased cAMP production on stimulation, but chronically it did not affect CREB.

Phosphoinositide pathway

Much of the early work implicating phosphoinositide signalling in the pathogenesis of bipolar disorder and as providing targets for

drugs was equivocal because of the limitations of the experimental models and chemical tools available at the time. Now with new models, such as mice with genes knocked out for IMPase 1, IMPase 2, and *myo*-inositol uptake, combined with a blood-brain barrier-permeant putative lithium mimetic ebelsen and with L690330 delivered directly into mouse brains [19], the phosphoinositide area is experiencing a renaissance.

Receptors that employ this pathway are coupled to G α_q , which activates phospholipase C (PLC), which catalyses the hydrolysis of phosphatidyl inositol 4,5-bisphosphate (PIP₂) to diacylglycerol (DAG) and IP₃ (Fig. 69.3). Both IP₃ and DAG then go on to control several physiological processes, before being recycled back to PIP₂ via a series of intermediary phosphoinositides. As G α_q is linked to nearly all of the known neurotransmitter systems (noradrenergic, serotonergic, glutamatergic, cholinergic, as well as dopaminergic through heterodimers), it is perfectly plausible that lithium might be regulating mood via its actions on phosphoinositide signalling.

Allison and Stewart first showed that inositol levels were decreased in rat brains treated with lithium and postulated that this reduction might be due to lithium interfering with active transport, synthesis, or incorporation into phosphoinositides [20]. Although *myo*-inositol levels decreased in the cerebral cortex of rats treated with lithium, levels of Ins1P increased [21], suggesting inhibition of the enzyme inositol monophosphatase (IMPase), which converts

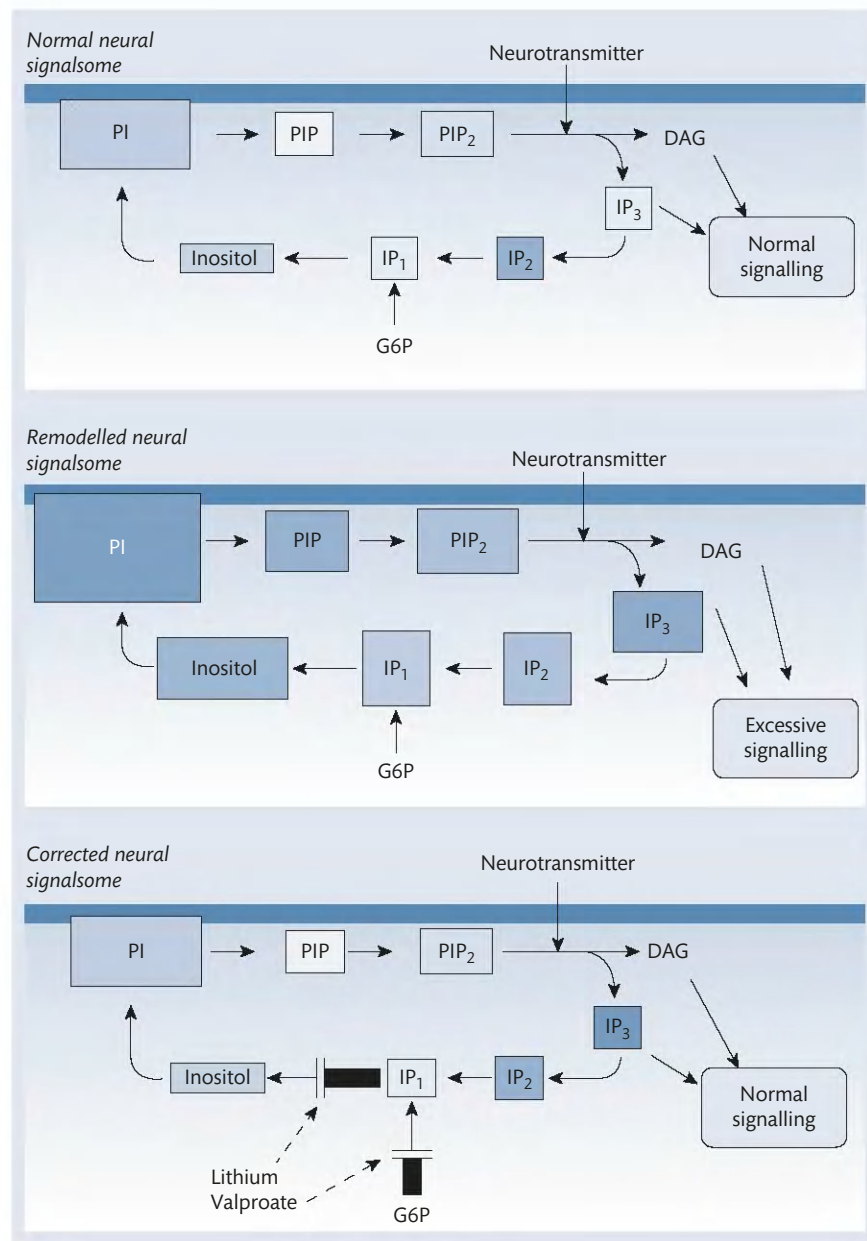

Fig. 69.4 Diagram illustrating the inositol depletion hypothesis whereby overactive signalling in neurons can be corrected by slowing the inositol cycle.

Adapted from *Cell Signalling Biology*, 6, Berridge MJ, Module 2: Figure heterotrimeric G protein signalling. Copyright (2014), with permission from Portland Press Limited.

three mood stabilizers lithium, valproate, and carbamazepine inhibit the uptake of *myo*-inositol from blood into the brain using the sodium/*myo*-inositol transporter 1 (SMIT1) [26].

Evidence for inositol depletion

Besides the observation that lithium, valproate, and carbamazepine all deplete inositol, the strongest evidence for the inositol depletion hypothesis comes from lithium's inhibition of IMPase at therapeutic concentrations. This inhibition causes a decrease in inositol and PIP₂, which can be measured. Shimon *et al.* in 1997 showed decreased levels of inositol in the prefrontal cortex in post-mortem brains

of bipolar patients using gas chromatographic techniques [27]. Magnetic resonance spectroscopy has also been extensively used, with mixed findings [28], but several studies have found decreased levels of *myo*-inositol in the frontal lobe of bipolar patients treated acutely and chronically with lithium, compared to controls [28]. Additionally, increased levels of phosphomonoesters (including Ins1P) have been shown to be increased in the frontal lobe of both bipolar manic and bipolar depressed patients treated with lithium [28]. According to the inositol depletion theory, a decrease in inositol leads to a reduction in phosphoinositides, such as PIP₂, a precursor for IP₃. This was demonstrated by showing that reduced PIP₂ levels were found in platelets from bipolar I patients treated with lithium, compared to control volunteers [29]. Preliminary evidence

also comes from genetic linkage studies that have suggested a susceptibility locus for bipolar disorder on chromosome 18p11, the location of one of the genes that codes for IMPase [30]. There is a caveat that this locus, like that for *GRK-3*, has not yet been confirmed in subsequent meta-analyses (see Chapter 70).

Ebselen: a blood-brain barrier penetrant IMPase inhibitor

Lithium has wanted and unwanted effects that are concentration-dependent, but the therapeutic index is small. It does not work in all patients; side effects are unwanted and lead to non-compliance, and compared to other drugs, there is an increased burden on physicians as blood levels must be monitored. Therefore, there has been an effort to find a 'lithium mimetic': a drug with lithium's advantages without its disadvantages. One strategy is to find agents that modulate the target of lithium. However, as described previously, this is unknown. An approach can then be taken whereby a putative target is explored.

Taking inositol monophosphatase as a putative target has resulted in several efforts, both commercial [31] and academic [32–34], to find inhibitors. On this background, an effort in drug rescuing was undertaken using the NIH Clinical Collection, which is a library of drugs known to be safe and with a history of use in humans but that have not been marketed due to clinical trials showing a lack of efficacy in a given indication or due to business reasons [35]. Using isolated IMPase revealed an inhibitor called ebselen. Ebselen was originally designed as an antioxidant and was used in clinical trials for stroke and atherosclerosis [36]. In contrast to all previous studies with inhibitors of inositol monophosphatase [37], ebselen was bioavailable and blood–brain barrier-permeant. As ebselen exhibits polypharmacology (in drug discovery, this is a term for one drug affecting many targets), it alone cannot reveal the mechanism, but it inhibits IMPase at 40-fold lower concentrations than GSK3 β , the other most likely target of lithium's therapeutic action. Ebselen exhibited certain lithium-like behavioural effects in animal models that were reversed *in vivo* by the administration of inositol, strongly indicating IMPase inhibition as the mechanism [33, 34]. More directly, ebselen reduced *myo*-inositol in both mouse brains, as well as in the anterior cingulate cortex in healthy volunteers, consistent with the inositol depletion hypothesis [23, 24]. Ebselen also decreased impulsivity [38], which may relate to lithium's anti-suicidal effects.

Protein kinase C and diacylglycerol kinase

PKC is a serine/threonine kinase that phosphorylates substrates to activate or inactivate them and thus modulates cell signalling pathways. PKC itself is activated by DAG and calcium (Ca²⁺). Although lithium does not directly inhibit PKC, chronic administration decreases the activity of two isoforms of PKC—PKC α and PKC ϵ —in the frontal cortex and hippocampus [39], without affecting the other PKC isoforms [40]. PKC, as a component of the calcium signalling pathway discussed previously, can modulate glutamatergic, noradrenergic, and serotonergic pathways in the CNS, indicative that it may be important for mood stabilization [39]. PKC shows increased activity in platelets from patients in the manic phase [41]

and in post-mortem brains [42], which is consistent with a hyperactive phosphoinositide cycle in bipolar disorder. Tamoxifen, an anti-oestrogenic drug that inhibits PKC at high concentrations, showed anti-manic effects in some small trials [43], highlighting a possible role for PKC in bipolar disorder. After chronic treatment, both lithium and valproate show a reduction in PKC activity, through differing mechanisms [15, 39, 44].

DAGK converts DAG to phosphatidic acid, an essential step in the resynthesis of PIP₂ from inositol (Fig. 69.3). Additionally, DAG also activates PKC isoforms, along with calcium. Therefore, hyperactive production or reduced removal of DAG may further result in PKC hyperactivity. In a genome-wide association study, a strong link between bipolar disorder and DAGK was observed [45]. This finding has been replicated in some, but not all, studies [46]. Although lithium or valproate have not shown any direct effects on DAGK, as it is an upstream regulator of PKC, it might be another valid target in the treatment of bipolar disorder.

GSK-3 β

GSK-3 is another serine/threonine protein kinase that modulates substrates by phosphorylation. It has two isoforms GSK-3 α and β , which have essentially the same function. GSK-3 phosphorylation of glycogen synthase renders it inactive. Lithium was shown to inhibit GSK-3 uncompetitively at therapeutic concentrations with an IC₅₀ of about 2 mM [47]. This suggests that there is partial inhibition of GSK-3 *in vivo* (therapeutic concentration of approximately 0.8 mM). However, some evidence indicates that lithium also inhibits the phosphatase that activates GSK-3, thereby reinforcing the inhibition of GSK-3 activity [48]. GSK-3 has a role in neuroplasticity and cellular resilience, and it is believed that lithium's neuroprotective effects may be partially mediated by GSK-3 inhibition [49].

Circadian rhythm disruptions are seen in bipolar patients, and lithium corrects these, possibly through GSK-3 β inhibition [49]. Moreover, GSK-3 is at the crucial juncture of neurotransmitters, like noradrenaline, dopamine, and 5-HT, and gene transcription. GSK-3 inhibition may also be involved in the teratogenic effects seen with lithium treatment [47]. Overall, GSK-3 has only recently been considered as a target for lithium and hence requires further investigation to understand lithium's effects via GSK-3 β . Given that lithium must be dosed chronically to be effective, more studies are needed. Valproate does not directly inhibit GSK-3 β at therapeutic concentrations [49].

Although GSK-3 β has been contested vociferously as a likely target for lithium's efficacy, there are substantial caveats. For an excellent review, see [50]. Briefly, the phosphorylation patterns are inconsistent with lithium therapy. Additionally, inhibiting GSK-3 β signalling causes stabilization of β -catenin and activation of the canonical Wnt signalling pathway [51]. The Wnt pathway is strongly associated with oncogenic changes, and even a moderate surge in β -catenin promotes oncogenesis [50].

Calcium signalling as a central unifying concept

The best experimental evidence, both historical and current, from pathophysiology, genetics, and drugs is converging on calcium

signalling. Calcium controls all facets of brain function, including axonal growth, memory, excitability, brain rhythms, gene transcription, neuronal firing, neurotransmitter uptake, hormone release, mitochondrial activity, neurogenesis, and apoptosis [51, 52]. Thus, calcium can control brain activity in several ways, including effects on neural circuit activity generated through interactions between excitatory and inhibitory neurons and short-term events that underlie neural excitability, as well as long-term processes such as gene transcription (Fig. 69.5). Calcium relays and integrates signals from extracellular messengers (neurotransmitters and neuromodulators) and other intracellular signalling pathways, to affect neuronal excitability over the short term and gene transcription over the longer term. Therefore, calcium is uniquely placed at a key position to influence neural activity, growth, and neural plasticity. Indeed, excessive calcium signalling has been hypothesized to drive the neuronal excitatory–inhibitory imbalance that can explain mood swings in bipolar disorder [52]. Although there is great complexity in the number and interactions of genes and molecular players in calcium signalling (Fig. 69.5), it does not mean that it will take a drug for each defect; rather, promisingly, it means that there are a great number of ways to intervene with a single drug that would affect the entire pathway.

An overview of calcium signalling

Unlike other messengers that can be created and destroyed, calcium can only be moved around in time and space (Fig. 69.6). Cytosolic calcium concentration is at steady state and is the sum of the activity of all channels and pumps at both the plasma membrane and intracellular organelles. Extracellular calcium is approximately 1 mM and intracellular cytosolic calcium is approximately 100 nM, so there is a chemical gradient of about 10,000-fold, as well as an electrical gradient combined to drive calcium into a cell. Inside cells, many organelles also store calcium to create approximately the same concentration gradient. Maintaining low cytosolic calcium is essential, as calcium itself is inherently toxic as it precipitates phosphates and phosphate-containing molecules and induces cell death through apoptosis. The cell expends much energy maintaining low cytosolic calcium through pumps at the plasma membrane such as the plasma membrane calcium–ATPase and a sodium/calcium exchanger. The endoplasmic reticulum is the major intracellular calcium store and has the sarco(endo)plasmic reticulum calcium ATPase (SERCA) on it. Mitochondria take up calcium through an electrogenic uniporter that operates in the presence of high cytosolic calcium in microdomains close to channels.

In the cytosol, calcium is heavily bound by immobile binding proteins (buffers), which greatly limits its diffusion. This enables calcium increases to be very rapid and localized, or as calcium can stimulate its own release at certain channels, the responses can be greatly amplified in time and space. This highlights that not all calcium within a cell has the same effect—what matters is the spatial distribution, the timing, and the amplitude [51]. Indeed, different frequencies of calcium spikes can drive different transcription factors. Similarly, the amplitude of localized calcium responses in neuronal growth cones controls attractive or repulsive migration towards a chemotactic substance. There are many families and isoforms of each pump and channel to provide for fine-tuning calcium signals and their cellular

responses (Fig. 69.5). In one example, there is plasma membrane to nucleus signalling in which the calcium emanating from a Cav1.2 channel can result in changes in gene transcription, whereas calcium emanating from an NMDA receptor channel is far less effective [52]. This selectivity results from better coupling to MAPK and cAMP signalling cascades through calcium.

In neurons, calcium signalling can operate in a primary or modulatory mode [53] (Fig. 69.7). In the primary mode, calcium enters through channels in the plasma membrane, which may be amplified by ryanodine receptors through calcium-induced calcium release and often drives presynaptic vesicle fusion and neurotransmitter release. In the modulatory mode, calcium signalling is controlled through the IP₃/calcium pathway (Fig. 69.7). This modulatory calcium regulates membrane excitability and, in turn, neural networks and mood. Alteration in the function of components in either the primary or the modulatory pathways can contribute to the onset and treatment of bipolar disorder.

Plasma membrane calcium channels

The plasma membrane contains many diverse families of calcium channels, all with unique activation and physiological function and classified as operating in the primary mode, as defined previously (Fig. 69.7). Voltage-operated calcium channels mediate calcium influx upon plasma membrane depolarization and are classified as L-, N-, and P/Q- types (Fig. 69.5). Calcium influx controls physiological responses such as neurotransmitter release and gene expression [51–53]. Receptor-operated types respond to neurotransmitters such as the NMDA receptor that responds to glutamate and the 5-HT₃ receptor that responds to serotonin. There are also second messenger-operated channels (SMOCs) that respond to calcium, cyclic nucleotides [for example, the cyclic nucleotide-gated channel (CNGC)], and arachidonic acid (AA), as well as store-operated channels (SOCs) that respond to the calcium load in the endoplasmic reticulum (Fig. 69.8). Intracellular calcium can modulate membrane excitability by acting on other channels such as inhibition of the KV7.2/KV7.3 channels responsible for the hyperpolarizing M current or stimulation of the non-selective cation channel leading to a depolarizing current.

Intracellular calcium channels

Calcium signals that arise from intracellular channels operate in the modulatory mode and are common to all types of neurons. The regulation is also subtler in that it will influence excitability, but not actually cause firing of action potentials. There are two well-characterized families of intracellular calcium channels: the IP₃ receptor and the ryanodine receptor (Fig. 69.7). The IP₃ receptor is under control of extracellular signals, including neurotransmitters, neuromodulators, and hormones when they act through GPCRs or receptor tyrosine kinases or through the phosphoinositol pathway, as described previously (Fig. 69.5). In this pathway, a soluble messenger IP₃ is generated and binds to, and opens, a ligand-gated ion channel called the IP₃ receptor, located on the endoplasmic reticulum, to release calcium. The ryanodine receptor is primarily regulated by calcium through a process termed calcium-induced calcium release, but it is also sensitized by the second messenger

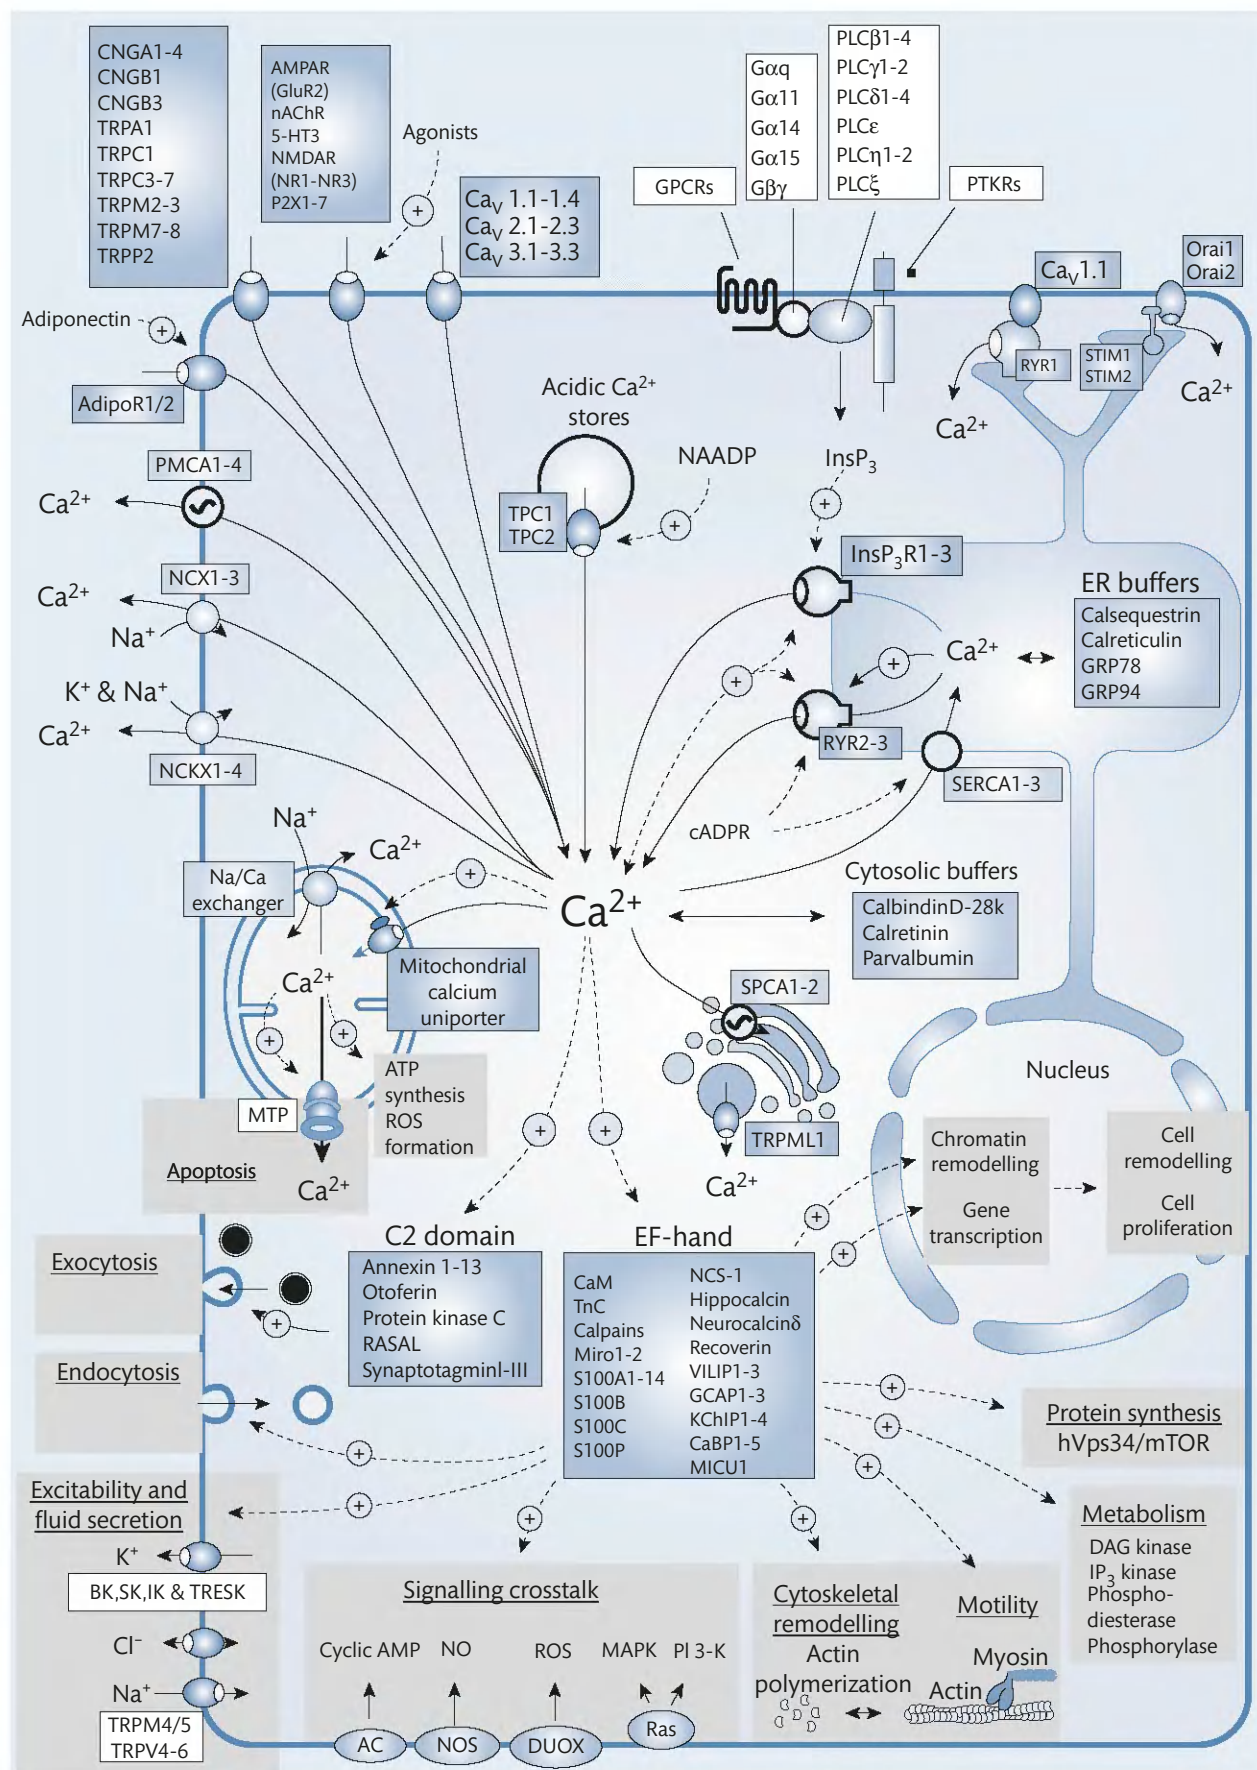

Fig. 69.5 Calcium signalling plays a central role as a transducer of signal inputs and outputs and can be finely tuned by selecting components (channels, pumps, and effectors) from the calcium signalling toolkit. The green boxes illustrate the membrane calcium channels, whereas the red boxes are the pumps and exchangers that move calcium either out of the cell or back into the endoplasmic reticulum (ER). The purple boxes represent the buffers located in the cytoplasm or in the ER.

cyclic adenosine diphosphate (ADP) ribose. Calcium-induced calcium release amplifies calcium responses in amplitude, time, and space (Fig. 69.9). The IP_3 receptor also shows this phenomenon. Both channels have very large cytosolic heads with sites for regulation by almost all kinases, to sense calcium, ATP, redox, and other metabolites, so that they can integrate many facets of cellular status and integrate these into a calcium signal.

Relation to treatment

In terms of drugs, most bipolar patients respond to lithium and valproate. As these are mood stabilizers and buffer swings to either pole, they are telling us something about the underlying regulation. These drugs have different chemical structures and possibly different molecular targets. They unify in their action at the level of intracellular

Fig. 69.7 In neurons, calcium acts in either a primary or a modulatory mode. The primary calcium signal is generated by receptor-operated channels (ROCs) or voltage-operated channels (VOCs) that promote the entry of external calcium. This primary signal can be augmented by calcium-stimulating ryanodine receptors (RYRs) to release calcium from internal stores. The modulatory calcium signal is generated by agonists operating through InsP_3 and calcium release from intracellular stores.

Fig. 69.8 Mechanisms of calcium entry through agonist-operated calcium channels on the plasma membrane. The most direct mechanism occurs in the receptor-operated channels (ROCs) where the agonist binds directly to the ion channel. Agonists can also activate entry indirectly by recruiting various internal signalling pathways to activate second messenger-operated channels (SMOCs) or a store-operated channel (SOC).

signal transduction, at the pathways leading to and from calcium signalling (Fig. 69.5). Efficacious drugs do not induce an all-or-none effect, but a subtle modulation of calcium release and uptake which creates an environment where variations from the mean are prohibited. The calcium signalling pathway provides for numerous unexplored potential treatment targets for new drugs.

Evidence for calcium signalling defects in peripheral cells

Elevated intracellular Ca^{2+} is recognized as a marker of bipolar disorder [54, 55]. In platelets and lymphocytes from patients with bipolar disorder, both baseline and agonist-stimulated levels of calcium were greater, consistent with overall calcium overload [55, 56]. Moreover, thapsigargin, an inhibitor of the SERCA calcium pump (Figs. 69.5 and 69.6), also showed an increase, indicating increased storage of calcium [55]. Increased cytosolic calcium occurred in both depression and mania [56]. However, elevated basal calcium concentrations have been detected in transformed B lymphoblasts from patients with bipolar I disorder, compared with those with bipolar II disorder or major depression or healthy controls [55]. Increased total serum and ionized calcium have also been reported in euthymic lithium-treated patients, compared to healthy controls [57]. Thus, calcium homeostasis appears altered across all mood states in bipolar disorder and treatment relating to bipolar disorder [2]. The mechanistic origins of these elevations in calcium are unknown, but suggestions have included dysfunction of almost all calcium pumps and channels (Fig. 69.5) [55].

Evidence from iPSCs, genetics, and calcium antagonist drugs implicates calcium channels

An obvious limitation of studies with peripheral cells is whether calcium signalling in these cells accurately represents signalling in neurons. Recent studies with induced pluripotent stem cells (iPSCs), fibroblasts dedifferentiated and then redifferentiated into neurons, also add support to a defect in calcium signalling that can be normalized with drugs used to treat bipolar disorder. For example, iPSC neurons derived from fibroblasts taken from lithium responders showed hyperexcitability and signalling defects in both calcium and mitochondria [58]. Importantly, this hyperactivity and calcium signalling were corrected with lithium when the fibroblasts were taken from lithium responders [58]. Additionally, compared to controls, iPSC neurons derived from bipolar patients exhibited dysregulated calcium transients and wave amplitudes that were corrected with lithium [59].

One of the most promising findings is that a component of the calcium signalling pathway appears to be both involved in bipolar disorder and a therapeutic target. Specifically, the voltage-operated calcium channel Cav1.2, for which the gene *CACNA1* encodes its alpha subunit, which forms the pore, voltage sensor, and drug-binding sites (Fig. 69.10), is implicated by several distinct sources of evidence [54]. *CACNA1C* is consistently identified in genome-wide association studies (GWAS) [60, 61].

As with most findings in bipolar disorder, this hypothesis has not been fully tested but is tantalizing and theoretically straightforward.

Evidence comes from peripheral cells taken from bipolar patients, the efficacy in certain individuals with bipolar disorder of drugs that block voltage-operated calcium channels, and GWAS [54]. The voltage-operated calcium channel Cav1.2 is encoded by the gene *CACNA1*, and this has turned up reproducibly in several GWAS and has the strongest evidence of any GWAS hit [61]. Interestingly, the risk locus is within the large third intron (non-coding), and therefore, it likely affects function through the level of expression or alternative splicing. Indeed, when iPSCs were made from individuals with this variant, the cells had elevated mRNA expression and more calcium influx [62]. Results from GWAS reveal polymorphisms in the alpha 1C subunit of the L-type voltage-gated calcium channel gene (*CACNA1C*) as a risk factor for bipolar disorder. In regard to iPSCs, cells derived from bipolar patients and patients with *CACNA1* (which encodes the L-type calcium channel Cav1.2 $\alpha 1$) risk genotype exhibit aberrant calcium channel gene expression and functional calcium signalling. The risk variant is likely associated with increased channel expression and function.

Consistent with the involvement of Cav1.2 is that calcium channel blockers designed to treat cardiovascular disorders have been used to treat bipolar disorder. Although all three main groups of calcium channel blockers have been tested—dihydropyridines (for example, nifedipine), phenylalkylamines (for example, verapamil), and benzothiazepines (for example, diltiazem), the results are conflicting and lack definitive evidence for efficacy [54]. Problems include cohort size and low statistical power, lack of penetration of the blood–brain barrier, and lack of selectivity for isoforms found in the brain, limiting the dose to that tolerable for peripheral side effects. A recent meta-analysis concluded that the current evidence is equivocal but deserves proper study, both through design and through the development of blockers selective for the brain splice variant isoforms [54].

Theoretically, the involvement Cav1.2 will have profound effects on neural function, as it regulates both excitability and synaptic plasticity [52]. Indeed, in a model system in which a mutation in Cav1.2 in mice gives rise to Timothy syndrome, in humans, this shows effects on synaptic plasticity and spatial learning [63]. Mutations in Cav1.2 result in Timothy syndrome, dysfunction in multiple organs, and severe cognitive impairment [52].

Future drug discovery

All drugs used in bipolar disorder were either approved before current rigorous regulatory and ethically sound clinical trials (lithium) or were repurposed from other uses as antipsychotics and anti-epileptics. The community hopes to pursue rational drug design, in which our understanding of the pathophysiological or pharmacological mechanism will reveal targets for which we can develop drugs. Impeccable logic, but unfortunately there exist precious few examples where this has been achieved. The problem is that, of the many suggested therapeutic targets, none have been rigorously tested, and as the focus of biological interests in neuroscience has shifted, so has interest in possible targets. As none are validated or invalidated, we exist in a form of purgatory. Also, all mood stabilizers exhibit polypharmacology, making therapeutic target identification difficult. We need to move forward, using the best imperfect knowledge we have. For example, the putative targets of lithium have

Fig. 69.10 Structure and regulation of the Cav1.2 L-type calcium channel implicated in bipolar disorder. PKA, protein kinase A; AKAP18, A-kinase-anchoring protein; PKC, protein kinase C; CaM, calmodulin.

not been properly explored and thus cannot conclusively be validated or invalidated. Similarly, there is much evidence from several sources that converges on the involvement of L-type calcium channels. This forms a solid working hypothesis that can be pursued. If we had drugs with good selectivity and favourable blood–brain barrier permeability, we could test these hypotheses and targets. To move on, a definitive ‘no’ would be more useful than a feeble ‘yes’.

Genetics of bipolar disorder

Francis J. McMahon and Sevilla Detera-Wadleigh

Genetic epidemiology

The earliest studies of the genetic basis of bipolar disorder (BD) were based on families, twins, and adoptees and used epidemiologic methods to draw their conclusions (*Fig. 70.1*). These studies provided the first systematic evidence of a genetic basis for BD, setting the stage for the molecular genetic studies of recent years.

Family studies

The tendency of illnesses to run in families is one of the most obvious observations giving rise to genetic hypotheses. Familial transmission of BD was reported long before modern concepts of the illness [1, 2] were widely adopted. In one of the earliest systematic family studies, Slater [3] described rates of ‘manic–depressive’ disorder among the parents and children of diagnosed patients that were remarkably close to the estimates of modern studies using criterion-based diagnoses and family study [4] or population-based methods [5].

Family studies may reveal patterns of transmission that can give clues about the nature of genetic influences. In segregation analysis, observed patterns of transmission in families are compared to patterns that would be expected under various inheritance models such as autosomal dominant or X-linked recessive. Many such studies were carried out for BD in the 1980s and 1990s (reviewed in [6]). While some studies reported transmission patterns that were most consistent with a single major (dominant) gene, most could not confidently reject more complex, multifactorial models. Such inconsistency probably reflects what we now know to be the considerable genetic heterogeneity that underlies BD.

Family studies have also been used to explore the range of phenotypes that cluster among close relatives. Such studies can give clues to the variable expressivity of shared genetic factors. Most family studies of BD have used a proband-wise, case-control approach, comparing the rates of various illnesses among the relatives of ‘cases’ diagnosed with BD vs relatives of psychiatrically healthy ‘controls’. Results of the largest studies are reviewed in [6]. Most studies found that 10–15% of first-degree relatives of people diagnosed with bipolar I disorder met criteria for a major mood disorder themselves when directly interviewed, although the disorder could range from major depression to schizoaffective disorder. Increased rates of other disorders were also found, including alcoholism and anxiety

disorders. Some studies also reported an increased rate of schizophrenia, but this was an inconsistent observation [4, 7, 8].

Some family studies have examined clinical features of BD or its associated neurocognitive traits. These studies have found that age at onset [9], psychotic features [10], frequency of episodes [11], polarity (manic or depressive) of the initial episode [12], suicidal behaviour [13], and response to lithium treatment [14] are all familial. Studies of neurocognitive traits have also reported a number of measures that are associated with BD in families [15]. Some traits, such as resting state EEG and deficits in facial recognition, also seem to occur in unaffected relatives, suggesting that they reflect a subthreshold liability distinct from recognized clinical manifestations of the illness [16, 17]. Daily activity patterns also seem to run in families and are associated with BD in some studies [18]. So far it has proven difficult to define robust subtypes of BD based on any of these traits, but this is an area of active investigation.

Population-based family studies have only become possible in recent years, thanks to universal health registries and electronic health records. Lichtenstein and colleagues have exploited the electronic records of the Swedish health system to link related individuals who received psychiatric diagnoses at multiple time points. These studies have shown results that largely agree with the proband-wise case-control studies, but with much larger sample sizes, reduced recall bias, and more complete ascertainment [5]. The results support the finding that schizophrenia is increased among the close relatives of individuals diagnosed with bipolar I disorder, but at less than half the rate of major mood disorders [19].

While they have provided some important clues to the familiarity of BD, its complex mode of transmission, and its familial clustering with other diagnoses, family studies in themselves provide only weak evidence in support of genetic aetiology. Families share environments, life experiences, and habits that could easily contribute to illness, with no necessary contribution of genes per se. Other study designs are needed to dissociate the effects of genes and family environment.

Twin studies

Twin studies allow a more unbiased estimate of genetic influences, since they control for shared non-genetic influences that complicate the interpretation of family studies. Twin studies typically compare monozygotic (MZ or identical) twins—who inherit the same

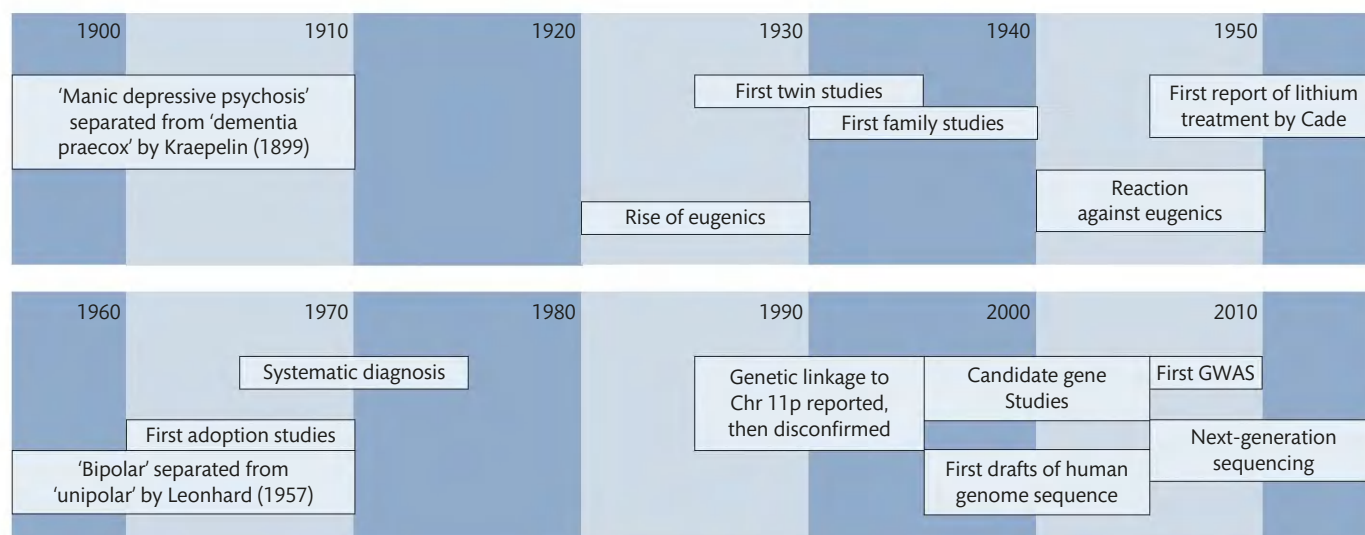

Fig. 70.1 A timeline of bipolar disorder genetics discoveries over the past century, with a selection of key findings placed in approximate chronological order.

DNA—with dizygotic (DZ or non-identical) twins—who share, on average, half their DNA. Since both MZ and DZ twins are expected to experience the same family environment and similar early life experiences, non-genetic influences should be the same in both types of twins and traits influenced by inherited genetic factors should show more resemblance between MZ than DZ twins. Based on this principle, twin studies can estimate the fraction of trait variability that is attributable to genetic differences, a quantity known as heritability (for review, see [20]).

Twin studies have been conducted in BD since at least the 1930s. While methods of ascertainment, diagnosis, and statistics have changed substantially, heritability estimates have been remarkably consistent (reviewed in [6]). Most studies find that BD is 70–90% heritable. Such heritability estimates are among the highest of the major mental illnesses [21] and underscore the major role that inheritance plays in the aetiology of BD.

Twin studies have several limitations. Most importantly, they do not indicate which genes or how many different genes are involved. Even a highly heritable trait like BD seems to be influenced by numerous genes of small effect (see Polygenic models, p. 737). Twin studies may underestimate genetic influences when non-inherited sources of genetic variation, such as epigenetic marks and somatic mutation, play a major role. Twin studies may also overestimate heritability when the assumptions about shared environment are violated, when genetic and environmental influences are strongly correlated, or when ascertainment is biased or incomplete [22]. Despite these inherent limitations, the consistency in heritability estimates over many different studies and decades of investigation suggests any error should be modest.

Adoption studies

Another approach to parsing the influence of genes and environment is the adoption study. Typically, adoption studies compare traits in the biological and adoptive parents of adoptees who manifest a trait of interest. This approach thus separates the effects

of parental environment from those of inheritance, reducing or eliminating gene–environment correlations that can complicate the interpretation of twin studies [8]. Adoption studies cannot control for the effects of the intrauterine environment, which may play a role in some mental illnesses such as schizophrenia [23].

Three adoption studies of BD have been published [24–26]. Although they differed somewhat in methodology and had small sample sizes, all three studies found that rates of BD were increased in the biological parents of adoptees with BD, while no such increase was observed in their adoptive parents. These results support the view that inherited influences are most important in BD.

One population-based study linked electronic health records of adoptees with those of their biological and adoptive parents [19]. This study achieved a much larger sample size than the traditional adoption studies, although parents and adoptees with BD who did not seek treatment would be missed by this study design. The results again showed that rates of BD were elevated among the biological parents of adoptees diagnosed with BD.

Assortative mating

Assortative mating describes mating patterns in a population that are non-random with regard to particular traits. For example, people tend to choose mates of similar height, education, and smoking habits. Assortative mating is important since it can concentrate genetic risk factors in certain families (while reducing them in others), increasing the risk or severity of illness in the offspring.

Assortative mating for mood disorders has long been observed in both clinical and epidemiological samples [27–29]. While such mating patterns could, in principle, reflect the influence of secondary factors associated with mood disorders (such as alcoholism), most studies have found that people often choose mates with similar (or identical) psychiatric diagnoses. A large electronic health record-based study in the Swedish population confirmed these findings and revealed strong patterns of assortative mating across a range of mental illnesses [30].

Molecular genetics

Genetic linkage in bipolar disorder

The ultimate goal of genetic linkage studies is to define genetic loci that underlie an inherited disorder. A considerable number of genetic linkage studies of BD were conducted between the 1980s and 1990s. To support this effort, collections of densely affected pedigrees and sib-pairs were assembled. The National Institute of Mental Health (NIMH) Genetics Initiative (<https://explorer.nimhgenetics.org/subject-counts/explore/?c=bipolar-disorder>), one of the largest efforts, established a resource of DNA, immortalized cell lines, and extensive clinical phenotype information from over 4000 individuals in 850 families. The DNA and associated source information are available to qualified researchers studying the genetics of mental disorders and other complex diseases at recognized biomedical research facilities.

Early linkage studies depended on phenotypic markers such as blood type or colour blindness (reviewed in [31]). Genetically mapped DNA markers, including restriction fragment length polymorphisms (RFLPs) [32] and highly informative short tandem repeat or microsatellite markers [33], were later developed.

An early study in an extended Old Order Amish pedigree reported linkage to a locus on chromosome 11 [34], but this finding was not supported in an independent set of pedigrees [35] and the original evidence for linkage was greatly diminished after a relative developed BD [36]. Linkage to chromosome 18 was also reported [37], with some support in an independent sample [38], but a causal gene was not identified.

In 1997, the NIMH Genetics Initiative published a genome-wide scan of 97 families with 540 individuals [39]. Non-parametric methods showed the strongest findings on chromosomes 1, 6, 7, 10, 16, and 22. To increase power, meta-analytic studies were performed that combined several different sets of pedigrees [40–42]. The results were stronger, but no more consistent.

Some studies sought to reduce genetic heterogeneity by focusing on clinical subtypes of BD. While most were unsuccessful, increased linkage signals were found for bipolar II disorder [43], BD with psychosis [10], age at onset [44], and polarity at onset [12]. These reports were not followed by clear replications, suggesting that the subtype strategy did not identify subsets of families that were substantially more homogenous.

Candidate gene studies

For many years, candidate gene screening was pursued as an alternative to linkage studies. The aim was to determine whether genes postulated to serve important neuronal functions had a role in genetic predisposition to BD. The burgeoning list of potential candidate genes was presented previously [45]. So far, definitive evidence is lacking for the role of three of the most commonly investigated brain-expressed genes: brain-derived neurotrophic factor (*BDNF*), catecholamine-*O*-methyl transferase (*COMT*), and serotonin transporter (*SLC6A4*). Methodological limitations of the candidate gene strategy eventually led to its replacement by genome-wide association studies (GWAS) [46].

Genome-wide association studies

Design and theory

GWAS were initially conceived as a way to overcome many of the problems inherent in candidate gene studies [47]. Initially a

theoretical idea, GWAS soon became practical with the advent of microarrays. Thanks to this technology, it is now routine to genotype millions of common genetic variants (known as single nucleotide polymorphisms, or SNPs) in thousands of samples, at less than a penny per genotype. GWAS have represented a major breakthrough for BD (and hundreds of other common, complex traits), for the first time revealing robust biomarkers that point towards genes. GWAS have also revealed the hitherto underappreciated role of small chromosomal deletions and duplications (known as copy number variants, or CNVs) in risk for a range of neuropsychiatric disorders.

Since the typical GWAS assays thousands of independent SNPs, statistical testing needs to correct for the large number of hypotheses tested. This is typically accomplished by use of a Bonferroni-corrected significance threshold of $P < 5 \times 10^{-8}$. One consequence of this multiple testing problem is that GWAS need very large samples to achieve adequate statistical power. Thousands of cases and controls are typical; some studies use even more. Such sample sizes are difficult to achieve in a single collection, so many GWAS use meta-analysis methods to combine the results of different collections. This calls for sophisticated detection and correction of biases that can arise from even subtle differences in ancestry, genotyping platform, or other sample-specific sources.

GWAS are best powered for detecting association with common variants [48]. Such common variants typically confer only a slight increase in disease risk, since natural selection keeps higher-risk variants from rising to high frequencies under most circumstances [49]. The goal of GWAS is to detect genes involved in the trait of interest, but the genetic markers used in a GWAS do not unambiguously implicate particular genes and often fall within large stretches of DNA between genes. For a review of the experimental route from GWAS hit to disease gene, see [50].

Results to date

The first GWAS of BD were published in 2007, with few genome-wide significant markers [51–53]. As samples have grown, findings have grown as well. To date, over 20 distinct genetic associations with BD have been detected at genome-wide significance (Fig. 70.2). Some of these have been replicated in at least one independent sample. This is perhaps the greatest advance of the GWAS method for psychiatry—identification of robust genetic markers for disorders that had hitherto defied genetic analysis. Given the steady pace of new findings—approximately one new genetic association for every 1000 cases of BD studied—it seems likely that GWAS will yield many additional associations as sample sizes increase [54].

As expected, all of the markers found so far are common and each confers a modest increased risk for illness (odds ratios < 1.2). The associated SNPs lie near genes that encode signalling molecules, ion channels, neuronal growth factors, and other molecules [55], but as noted previously, firm experimental links between associated SNPs and particular genes remain to be established. Interestingly, many of the same genetic markers have been implicated by GWAS of schizophrenia, supporting the view that BD and schizophrenia share some genetic risk factors [5, 56].

Polygenic models

The large number of associated markers and low risk conferred by each marker have led to intensive investigation of the ways in which markers found by GWAS may act together to influence risk in each individual case. Early expectations of multiplicative

Fig. 70.2 Significant associations with bipolar disorder from genome-wide association studies published through December 2016.

Source: data from NHGRI-EBI GWAS Catalog; graphic generated with NCBI Genome Decoration Page.

effects—where the risk conferred by a set of distinct markers is greater than the sum of each individual marker—have been largely unfulfilled. Instead, it appears that common risk variants add together to confer risk, in much the same way as predicted by classic polygenic models [57].

A landmark study [56], published in 2009, offered one way to assess the effects of many markers of small effect. By assigning each allele a weight, based on its association odds ratio, that study showed that it is possible to estimate the total risk of illness conferred by the full set of alleles carried by each individual. Known as the polygenic risk score, this estimate has proven to be useful to gauge the impact of common risk variation across studies and traits. Since it does not seek to implicate any one particular marker, the polygenic risk score

can use information from markers that have not yet been implicated at the stringent genome-wide significance threshold.

The polygenic risk score approach shows that common variants can account for approximately 5% of the variance in risk for BD [58]. The remaining risk remains unexplained, leading to what has come to be known throughout the GWAS literature as the ‘missing heritability’ problem [59]. As sample sizes grow, we expect that the proportion of risk that can be explained by common variants will grow but will probably remain below the inherited genetic risk estimated by twin studies. This is one of the rationales for studies of rare variation, discussed later in this chapter.

The polygenic risk score approach has also shown that most of the common genetic risk for BD overlaps with that seen in schizophrenia

and—to a lesser extent—major depression [58]. This important finding is again consistent with the idea that the major mood and psychotic disorders share many common genetic risk factors.

SNP heritability

Since they sample genetic variation across the entire genome, SNPs can also be used to estimate distant relatedness between individuals. This fact can be harnessed to estimate heritability without some of the limitations and challenges inherent in traditional twin studies. This has come to be known as the ‘SNP heritability’ [60].

Several SNP heritability studies have been published. Heritability estimates have generally been far below those of twin studies. SNP heritability estimates for BD are typically in the range of 30–40%, less than half the heritability estimated from twin studies [61]. Additional research is needed to understand the sources of this large difference in heritability estimates.

Copy number variants

As high-resolution studies of human chromosomes became feasible in recent years, it became clear that SNPs were not the only kind of variation in the human genome. Copy number variants, or CNVs, are small chromosomal segments that are deleted or duplicated across individuals in the population [62]. Individually rare, CNVs that may span several genes are, as a group, quite common in the human genome. Some of these CNVs play a role in human disease. For reasons not yet fully understood, CNVs seem to play an especially important role in diseases of the central nervous system, such as intellectual disability, autism, and schizophrenia, where they can contribute to over 5% of cases [63].

While it seems clear that CNVs do not play a major role in BD [64], several large studies have implicated particular CNVs in a range of psychiatric disorders, including BD [65, 66]. The clearest example is a duplication on chromosome 16p11.2 that spans about 650,000 base pairs of DNA and encodes a number of genes [67]. The 16p11.2 duplication is found in under 1% of people with BD but appears to confer a substantial risk of illness—about 10-fold—much higher than any other known single genetic event [65]. This same duplication also confers a high risk of schizophrenia and intellectual disability, so it cannot be considered a specific risk factor for BD. Further research is needed to understand how this CNV affects gene function and neurodevelopment and why it is such a potent risk factor for a range of neuropsychiatric disorders.

Sequencing studies

Thanks to advances in sequencing technology, it is now possible to determine the precise nucleotide sequence of long stretches of DNA with great accuracy and relatively low cost. Sequencing can be performed at the level of individual genes, expressed sequences (known as the exome), or whole genomes, including long stretches of DNA that are coming to be understood as the major sites of gene expression regulation.

Since they do not rely on discreet genetic markers, sequencing studies can uncover the full range of genetic variation, both common and rare, that exists in the human genome. Large-scale studies have already demonstrated that each individual harbours numerous rare variants [68], including 1–3 that arose *de novo* as new mutations not present in either parent [69]. Variants within coding regions of genes may change amino acids, alter splice patterns, or shift the

reading frame, leading to substantial differences in protein function, including complete loss of function.

Rare alleles could help explain the large portion of heritability apparently not explained by common variants [59]. This hope has fuelled a growing set of studies aimed at sequencing individuals with common neuropsychiatric disorders. Only a few large-scale sequencing studies have been performed so far in BD. Both case-control and family designs have been utilized [70–73]; one study has focused on *de novo* variants [74]. The results have been largely inconclusive, probably owing to the very large samples needed to establish unambiguous associations with rare variants [75]. As sample sizes grow, rare risk alleles may be found that will contribute to a more complete understanding of the full range of genetic variation underlying BD.

Genetic modelling studies

Animal models

Modelling psychiatric disorders in animals is challenging, since current psychiatric diagnosis is based on aspects of mood, cognition, and perception that are difficult to infer in animals. Despite this problem, certain behavioural phenotypes thought to model aspects of BD have been widely studied in rodents such as hyperactivity as a model for mania, and learned helplessness as a model for depression. Animal models offer many advantages such as rapid evaluation of therapeutic interventions, genetic engineering, and experimental control of environmental risk factors. Critical reviews on animal models for neuropsychiatric disorders [76], recurrent or bipolar depression [77], and bipolar mania [78] have been presented recently.

General approaches for creating animal models are typically based on genetics, pharmacology, environmental manipulation, or brain lesions [76]; each of these approaches has its own limitations. Evaluating the appropriateness of a model is fraught with many challenges. The latter review listed three types of validators: construct, face, and predictive validity. Criteria for construct validity could be met, for example, by knockout of a highly penetrant single gene, but such genes have not been identified in BD. Face validity depends on the extent to which the animal model displays biochemical, neuropathological, and behavioural properties analogous to those observed in human disease. Predictive validity can be claimed when the response to pharmacologic agents in the animal model predicts drug response in human patients.

Numerous attempts at modelling a specific phenotype relevant to BD have been published. Mania-like behaviour in animals has been induced through administration of psychostimulants such as amphetamine, ouabain, or quinpirole [76, 78]. In these animals, hyperactivity has been shown to be diminished by mood-stabilizing agents such as lithium or valproate. A review of studies modelling mania in mice through genetic manipulations has been presented recently [78]. Expression profiling of genes changed under mania-like conditions and during subsequent behavioural rescue with drugs could reveal perturbed pathways that may have a role in pathophysiology.

Some examples illustrate the strengths and weaknesses of this strategy. GSK-3 β is a well-established target of lithium via the Wnt signalling pathway. Overexpression of GSK-3 β in mice induces hyperactivity, lower food intake, and other behavioural

abnormalities broadly resembling mania in humans (reviewed in [78]). The *Clock* Δ 19 mutant mouse, which could model some of the circadian rhythm disturbances in BD, exhibits various mania-like behaviours that can be normalized by chronic lithium treatment (reviewed in [78]). Knockdown or heterozygous disruption of exon 1b in the gene *ANK3*, which has been implicated in BD by GWAS, provokes mania-like behaviour in mice that can be reversed by lithium (reviewed in [78]). The function of genes implicated in BD is perturbed in each of these models, thus providing support for an impact of these individual genes on behaviour, as well as an experimental system in which mechanisms can be investigated. However, such models cannot capture the additive effects of multiple common variants in several genes, even though this is currently the most widely accepted genetic architecture for BD and other mental illnesses.

Animal models that might recapitulate both mania and depressive-like behaviours could meet requirements of construct, face, and predictive validity. Two such mouse models have been developed and studied—the Black Swiss mouse, which was generated by crossing outbred Swiss mice with the inbred strain C57BL6/JN, and the Madison mouse [78]. Lithium treatment reverses some of the mania-like phenotypes in both of these models, suggesting they may be exploited to screen new compounds for lithium-like effects.

Several mouse models of depression have been developed. Most are built on the learned helplessness construct [79], such as the forced swim test and the tail suspension test (reviewed in [77]). Historically, these models have played a valuable role in the discovery of antidepressants [80], which are often prescribed for people with BD, but the heuristic value of the learned helplessness construct has been questioned in recent years as the pace of discovering new antidepressants has slowed [81].

Cellular models

Various cells, including lymphoblastoid cell lines, fibroblasts, and immortalized neuronal cells, have been used to examine diverse aspects relevant to BD. In this section, we will focus our discussion on induced pluripotent stem cells (iPSCs). The development of iPSC technology through the Nobel Prize-winning work of Yamanaka [82, 83] has provided the unprecedented power to study previously inaccessible live human tissues by reprogramming an individual's adult somatic cells to stem cells. iPSCs could then be differentiated into cells of interest, including neural progenitor cells, astrocytes, and neurons that could be targeted for various studies. iPSCs and their derivatives provide a person-specific cellular template to pursue functional, drug response, drug discovery, and toxicology studies. In contrast to animal models, studies on iPSC derivatives would deliver data on cells that carry the genetic background of the patient or that of the person under study. In addition, dish-derived stem cells could be tapped for further investigations *in vivo*, for example in mouse models, to either cause or rescue an abnormal phenotype.

To help assemble, characterize, generate, store, distribute, and promote expansion of the iPSC collection, the NIMH Repository and Genomics Resource (NIMH-RGR) (https://www.nimhgenetics.org/stem_cells/) established the NIMH Stem Cell Center to act as a repository for stem cells for neuropsychiatric disorders, assuring the research community of the availability of study samples.

Disease modelling in iPSC and iPSC derivatives in neurologic, neurodevelopmental, and neuropsychiatric disorders was recently reviewed [84]. The ability to transform stem cells into various

neuronal derivatives permits the comparative analysis of transcriptome, proteome, and epigenetic patterns at each stage of differentiation of cells that originate from affected and unaffected individuals. Integration of expression patterns with GWAS findings could strengthen support for loci and signalling pathways that contribute to disease risk. Cellular phenotypes revealed in the presence or absence of various pharmacologic or environmental agents, that could distinguish patients from controls, could be harnessed to develop functional assays and lead to the discovery of candidate therapeutic compounds. Production of isogenic lines using genome-editing methods, such as CRISPR-Cas9, might reduce the requirement for large sample sizes; however, the lack of a penetrant major effect mutation in BD presents a key impediment for such an approach.

Several studies on iPSC neuronal derivatives in BD have claimed phenotype differences between cells derived from people with BD and those from healthy controls [85–87]. Each study focused on different cellular phenotypes in small samples, highlighting the need for higher-throughput, standardized measures that can be carried out and tested for replication in larger samples. If consistent cellular phenotypes can be identified, they could serve as a basis for many important studies such as screening for novel therapeutic compounds.

Future directions

One of the important near-term tasks is to establish firm links between common variants identified by GWAS and specific genes. This task has become more tractable, as we learn more about the mechanisms of gene regulation [88]. At the same time, the task has also grown more complex. It is becoming increasingly clear that physical proximity is a poor indicator of which SNPs regulate which genes [89], that each SNP may regulate many different genes, and that the relationship between SNPs and the genes they regulate may vary by cell type and developmental stage. The identification of specific genes is important if we are to succeed in extracting insight from GWAS into the biological basis of BD.

In addition to those genes implicated by GWAS, many other genes may harbour rare variants that contribute to BD. While more difficult to achieve, firm rare variant associations may be particularly informative since they may be more easily linked to specific genes and often confer much larger risk than common variants.

The field of complex genetic disorders still lacks a unified framework that can fully encompass both common and rare genetic variants. How can both forms of variation be used to develop a more complete account of the inherited risk of BD? Are certain kinds of variants specific to BD, or are they all shared to some extent with other major mental illnesses such as schizophrenia or major depression? How can genetic variation be leveraged to improve and refine our diagnostic categories?

While it is clear that disease modelling using animal or cellular models cannot recapitulate, in its entirety, the complexity of BD, these models can illuminate certain aspects of pathophysiology. Recent developments in the generation of three-dimensional cultures and brain organoids [90] may lead to the creation of more physiologically meaningful models. Engrafting patient iPSC-derived neurons into rat brain could disclose impairments in connectivity and axonal transport that might be operative in neuropsychiatric disorders [91].

The potential role of glial cells may be revealed by tools such as chimeric mice whose native glia are replaced by human-derived cells [92, 93]. These advances and others that are being developed, such as optical electrophysiology [94], could help spur improvements in disease modelling and assay development that will form the basis for high-throughput therapeutic screening and the identification of novel drug treatments for BD.

As we move towards the identification of genetic variants that, taken together, confer substantial risk for BD, we will also have the opportunity to investigate more powerfully the role of non-genetic risk factors. By contrasting the life histories of individuals at high genetic risk who do or do not develop BD, we may finally be able to define specific non-genetic events that contribute to risk for bipolar illness. This could ultimately lead to preventive approaches, based on risk factors that are more easily modifiable than inherited genetic variants.

Conclusions

The last century has seen enormous progress in our understanding of the genetic basis of BD. From early studies aimed at assessing the overall contribution of genes to the obvious familial clustering of BD, we have now progressed to the point where we have reliably identified dozens of common genetic markers for this common disorder. Complex inheritance patterns, substantial genetic heterogeneity, and considerable genetic overlap with other major mental illnesses remain as real barriers to a complete genetic account of individual risk. Much still needs to be done to translate the great progress in genetic research into biological insights that can inform an understanding of the causes, treatment, and prevention of BD.

Neuroimaging of bipolar disorder

Mary L. Phillips and Wayne C. Drevets

Functional neuroimaging studies of bipolar disorder

Abnormal activity in emotion processing and emotion regulation neural circuitry

Emotional over-reactivity and emotion dysregulation are key clinical features of bipolar disorder [1]. Given this, it is not surprising that the majority of functional neuroimaging studies in bipolar disorder examined functioning in neural circuitries supporting emotion processing and emotional regulation when participants performed emotion processing and emotional regulation tasks. These neural circuitries centre on the amygdala, a region important for emotion processing, threat, and salience perception [2], and prefrontal cortical regions important for emotion regulation. Emotion regulation has been subdivided into voluntary and automatic (implicit) subprocesses where different prefrontal cortical regions, including the orbitofrontal cortex, ventrolateral prefrontal cortex, dorsolateral prefrontal cortex, and medial prefrontal cortex (including the anterior cingulate cortex and mediodorsal prefrontal cortex), underlie these different subprocesses [3]. Here, a predominantly lateral prefrontal cortical system, centred on the dorsolateral prefrontal cortex and ventrolateral prefrontal cortex, is thought to be important for *voluntary* emotion regulation, while a medial prefrontal cortical system, including the orbitofrontal cortex, anterior cingulate cortical subregions (subgenual, pregenual, and dorsal subregions), mediodorsal prefrontal cortex, and also the hippocampus, is thought to be important for *automatic* emotion regulation [3] (Fig. 71.1a).

Earlier studies reported abnormally elevated amygdala activity to emotional stimuli, and abnormally reduced activity in lateral and medial prefrontal cortical regions supporting emotion regulation [3] in individuals with bipolar disorder. More recent studies focused on elucidating specific fronto-subcortical functional abnormalities in adults with bipolar disorder during emotion regulation and inhibitory control [4]. Specifically, these studies showed abnormally decreased inferior frontal cortical activity, especially in the ventrolateral prefrontal cortex, during different positive and negative emotion processing and emotion regulation tasks in adults with bipolar disorder, even across different mood states. Altered (including abnormally elevated and abnormally decreased) activity in the amygdala and other emotion regulation circuitry regions was also

demonstrated in adults with bipolar disorder in these studies (Table 71.1; Fig. 71.2).

Abnormal activity in emotion processing circuitry to positive emotional stimuli

Other findings highlight abnormally elevated amygdala and striatal and medial prefrontal cortical activity to positive emotional stimuli in individuals with bipolar disorder (Table 71.1), with more recent studies demonstrating abnormally increased amygdala and medial prefrontal cortex activity [4] to emotional, especially happy, faces in adults with bipolar disorder. These findings may reflect a dysregulated amygdala response and an underlying attentional bias to positive emotional stimuli in individuals with bipolar disorder that predisposes to hypomania and mania.

Abnormal functional connectivity in prefrontal cortical-amygdala circuitries important for emotion processing and regulation

Several studies reported abnormally increased positive functional connectivity (that is, positive coupling of changes in magnitude of activity over time) or abnormally reduced inverse functional connectivity (that is, negative coupling of changes in magnitude of activity over time) between the amygdala and the ventrolateral prefrontal cortex in individuals with bipolar disorder, compared with healthy individuals, during performance of emotion processing and emotion regulation tasks [5] (Table 71.1). For example, studies reported weaker inverse functional connectivity or abnormal positive functional connectivity between the ventrolateral prefrontal cortex and the amygdala in individuals with bipolar disorder, compared with healthy controls, during emotion regulation tasks. Interactions between the amygdala and the ventrolateral prefrontal cortex may also be influenced by different types of emotional stimuli in individuals with bipolar disorder, but not in healthy individuals.

Other studies focused on functional connectivity between the amygdala and the medial regions of the orbitofrontal cortex. Here, reduced functional connectivity between the medial orbitofrontal cortex and the amygdala has been reported in depressed individuals with bipolar disorder, relative to healthy individuals, in both hemispheres, and on the left relative to depressed individuals with major depressive disorder. Functional connectivity between the amygdala and other medial regions of the prefrontal cortex is also altered in

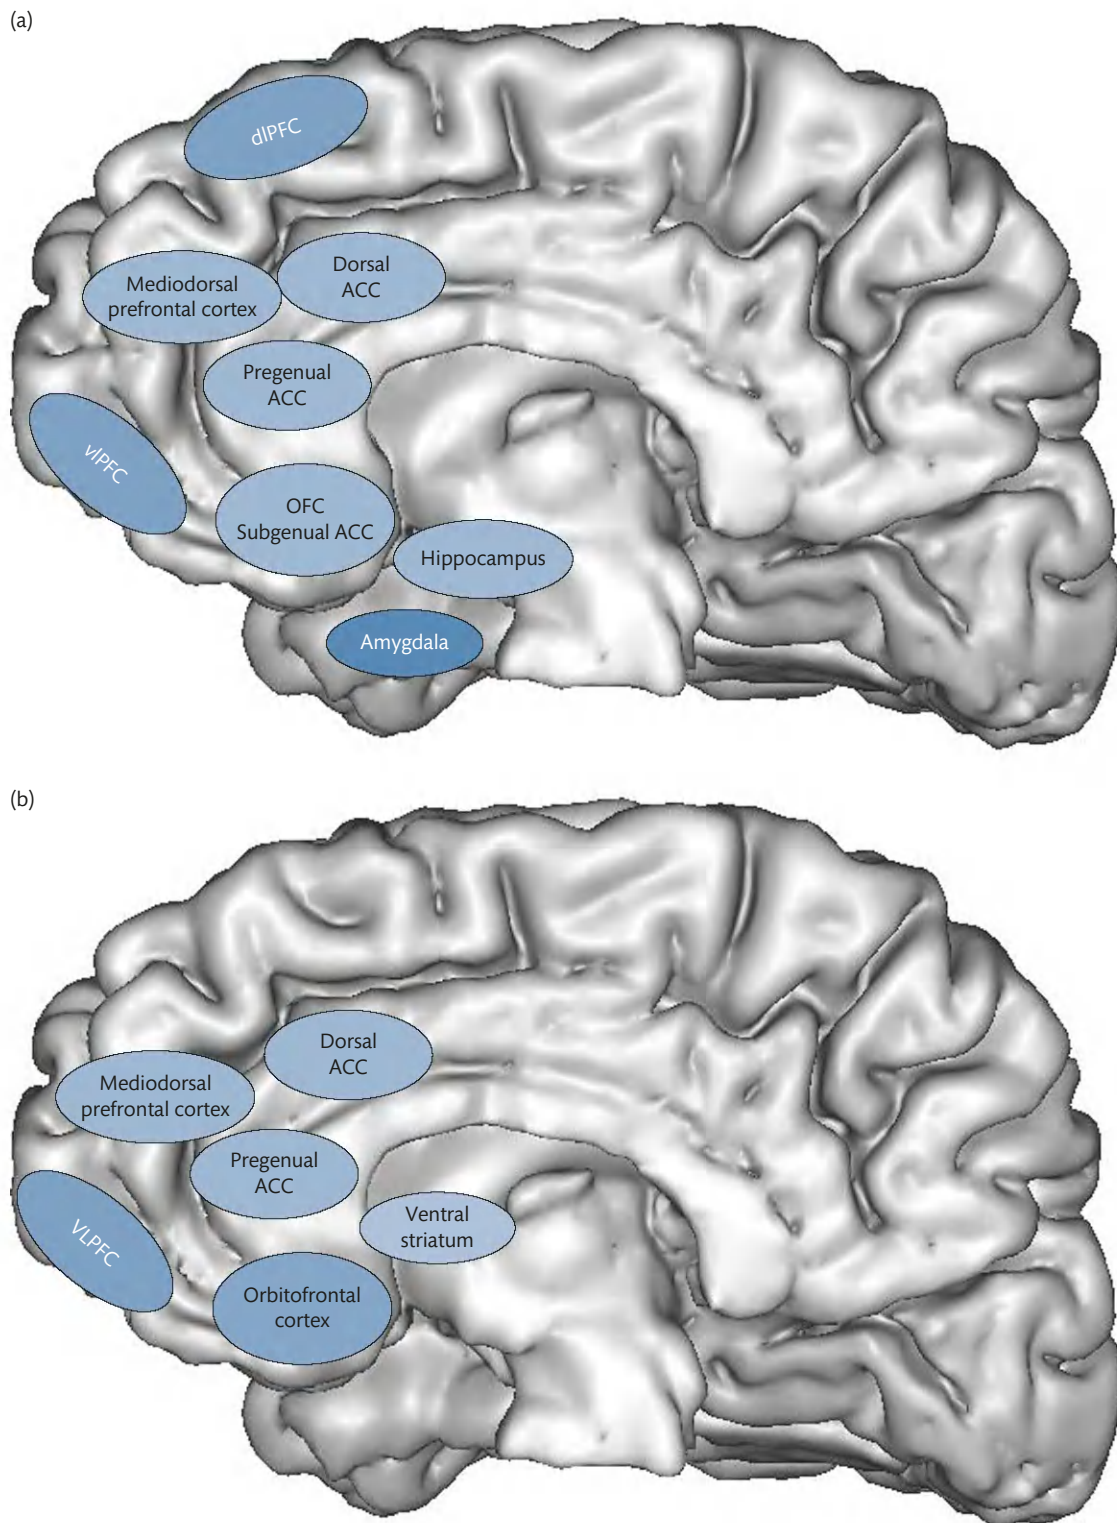

Fig. 71.1 (a) Key nodes in emotion processing and emotion regulation and neural circuitries in healthy individuals. dlPFC, dorsolateral prefrontal cortex; vlPFC, ventrolateral prefrontal cortex; ACC, anterior cingulate cortex. Regions in blue are involved in voluntary emotion regulation processes. Regions in purple are involved in automatic emotion regulation processes. In red is the amygdala, a key node in emotion processing, threat, and salience perception.

(b) Key nodes in reward processing neural circuitry in healthy individuals. In orange is the ventral striatum, a key neural region involved in the orientation to reward cues and prediction error encoding. In red is the orbitofrontal cortex, a key neural region important for encoding the incentive value of stimuli. In purple are different medial prefrontal cortical regions, including different anterior cingulate cortical regions and mediodorsal prefrontal cortex, that are implicated in the regulation of appetitive behaviours and regulation of the ventral striatum in rewarding or potentially rewarding contexts. In blue is the ventrolateral prefrontal cortex, which, in rewarding contexts, links stimulus representations to reward outcomes and encodes the value of different decision-making options.

Table 71.1 Main themes from functional neuroimaging studies in bipolar disorder

Abnormal activity in emotion processing and emotion regulation neural circuitry	1. Abnormally increased amygdala activity to emotional stimuli 2. Abnormally decreased ventrolateral prefrontal cortical activity during emotion processing, emotion regulation, and response inhibition
Abnormal activity in emotion processing circuitry to positive emotional stimuli	1. Abnormally increased amygdala, striatal, and medial prefrontal cortical activity to positive emotional stimuli
Abnormal functional connectivity in prefrontal cortical-amygdala circuitries important for emotion processing and regulation	1. Abnormally increased positive functional connectivity or abnormally reduced inverse functional connectivity between amygdala and ventrolateral prefrontal cortex during emotion processing and emotion regulation 2. Abnormally reduced or altered functional connectivity between medial orbitofrontal cortex and amygdala during emotion processing 3. Altered functional connectivity between ventrolateral prefrontal cortex and medial prefrontal cortex during task performance 4. Altered functional connectivity between dorsolateral prefrontal cortex and amygdala, and between dorsolateral prefrontal cortex, anterior cingulate cortex, and ventrolateral prefrontal cortex during emotion processing and emotion regulation
Abnormal activity and functional connectivity in emotion processing and emotion regulation neural circuitry during performance of non-emotional tasks	1. Abnormally increased amygdala, medial prefrontal cortical, orbitofrontal cortical, and temporal cortical activity during non-emotional cognitive task performance
Abnormal activity and functional connectivity in reward processing neural circuitry	1. Abnormally increased left ventrolateral prefrontal cortical activity and left orbitofrontal cortical activity during reward anticipation and receipt 2. Abnormally increased ventral striatal activity to reward anticipation and receipt in euthymic, but not in depressed, individuals with bipolar disorder 3. Abnormally reduced inverse functional connectivity between ventral striatum and medial prefrontal cortex

Fig. 71.2 Key functional abnormalities in emotion regulation neural circuitry in individuals with bipolar disorder. The most consistent abnormalities include: 1. abnormally increased amygdala activity to emotional stimuli; 2. abnormally decreased ventrolateral prefrontal cortical activity during emotion processing, emotion regulation, and response inhibition; 3. abnormally increased amygdala and medial prefrontal cortical activity to positive emotional stimuli; 4. abnormally increased positive functional connectivity or abnormally reduced inverse functional connectivity between the amygdala and the ventrolateral prefrontal cortex during emotion processing and emotion regulation; and 5. abnormally reduced or altered functional connectivity between the medial orbitofrontal cortex and the amygdala during emotion processing. Star shapes refer to neural regions that are most consistently reported as being affected as described previously in bipolar disorder. In parallel, there are widespread abnormal decreases in grey matter volume and cortical thickness in prefrontal cortical regions, decreased grey matter volume in the amygdala and the hippocampus, and abnormally decreased fractional anisotropy in white matter tracts connecting the ventral prefrontal cortex and anterior temporal regions. There are also abnormalities of regional glucose metabolism and microglial activation in the same regions showing grey matter loss.

individuals with bipolar disorder during task performance, but without a clear direction of effect emerging (Table 71.1). The differential pattern of findings regarding functional connectivity between the amygdala and the ventrolateral prefrontal cortex and between the amygdala and regions of the medial prefrontal cortex may thus reflect specific functional abnormalities in lateral prefrontal cortical-based voluntary/effortful emotion regulation pathway and medial prefrontal cortical-based automatic/implicit emotion regulation pathway. Abnormally elevated positive functional connectivity in the former pathway may reflect abnormally elevated encoding of emotion in the amygdala, resulting in an inefficient, compensatory regulation of the amygdala by the ventrolateral prefrontal cortex or by abnormally elevated signalling of emotion from the amygdala to the ventrolateral prefrontal cortex. By contrast, abnormally reduced functional connectivity in the latter pathway may reflect a relative disconnectivity pattern, resulting in deficient amygdala regulation by medial prefrontal cortical regions (Fig. 71.2).

There are also observations of altered connectivity between the ventrolateral prefrontal cortex and the medial prefrontal cortex in individuals with bipolar disorder. The dorsolateral prefrontal cortex may also play a role in regulating the amygdala, with alterations in dorsolateral prefrontal cortical–amygdala and dorsolateral prefrontal cortical–anterior cingulate cortical–ventrolateral prefrontal cortical functional connectivity reported in individuals with bipolar disorder (Table 71.1).

Abnormal activity and functional connectivity in emotion processing and emotion regulation neural circuitry during performance of non-emotional tasks

Abnormal patterns of activity in emotion processing circuitry, including the amygdala, medial prefrontal cortex, orbitofrontal cortex and temporal cortex, during non-emotional, cognitive task performance have also been reported in individuals with bipolar disorder [4] (Table 71.1). Key findings include abnormally elevated amygdala activity, abnormally reduced inverse functional connectivity between the amygdala and cortical regions, and abnormally reduced activity in prefrontal cortical regions implicated in cognitive control processes in adults with bipolar disorder during a variety of cognitive and motor tasks. These findings suggest a heightened perception of emotional salience in non-emotional contexts in bipolar disorder.

Abnormal activity and functional connectivity in reward processing neural circuitry

A number of behavioural and event-related potential studies have highlighted heightened reward sensitivity in individuals with bipolar disorder. The key role of the ventral striatum (nucleus accumbens) in response to reward cues, reward receipt, and prediction error (the difference between expected and actual outcomes) is well established [6]. Specific prefrontal cortical regions also have specific roles in reward processing. The ventrolateral prefrontal cortex, in addition to its role in emotion regulation, is activated during arousal in the context of emotional stimuli, encodes the value of different decision-making options, and links stimulus representations to specific reward outcomes [7]. The orbitofrontal cortex encodes reward values. In humans, both of these regions may have excitatory afferent connections with the ventral striatum, given studies reporting excitatory afferent connections between the homologues of these

prefrontal cortical regions and the ventral striatum in rodents. The medial prefrontal cortex (including dorsal and pregenual anterior cingulate cortical subregions and mediodorsal prefrontal cortex) regulates the ventral striatum and appetitive behaviours in potentially rewarding contexts [8] (Fig. 71.1b).

Functional neuroimaging studies of reward processing neural circuitry in individuals with bipolar disorder indicate abnormally elevated activity in the ventral striatum and left prefrontal cortex, in particular, the left orbitofrontal cortex and the left ventrolateral prefrontal cortex, during reward processing [4]. Here, studies reported abnormally increased left ventrolateral prefrontal cortical activity to reward anticipation in adults with bipolar disorder across different mood states and abnormally increased ventral striatal activity during reward anticipation in euthymic individuals with bipolar disorder; abnormally elevated left orbitofrontal cortex and amygdala activity to reward reversal and elevated left orbitofrontal cortex activity to reward in euthymic adults with bipolar disorder; and elevated ventral striatal activity to reward cues and outcomes in individuals with subthreshold hypomania. By contrast, patterns of either no ventral striatal activity abnormality during reward anticipation or receipt or abnormally reduced ventral striatal activity to reward receipt have been demonstrated in depressed individuals with bipolar disorder. Another study reported no differential activity in the ventral striatum to reward receipt vs omission in manic adults with bipolar disorder. These findings indicate abnormally elevated activity in distributed reward circuitry, particularly in the left ventrolateral prefrontal cortex, during reward processing in individuals with bipolar disorder (Table 71.1; Fig. 71.3). Only a small number of recent studies reported altered functional connectivity in reward circuitry, including significantly reduced inverse functional connectivity between the ventral striatum and medial prefrontal cortical regions. This is an area requiring future research effort.

Intrinsic (resting state) connectivity studies

These studies provide measures of tonic functional connectivity in neural circuitries of interest, rather than stimulus-related, phasic functional connectivity in these circuitries, and can thereby identify context-independent functional abnormalities that potentially represent core functional abnormalities in such circuitries in a given disorder. The majority of these studies in bipolar disorder employed a region of interest approach to examine functional connectivity among a priori regions and localized neural circuitries at rest, measuring, for example, correlations between time series of low-frequency fluctuations in activity among these regions. Predominant findings from these studies in individuals with bipolar disorder parallel findings from task-based fMRI studies [5] and include: (1) abnormally decreased, but also abnormally increased, positive resting connectivity between medial prefrontal cortical and amygdala and striatal regions; (2) abnormal positive and abnormally reduced inverse resting connectivity between the medial prefrontal cortex and the ventrolateral prefrontal cortex, but also abnormally reduced positive resting functional connectivity among medial and lateral prefrontal cortical regions; (3) abnormally elevated positive resting state connectivity between the ventrolateral prefrontal cortex (and the anterior cingulate cortex) and amygdala; and (4) abnormally reduced inverse resting connectivity between the amygdala

Fig. 71.3 Key functional abnormalities in reward processing neural circuitry in individuals with bipolar disorder, including: 1. abnormally increased left ventrolateral prefrontal cortical activity and left orbitofrontal cortical activity during reward anticipation and receipt; 2. abnormally increased ventral striatal activity to reward anticipation and receipt in euthymic, but not in depressed, individuals with bipolar disorder; 3. abnormally reduced inverse functional connectivity between the ventral striatum and the medial prefrontal cortex. Star shapes refer to neural regions that are most consistently reported as being affected as described previously in bipolar disorder. In parallel, there are widespread decreases in grey matter volume and cortical thickness in prefrontal cortical regions and striatal regions in individuals with bipolar disorder.

and the dorsolateral prefrontal cortex. Other studies in individuals with bipolar disorder show more widespread patterns of abnormally reduced positive functional connectivity among different prefrontal cortical and temporal regions, and reduced positive functional connectivity among midline cortical regions. Abnormalities in amygdala–ventrolateral prefrontal cortical resting functional connectivity may be determined, at least in part, by the medial prefrontal cortex.

Other resting state functional connectivity studies focused on larger-scale networks and reported in individuals with bipolar disorder diverse patterns of abnormally increased resting connectivity in paralimbic and fronto-temporal/paralimbic networks, abnormally decreased connectivity in the medial prefrontal cortex, and abnormal positive resting connectivity between the medial prefrontal cortex and the ventrolateral prefrontal cortex, and between the medial prefrontal cortex and the insula, together with abnormal decoupling between the mediodorsal prefrontal cortex and the dorsolateral prefrontal cortex.

Fewer studies used global connectivity methods (for example, independent components analyses) to study patterns of whole brain study resting functional connectivity in individuals with bipolar disorder. Findings from these studies are somewhat mixed, showing diverse patterns of abnormally elevated or reduced resting connectivity within and among different large-scale neural networks implicated in salience processing, executive function, emotion, and ‘default mode’ (non-task performance).

Recent studies examined the amplitude of low-frequency fluctuations (ALFF) and the homogeneity of time series within specific neural regions, as alternative measures of resting state connectivity. These studies reported both abnormally increased and decreased ALFF in fronto-temporal–striatal regions in individuals with bipolar disorder vs healthy individuals, decreased ALFF in left post-central parahippocampal regions in individuals with bipolar disorder vs healthy individuals, and greater regional homogeneity in left frontoparietal cortices in depressed bipolar disorder (subtype unspecified) vs healthy adults.

Together, these studies indicate intrinsic, context-independent abnormalities, both in functional connectivity between regions and in the amplitude and homogeneity of low-frequency fluctuations within neural regions, predominantly within prefrontal cortical, amygdala, and striatal circuitries implicated in emotion processing, emotion regulation, and reward processing in individuals with bipolar disorder [5]. Findings largely parallel those from task-based fMRI studies in bipolar disorder and also suggest abnormalities in resting state functional connectivity among larger-scale neural networks in the disorder (Table 71.2). The relative paucity of resting state functional connectivity studies, in comparison with task-based fMRI studies, in bipolar disorder, particularly those employing global network approaches, suggests that future studies should employ such approaches, in conjunction with task-based fMRI studies, to facilitate understanding of relationships between phasic and tonic-level functioning in neural circuitries of interest in bipolar disorder.

Table 71.2 Main themes from intrinsic resting state connectivity studies in bipolar disorder

Region of interest approaches	<ol style="list-style-type: none"> 1. Abnormal changes in resting connectivity between medial prefrontal cortical and amygdala and striatal regions (both abnormally increased and decreased resting connectivity) 2. Abnormal changes in resting connectivity between medial prefrontal cortex and ventrolateral prefrontal cortex (both abnormal positive and abnormally reduced inverse, and abnormally reduced positive, resting connectivity) 3. Abnormally elevated positive resting state connectivity between ventrolateral prefrontal cortex (and anterior cingulate cortex) and amygdala 4. Abnormally reduced inverse resting connectivity between amygdala and dorsolateral prefrontal cortex 5. Larger-scale network abnormalities across different prefrontal and temporal cortical and subcortical regions
Global connectivity approaches	<ol style="list-style-type: none"> 1. Diverse patterns of abnormally elevated or reduced resting connectivity within and among different large-scale neural networks implicated in salience processing, executive function, emotion, and 'default mode' (non-task performance)
Approaches using amplitude of low frequency fluctuations (ALFF) and regional homogeneity of time series	<ol style="list-style-type: none"> 1. Abnormally increased and decreased ALFF in fronto-temporal-striatal regions 2. Abnormally increased regional homogeneity in left fronto-parietal cortices

Structural neuroimaging studies

Key findings from earlier studies in bipolar disorder were an increased number of white matter hyperintensities [9] and enlarged amygdala grey matter volumes [10, 11], highlighting the potential role of abnormalities in emotion processing neural circuitry in bipolar disorder. More recent studies examined regional grey matter volumes in a wider range of cortical and subcortical regions in adults with bipolar disorder. Two main themes have emerged from these later studies that relate to emotion processing and regulation neural circuitries [4]. Firstly, findings indicate abnormally decreased grey matter volume, decreased white matter volume, and decreased thickness in cortical regions implicated in emotion processing and cognitive processes important for emotion regulation, that is, the prefrontal and anterior temporal cortices, and in cortical regions underlying salience perception, that is, the insula and the dorsal anterior cingulate cortex, in individuals with bipolar disorder, with some exceptions. One study implicated the ventrolateral prefrontal cortex, in particular, in bipolar disorder, reporting a negative association between right ventrolateral prefrontal cortex grey matter volume and illness duration, and smaller right ventrolateral prefrontal cortex grey matter volume in adults with bipolar disorder with long-term illness and minimal lifetime exposure to lithium vs healthy adults, but abnormally increased right ventrolateral prefrontal cortex grey matter volume in relatives of individuals with bipolar disorder and in younger adults in early stages of bipolar disorder [12]. Other studies replicated the finding of reduced right

ventrolateral prefrontal grey matter volume in bipolar disorder. Indeed, several findings indicate that prefrontal cortical grey matter volumes in general may decrease with illness progression, including a greater number of manic episodes, but may normalize (or even increase) with lithium. These findings of reduced grey matter volume in prefrontal cortical regions, especially in the right ventrolateral prefrontal cortex in adults with bipolar disorder, suggest a structural basis for findings from fMRI studies of decreased activity in this region during emotion processing and emotion regulation tasks.

A second key finding regarding structural findings in emotion processing and regulation neural circuitries in bipolar disorder is decreased subcortical regional volumes, especially in the amygdala, particularly during depressive episodes, which may normalize with lithium. For example, a meta-analysis reported amygdala volume decreases in youth, but not in adults, with bipolar disorder [13], suggesting a normalization of amygdala volume over development in bipolar disorder, potentially due to medication [12]. Abnormally decreased hippocampal and parahippocampal volumes have also been reported in adults with bipolar disorder; such abnormalities may also be masked by lithium.

Recent studies also provide evidence for abnormally increased gyrification of the anterior cingulate cortex in adults with bipolar disorder and have also employed newer techniques, such as high angular resolution molecular diffusion imaging, to examine the microstructure of different brain tissues in individuals with bipolar disorder. Findings confirm the presence of structural abnormalities in the hippocampus and striatum in bipolar disorder.

Diffusion imaging studies

The main diffusion imaging measures are longitudinal/axial diffusivity (AD), the diffusivity of water molecules along the principal axis; radial diffusivity (RD), the diffusivity of water molecules along transverse directions perpendicular to the longitudinal axis; and fractional anisotropy (FA), the ratio of longitudinal vs transverse diffusivity in white matter tracts. Given the properties of white axonal membranes and myelin sheaths, FA will be high in white matter tracts with densely packed collinear axons, but low in white matter with non-collinear axons. By contrast, RD will be high in white matter with non-collinear axons, but also high in white matter with damaged axonal membranes and/or myelin sheaths.

Studies measuring FA, RD, and AD reported specific abnormalities in the microstructure of white matter tracts in neural circuitries important for emotion processing, emotion regulation, and reward processing in individuals with bipolar disorder. Initial diffusion imaging studies reported white matter abnormalities in frontally situated white matter tracts in adults with bipolar disorder [4]. Recent diffusion imaging studies of adults with bipolar disorder reported abnormally reduced FA, often paralleled by abnormally increased RD, in these tracts, especially in tracts connecting prefrontal cortical and anterior limbic structures supporting emotion regulation and in temporal white matter. White matter tracts that most consistently show these abnormalities are the anterior regions of the corpus callosum, the anterior cingulum, the uncinate fasciculus, and the superior longitudinal fasciculus, tracts that interconnect frontal regions, and connect frontal regions with more posterior regions (including occipital, parietal, and temporal regions). These

abnormalities may be more apparent in a depressive episode than in remission and may be normalized by lithium. One study reported abnormal nodal networks in the left ventrolateral prefrontal cortex, left hippocampus, and bilateral mid anterior cingulate cortex in adults with bipolar disorder vs healthy adults [14], that may suggest a specific white matter structural basis for the observed pattern of abnormal left ventrolateral prefrontal cortex and orbitofrontal cortex activity during reward processing in bipolar disorder.

Together, findings from diffusion imaging studies in adults with bipolar disorder thus suggest either abnormal myelination or abnormal orientation of axons in white matter tracts connecting frontal and temporal (and also occipital and parietal) cortices, cortical regions that are in neural circuitries important for emotion regulation and reward processing. Interestingly, a recent diffusion imaging study measured magnetization transfer ratio (MTR) to assess the degree of myelin content in white matter tracts, and diffusion tensor spectroscopy (DTS) to measure metabolite diffusion specifically within axons in these tracts, in individuals with bipolar disorder [15]. This study reported specific reductions in MTR, but no abnormalities in DTS, in right prefrontal cortical white matter in individuals with bipolar disorder. These findings suggest that the major finding of reduced FA reported previously may result from reduced myelin content, rather than changes in axonal structure, in bipolar disorder.

These data appear consistent with post-mortem histopathological evidence showing a reduction in oligodendroglial cell counts and in the expression of myelin basic protein (MBP) and other oligodendroglial genes in the medial prefrontal cortical network in bipolar disorder [16]. In prefrontal cortical and hippocampal tissue of bipolar patients' studied post-mortem (predominantly from medicated subjects in the depressed or mixed phases prior to death), the genes involved in energy metabolism and mitochondrial function also are downregulated, while genes involved in immune response and inflammation are upregulated [17]. These data, taken together with the evidence reviewed in the following sections that bipolar disorder is associated with abnormal energy metabolism and neuroinflammation, may relate mechanistically to the white matter abnormalities identified using DTI, DTS, and structural MRI.

Magnetic resonance spectroscopy studies

Data obtained using magnetic resonance spectroscopy (MRS) technologies are relevant to functional and structural neuroimaging abnormalities since they can identify alterations in the bioenergetics underlying the metabolic and haemodynamic signals assessed during functional neuroimaging. Corroborating the evidence for reduced mitochondrial gene expression in bipolar disorder, *in vivo* MRS studies have revealed an abnormal reduction in frontal lobe pH in both medicated and unmedicated individuals with bipolar disorder, and a shift from oxidative phosphorylation to glycolysis in medication-free individuals with bipolar disorder [18]. More recently, phosphorus-31 (P-31) MRS studies of bioenergetics in bipolar disorder provided additional *in vivo* evidence of mitochondrial dysfunction in bipolar disorder.

Furthermore, since cerebral blood flow, glucose metabolism, and BOLD-fMRI signals are most heavily influenced by glutamatergic transmission, the application of proton (H-1) MRS to quantitate

glutamate, glutamine, and 'Glx' (a composite measure consisting mainly of glutamate and glutamine) levels in brain tissue also holds relevance for the interpretation of functional imaging data. In general, studies applying these methods have shown a pattern of abnormally elevated Glx levels in bipolar disorder, in contrast to abnormally reduced Glx levels in major depressive disorder. Moreover, the glutamine/glutamate ratio appears abnormally decreased in depression (whether unipolar or bipolar), but elevated in mania. In contrast to functional neuroimaging measures of cerebral glucose metabolism and blood flow, which predominantly reflect glutamatergic transmission, the H-1 MRS measures of glutamate and glutamine almost entirely reflect the intracellular pools, with glutamate residing largely in neurons and glutamine in glia. The abnormal patterns found in mood disorders thus have been interpreted to indicate that the glutamate-related metabolite pool is constricted in major depressive disorder, but expanded in bipolar disorder, and that depressive and manic episodes are characterized by modulation of the glutamine/glutamate ratio in opposite directions, suggesting reduced vs elevated glutamate conversion to glutamine within glial cells, respectively. Since glutamate is converted to glutamine in glial cells, and glutamine is converted to glutamate in neurons, these data suggest an abnormality in neuronal–glial cell interactions. The MRS literature thus appears consistent with the post-mortem findings of reduced oligodendroglial cell counts, impaired astrocyte function (especially with respect to glutamate transport), and loss of GABAergic neurons in structures where the glutamine/glutamate ratio also is altered in bipolar disorder (for example, pregenual anterior cingulate cortex) [16].

Positron emission tomography studies

PET studies of bipolar disorder have employed various radioligands to measure regional blood flow, glucose metabolism, neuroreceptor binding potential, or other parameters. Most of this literature is beyond the scope of this chapter and is reviewed elsewhere [19, 20]. A few pertinent studies are discussed here, which converge with the literature described in the preceding sections to implicate alterations in bioenergetic and neuroinflammation in the pathophysiology of bipolar disorder.

The concept that bioenergetics abnormalities exist in bipolar disorder has face validity because of the clinical observation and symptomatology indicating that psychomotor activity and subjective energy are generally elevated in mania, but reduced in depression. Consistent with this concept, glucose metabolism is increased in the unmedicated manic phase, but decreased in the unmedicated depressed phase of bipolar disorder in limbic–cortical regions such as the subgenual prefrontal cortex [21]. These data thus appear consistent with the P-31 MRS data reviewed previously, which suggested that the glutamine/glutamate ratio is modulated in opposite directions in mania vs depression.

The recent development of PET radioligands for the translocator protein (TSPO) on the outer mitochondrial membranes in microglia has enabled *in vivo* measures of microglial activation. This phenomenon is a central component of neuroinflammation and is manifest by a range of phenotypic changes in microglial cell morphology, as well as upregulation of cellular proteins, including TSPO. The first study using PET-TSPO imaging in bipolar disorder found

that individuals with bipolar disorder type 1 had elevated TSPO binding, relative to healthy controls, in the hippocampus [22].

It remains unclear whether microglial activation in these regions reflects a repair response or instead constitutes a pathological process that disrupts the normal physiology and precipitates disease in bipolar disorder. One line of evidence suggests that inflammation may contribute to reductions in hippocampal volume, as pro-inflammatory drive on the kynurenine metabolic pathway reduces the concentrations of the neuroprotective metabolite kynurenic acid, relative to levels of the putatively neurotoxic metabolites 3-hydroxykynurenine and quinolinic acid. Savitz *et al.* [23] reported that this ratio was reduced in plasma in bipolar disorder individuals, relative to controls, and also correlated directly with hippocampal volume in bipolar individuals (that is, lower neuroprotective indices were associated with smaller hippocampal volumes). Similarly, within the anterior cingulate cortex, a post-mortem study of brain tissue from a combined sample of unipolar and bipolar depressed individuals who died by suicide showed that microglial activation and quinolinic acid expression were increased to the greatest extent in the subgenual anterior cingulate cortex [24], which has been associated with reduced grey matter in both mood disorder subtypes [21].

Interim summary

Neural circuitry abnormalities in bipolar disorder thus comprise: (1) dysfunction in bilateral prefrontal cortical (especially ventrolateral prefrontal cortex and orbitofrontal cortex)–hippocampal–amygdala emotion processing and emotion regulation neural circuitries; (2) hyperactivity in predominantly left-sided ventral striatal–ventrolateral prefrontal cortex reward processing circuitry; (3) parallel resting state functional connectivity abnormalities in these, and more widespread, neural circuitries; (4) abnormalities in regional grey matter structure in these neural circuitries; (5) microstructural abnormalities in white matter tracts in these neural circuitries, with more recent findings suggesting myelin abnormalities in these tracts; (6) bioenergetic abnormalities suggestive of mitochondrial dysfunction and altered neuronal glial interactions; and (7) abnormalities of regional glucose metabolism and microglial activation in the same regions showing grey matter loss. The combination of these functional and structural abnormalities may be characteristic of the behavioural abnormalities associated with bipolar disorder, that is, emotional lability, emotional dysregulation, and reward sensitivity (Figs. 71.2 and 71.3).

Newer neuroimaging research areas in bipolar disorder

(See Table 71.3.)

Mood state-specific functional abnormalities in emotion processing, emotion regulation, and reward processing in neural circuitries

A small number of cross-sectional studies examined individuals with bipolar disorder in different mood states during emotion processing and emotion regulation [4, 5]. One finding is abnormally

Table 71.3 Newer neuroimaging research areas in bipolar disorder

Mood state-specific abnormalities	<ol style="list-style-type: none"> 1. Cross-sectional studies of emotion processing and emotion regulation neural circuitries: (1) differential patterns of activity in orbitofrontal cortex, insula, ventrolateral prefrontal cortex, amygdala, and dorsolateral prefrontal cortex across different mood states; (2) differential patterns of emotion processing task-based connectivity and resting connectivity between amygdala and medial prefrontal cortex, hippocampus, and orbitofrontal cortex 2. Longitudinal studies: differential patterns of prefrontal cortical and amygdala activity and amygdala connectivity across different mood states
Different bipolar disorder subtypes	<ol style="list-style-type: none"> 1. Abnormally decreased prefrontal cortical activity (especially ventrolateral prefrontal cortex) across different tasks in bipolar disorder type II 2. Similar patterns of abnormally elevated activity in amygdala and dorsolateral prefrontal cortex during emotion regulation and working memory, and abnormally elevated left ventrolateral prefrontal cortical and ventral striatal activity during reward anticipation, in bipolar disorder types I and II. Graded differences in magnitude of activity between bipolar disorder subtypes 3. More widespread reductions in grey matter across different cortical regions in bipolar disorder type I, relative to bipolar disorder type II
Youth with bipolar disorder	<ol style="list-style-type: none"> 1. Similar patterns to adult bipolar disorder of abnormally increased amygdala activity, decreased ventrolateral prefrontal cortical activity, and decreased prefrontal cortical–amygdala functional connectivity during emotion processing and emotion regulation 2. Abnormally decreased amygdala volumes and abnormally reduced prefrontal cortical volumes and cortical thickness 3. Abnormally reduced FA in white matter tracts connecting prefrontal cortical and subcortical regions
Adults and youth at risk of bipolar disorder	<ol style="list-style-type: none"> 1. Healthy at-risk adults and youth: (a) abnormally increased prefrontal cortical and amygdala activity during emotion and cognitive control tasks; (b) abnormally increased left ventrolateral prefrontal cortical activity to reward; (c) abnormally increased frontal and subcortical grey matter volumes; (d) abnormally reduced FA in white matter tracts connecting prefrontal cortical and subcortical regions 2. Psychiatrically affected at-risk adults and youth: (a) predominantly abnormally increased prefrontal cortical activity and prefrontal cortical–amygdala functional connectivity during emotion regulation and cognitive control tasks; (b) abnormally increased activity in <i>left-sided</i> prefrontal cortical regions and insula, regardless of task; (c) abnormally decreased grey matter volumes in prefrontal and temporal cortical regions, striatum, and insula; but increased volumes in right ventrolateral prefrontal cortex and left caudate; (d) decreased white matter volume and white matter integrity, especially in prefrontal regions

decreased orbitofrontal cortex activity during emotion processing across different mood states. Other findings indicate differing roles of the insula and ventrolateral prefrontal cortex in adults with bipolar disorder across different mood states during emotion regulation; different mood state-specific increases in amygdala activity to negative emotional faces; abnormally decreased right dorsolateral

prefrontal cortex activity during non-emotional working memory across different mood states; increased ventrolateral prefrontal cortex–thalamic activity in adults with bipolar disorder in mixed mood episode vs depression during response inhibition; and failure to deactivate ventral regions of the medial prefrontal cortex during a working memory task.

Cross-sectional studies also reported differences in amygdala–medial prefrontal cortical functional connectivity across different mood states, including differential patterns of amygdala functional connectivity with the medial prefrontal cortex between depressed and remitted individuals with bipolar disorder during emotion processing; differential patterns of resting state functional connectivity between the amygdala and the anterior cingulate cortex (pregenual subdivision) in manic and depressed mood states and between manic and euthymic states; and abnormally increased vs reduced resting state connectivity between the amygdala and the hippocampus in mania vs depression, respectively. Contrasting patterns of variability in large-scale network resting state signal amplitude in bipolar depression vs mania are also reported [25].

Longitudinal studies reported an abnormally reduced extent of activity in prefrontal cortical regions implicated in emotion regulation during an emotional face–word interference emotion regulation task in individuals with bipolar disorder, relative to healthy controls, but to a greater extent during hypomanic than depressed and euthymic mood states; differential patterns of amygdala functional connectivity in the same individuals with bipolar disorder during mania vs depression; and normalized activity in the amygdala and prefrontal cortical regions in remitted vs manic adults with bipolar disorder during reward and motor tasks.

While there are no clear patterns of mood state-specific functional neural abnormalities in bipolar disorder, findings suggest amygdala–prefrontal cortical functional abnormalities across different mood states, which normalize with remission. Clearly, more longitudinal, within-subject studies are required to identify functional abnormalities in neural circuitries that predispose to switches between different mood states in bipolar disorder.

Bipolar disorder subtypes

A small, but increasing, number of neuroimaging studies focused on adults with bipolar disorder type II [4]. One study reported abnormally reduced amygdala and bilateral ventrolateral prefrontal cortex activity, and reduced amygdala–orbitofrontal cortex and amygdala–dorsolateral prefrontal cortex functional connectivity, during emotional face processing in depressed adults with bipolar disorder type II. Other studies reported abnormally reduced activity in different prefrontal cortical regions during working memory and response inhibition in depressed individuals with bipolar disorder type II. The finding of decreased prefrontal cortical activity, in particular in the ventrolateral prefrontal cortex, parallels that shown during similar tasks by euthymic and depressed adults with bipolar disorder type I and suggests that reduced ventrolateral prefrontal cortex activity during emotion processing and emotion regulation may be a trait marker of bipolar disorder across types I and II.

Other fMRI studies directly compared adults with bipolar disorder type I and bipolar disorder type II and healthy adults. One study compared euthymic adults with bipolar disorder type I, euthymic adults with bipolar disorder type II, and healthy controls during a working memory task and reported a graded pattern of abnormally

elevated activity in the dorsolateral prefrontal cortex during the task in individuals with bipolar disorder type I, relative to bipolar disorder type II, suggesting greater functional abnormalities in prefrontal cortical recruitment during the task in bipolar disorder type I than in type II. Another study reported similar patterns of abnormally elevated activity in the amygdala and dorsolateral prefrontal cortex during an emotion regulation task in both euthymic individuals with bipolar disorder type I and euthymic individuals with bipolar disorder type II, but abnormally increased inverse functional connectivity between the amygdala and the dorsolateral prefrontal cortex during the task only in individuals with bipolar II disorder.

Another study focused on reward circuitry and reported significantly increased ventral striatal and left ventrolateral prefrontal cortical activity in adults with bipolar disorder type II vs adults with bipolar disorder type I and healthy adults during reward anticipation, again paralleling previous studies that highlighted abnormally increased left ventrolateral prefrontal cortex and ventral striatal activity during reward anticipation in euthymic and depressed adults with bipolar disorder type I [26]. Findings from this study are the first to suggest that bipolar disorder type II may be characterized by a greater magnitude of functional abnormalities in reward neural circuitry than bipolar disorder type I, supporting findings associating bipolar disorder type II with more disabling functional impairments in daily living than bipolar disorder type I [27, 28].

Regarding other neuroimaging modalities, abnormally elevated resting state functional connectivity across several regions within a temporo-insular neural network, identified with independent components analysis, was observed in individuals with bipolar disorder type II. Other studies reported more widespread grey matter reductions in the prefrontal, temporal, and parietal cortices in euthymic/moderately depressed adults with bipolar disorder type I vs depressed adults with bipolar disorder type II, and greater magnitude of reductions in grey matter volume and cortical thickness in individuals with bipolar disorder type I relative to bipolar disorder type II. Diffusion imaging studies that compared individuals with bipolar disorder type I and those with bipolar disorder type II reported abnormalities in fronto-thalamic-temporal white matter in both disorders, although findings across studies are inconsistent, with abnormalities only in bipolar disorder type I or, by contrast, abnormalities only in bipolar disorder type II.

There is clearly a need for more neuroimaging studies comparing individuals with bipolar disorder type I with those with bipolar disorder type II and those with other bipolar disorder subtypes.

Neuroimaging studies adopting dimensional approaches

Guided by the NIMH Research Domain Criteria initiative (see Chapter 8), neuroimaging studies are beginning to adopt a dimensional approach to the study of psychiatric disorders, including bipolar disorder. One focus has been to examine individuals across the mood disorders spectrum. One study reported a positive correlation between reward sensitivity (fun-seeking) and ventral striatal activity across adults with bipolar disorder type I, adults with bipolar disorder type II, and healthy adults [26]. This study thus associated patterns of function in reward circuitry with information processing domains that cut across diagnostic boundaries.

Another focus has been to examine the psychosis spectrum by including individuals with bipolar disorder and individuals with schizophrenia. Here, studies examined relationships between

neuroimaging measures of structure and function across the whole brain and in neural circuitries of interest and psychotic symptoms, regardless of diagnosis. Recent findings include significant relationships between psychotic symptom severity and abnormally reduced local resting state functional connectivity [29] and reductions in prefrontal cortical and temporal cortical grey matter volume [30] across individuals with schizophrenia and bipolar disorder.

These findings suggest that the conceptualization of mood disorders and schizophrenia in terms of different psychiatric spectrum disorders may lead to a better understanding of neuropathophysiological processes in these illnesses [31]. Here, for example, bipolar disorder type I, bipolar disorder type II, other bipolar disorder subtypes, and major depressive disorder could perhaps be included along a mood disorders spectrum, and schizophrenia and bipolar disorder along a psychotic disorders spectrum.

Youth with bipolar disorder

Studies reported in youth with bipolar disorder similar patterns to those in adult with bipolar disorder of abnormally increased amygdala activity, decreased ventrolateral prefrontal cortical activity, and decreased prefrontal cortical–amygdala functional connectivity during emotion processing and emotion regulation paradigms [32]. Abnormally increased amygdala activity may be more evident in youth than in adults with bipolar disorder. Studies in bipolar disorder youth also demonstrated abnormally decreased amygdala volumes; reduced orbitofrontal cortex and anterior cingulate cortex grey matter and reduced prefrontal cortical thickness; abnormally reduced FA in white matter tracts connecting prefrontal and subcortical regions, and reduced volume of the corpus callosum; and altered resting state and regional homogeneity in prefrontal cortical–amygdala–striatal circuitry and large-scale networks.

Adults and youth at risk of bipolar disorder

These studies can be divided into those examining healthy adults and youth at future risk of bipolar disorder by virtue of having a parent or sibling with the disorder, and those examining at-risk adults and youth who are already affected with some psychiatric symptoms, but not with bipolar disorder (reviewed in [32]).

Healthy adults and youth at risk of bipolar disorder

During emotion processing, healthy at-risk youth show abnormally elevated amygdala activity, abnormal inverse anterior cingulate–amygdala functional connectivity, and abnormally elevated left ventrolateral prefrontal cortical–amygdala functional connectivity during emotion processing. During emotion regulation and non-emotional cognitive control tasks, healthy at-risk adults and youth showed abnormally elevated, predominantly right-sided activity in frontal control regions (ventrolateral and dorsolateral prefrontal cortices) and in the amygdala, and decreased right ventrolateral prefrontal cortical–amygdala and dorsolateral prefrontal cortical–amygdala functional connectivity. Regarding reward processing, healthy at-risk youth showed abnormally elevated left ventrolateral prefrontal cortical activity to reward, and abnormally reduced functional connectivity between the ventrolateral prefrontal cortex and the anterior cingulate cortex during reward anticipation. In unaffected relatives of adults with bipolar disorder, abnormally elevated right orbitofrontal cortical activity to reward, but abnormally

elevated left orbitofrontal cortical activity to loss, was reported. Resting state findings indicate abnormally reduced resting state functional connectivity between the amygdala and the anterior cingulate cortex and between the amygdala and the ventrolateral prefrontal cortex in healthy at-risk youth.

Regarding structural findings, the main pattern is abnormally *increased* grey matter volume in several areas, including the amygdala, the bilateral ventrolateral prefrontal cortex, the left dorsolateral prefrontal cortex, the left parahippocampal gyrus, and the left caudate. Diffusion imaging studies indicate abnormal, predominantly right-sided decreases in FA and volume in white matter tracts connecting prefrontal cortical and subcortical regions.

These findings may represent two separate kinds of markers: those representing resilience and those representing risk. Resilience markers might include increased prefrontal activity and increased frontal and subcortical volumes, given that at-risk individuals who demonstrated these patterns were psychiatrically healthy at the time of study. Risk markers might include increased amygdala activity and abnormal prefrontal white matter, as these patterns are similar to findings from studies of adults with bipolar disorder.

Psychiatrically affected adults and youth at future risk of bipolar disorder

Regarding emotion processing, findings indicate abnormally elevated amygdala activity, abnormal inverse anterior cingulate–amygdala functional connectivity and abnormally elevated left ventrolateral prefrontal cortical–amygdala functional connectivity during emotion processing, and abnormal functional connectivity among the ventrolateral prefrontal cortex, the anterior cingulate gyrus, and the dorsolateral prefrontal cortex in affected first-degree relatives of individuals with bipolar disorder. During emotion regulation and non-emotional cognitive control tasks, studies indicate abnormally increased dorsolateral prefrontal cortical activity and increased ventrolateral prefrontal cortical–bilateral amygdala functional connectivity in youth with milder-level behavioural and emotional dysregulation symptoms, and abnormally increased activity in the left frontal pole in first-degree relatives who currently have depression or substance abuse diagnoses. Such individuals also show abnormally decreased activity in cognitive control regions and abnormally decreased functional connectivity between prefrontal cortical regions implicated in emotion regulation and subcortical regions.

Regarding reward processing, one study reported increased left ventrolateral prefrontal cortical/middle prefrontal cortical activity to reward, with increasing magnitude of non-specific behavioural and mood dysregulation symptoms in youth. A meta-analysis concluded that high-risk individuals (both those with and without a current psychiatric diagnosis) showed abnormally increased activity in *left-sided* prefrontal cortical regions and the insula, regardless of task [33].

Structural findings indicate abnormally decreased volumes in a variety of regions, including the dorsolateral prefrontal cortex, orbitofrontal cortex, insula, anterior cingulate cortex, ventral striatum, and bilateral frontal and left temporo-parietal regions. Increased volumes are also observed in the right ventrolateral prefrontal cortex [12], the left insula, and the left caudate. Diffusion imaging studies report decreased white matter volume and white matter integrity, particularly in prefrontal regions.

Abnormally increased prefrontal cortical activity during emotion regulation and non-emotional cognitive control tasks may represent resilience factors in non-bipolar disorder-affected at-risk individuals. Similarly, findings of abnormally increased prefrontal cortical volume may also represent resilience factors, while findings of abnormally decreased prefrontal cortical volumes parallel findings in adults with bipolar disorder. Risk factors include left-sided subcortical volume increases that may be associated with left-sided increases in prefrontal cortical and subcortical activity during reward and other task performances observed across at-risk individuals and individuals with bipolar disorder. Diffusion imaging studies reporting decreased white matter volume in these at-risk individuals may also represent risk factors as they, too, parallel findings in adults with bipolar disorder.

Longitudinal studies are clearly needed to examine developmental trajectories of structural and functional changes in prefrontal cortical-subcortical circuitry in individuals with bipolar disorder and those youth at risk of future mood and psychotic disorders. Such studies will help identify abnormal developmental trajectories in this circuitry that are associated with having bipolar disorder or other mood disorders in youth, and biomarkers that can help identify which at-risk youth are most likely to develop these disorders in the future.

Multimodal neuroimaging studies

A future area for neuroimaging research in bipolar disorder is the use of multimodal techniques to identify structure–function relationships in the neural circuitry. A very small number of studies examined structure–function relationships in the prefrontal cortical–amygdala circuitry in adults with bipolar disorder type I and bipolar disorder type II, but there is a need for more such studies in individuals across the mood disorders spectrum. In parallel, studies are beginning to identify relationships between genetic variants and functioning and structure within the neural circuitry in adults and youth with bipolar disorder and in individuals at risk for bipolar disorder. Ultimately, an integrated systems approach will help identify biomarkers that reflect the neuropathophysiological processes in individuals with mood, psychotic, and other psychiatric disorders that span genetic, molecular, neural circuitry, and behavioural levels of investigation [31, 34, 35].

Neuroimaging studies using pattern recognition approaches

A key criticism of neuroimaging studies is their reliance upon group-level statistics, rather than providing data that are useful at the individual level. If neuroimaging techniques are to provide clinically relevant information, then useful individual-level measures of brain structure and function need to be obtained from these techniques. One recent advance has been to combine neuroimaging with pattern recognition approaches, which develop algorithms to automatically learn and recognize complex patterns to inform decision-making based on large data sets. Studies combining these approaches have been able to help classify individuals, case by case, into different diagnostic categories, including bipolar disorder vs major depression, based on their patterns of neural activity [36, 37] and grey and white matter structure [38]; bipolar disorder vs schizophrenia, based on grey matter structure [39]; and youth with bipolar disorder vs healthy youth, based on grey matter structure [40]; and also accurately discriminated between individual healthy youth at high genetic risk vs those at low risk for future bipolar disorder

[41]. Combining neuroimaging with pattern recognition techniques thus holds much promise for future elucidation of clinically useful, individual-level biomarkers to inform diagnosis, risk identification, and personalized treatment choice.

Limitations of extant studies

There are many limitations of existing neuroimaging studies in bipolar disorder. Firstly, the majority of studies, especially studies employing fMRI or resting state, recruited relatively modest (for example, <30) numbers of participants per group, thereby allowing only limited conclusions about the generalizability of the findings to the wider population of individuals with bipolar disorder. Similarly, there are few studies comparing individuals with bipolar disorder across different mood states and few replication findings, especially for fMRI and resting state studies. For resting state studies, this is likely due to the different resting state methodologies used, in addition to modest sample sizes. Many studies focused solely on a priori prefrontal cortical-subcortical regions of interest, with little reporting of findings in other regions, thereby limiting inferences about potential roles of other neural circuitries in bipolar disorder. Furthermore, there is a dearth of neuroimaging studies directly comparing different bipolar disorder subtypes (for example, bipolar disorder type I vs bipolar disorder type II) or bipolar disorder vs other major psychiatric disorders (for example, schizophrenia). It is therefore difficult to determine the extent to which bipolar disorder subtypes or different psychiatric disorders share, or are distinguished by, underlying neural mechanisms. Such studies can identify neural biomarkers reflecting these neural mechanisms that can aid diagnosis and treatment choice, particularly for those disorders that are often difficult to distinguish, based on clinical assessment alone, for example, bipolar disorder type I vs bipolar disorder type II, bipolar disorder types I and II vs major depressive disorder, and bipolar disorder vs schizophrenia. There are also few multimodal neuroimaging studies examining relationships between structure and function in neural circuitries of interest in bipolar disorder, or between resting and task-related functional connectivity in these neural circuitries in bipolar disorder. These studies will facilitate more in-depth understanding of the neural mechanisms underlying bipolar disorder.

Another major criticism is the potentially confounding effects of psychotropic medication upon neuroimaging measures. An increasing number of studies in bipolar disorder suggest that psychotropic medications either have normalizing effects on neuroimaging measures or do not significantly impact these measures [42], although, as is apparent from these studies, lithium in particular may have neurotrophic effects in some neural regions in bipolar disorder, while antipsychotic medications are associated with grey matter decreases [43]. Further studies are thus needed to determine the nature of effects of specific medications on neural circuitries of interest in bipolar disorder. Longitudinal neuroimaging studies examining individuals pre- and post-medication can address this important point, as can large cross-sectional studies comparing medication-free individuals with those taking different medication types.

Summary

The field of neuroimaging in bipolar disorder is progressing considerably, with findings from these studies making significant

contributions to understanding of the neuropathophysiology of bipolar disorder [4]. To move the field forward, the next wave of bipolar disorder neuroimaging studies should aim to adopt the following strategies. Firstly, studies should examine emotion processing, emotion regulation, and reward neural circuitry functional, structural, white matter, and intrinsic connectivity abnormalities associated with dimensions of pathological behaviours that cut across conventionally defined bipolar disorder and other mood disorder diagnostic categories. These studies should also include longitudinal designs to identify the extent to which alterations in these neural circuitry abnormalities are associated with changes in affective state. This approach has potential to identify neural circuitry markers that better reflect neuropathophysiological processes in bipolar disorder and other mood disorders and the nature of neural mechanisms underlying abnormal mood switches. Secondly, studies should examine developmental trajectories of these neural circuitries in individuals with bipolar disorder across the lifespan and in at-risk youth, with longitudinal follow-up designs. This approach will identify neural circuitry markers that can help identify those individuals at highest risk of developing future affective pathology, and thereby pave the way forward for studies that utilize these markers to guide early intervention and prevention strategies. Thirdly, studies should incorporate multimodal neuroimaging techniques and biological system level approaches, to examine the impact of genetic variation and molecular-level processes upon neural circuitry development in at-risk individuals and individuals with bipolar disorder and other mood disorders. Fourthly, studies should take advantage of advances in the application of pattern recognition techniques to neuroimaging to identify individual-level neural circuitry markers that not only help classify individuals into present diagnostic groups, but also help predict individual-level future clinical course. Fifthly, collectively, these four approaches will help elucidate more complex neuropathophysiological processes underlying the dimensions of abnormal behaviours associated with affective pathology and yield individual-level biological markers reflecting these processes that have clinical utility for diagnosis, future illness development prediction, and guiding personalized treatment choice in at-risk and mood-disordered individuals.

Management and treatment of bipolar disorder

Eduard Vieta, Isabella Pacchiarotti, and David J. Miklowitz

Pharmacological treatment of bipolar disorder

Introduction

The pharmacological treatment of bipolar disorder (BD) is complex because it combines different therapeutic approaches and needs to take into account acute phases and long-term management [1, 2]. Several factors are involved in the treatment choice such as the predominant polarity [3], the risk of suicide, the treatment adherence, and the polarity index of a drug [4, 5]. Clinical guidelines have been published recently on the latest developments on pharmacological treatment of BD [6–10]. A summary of the clinical management of BD is synthesized in [Table 72.1](#).

The challenge of treating bipolar disorder in women in the perinatal period is considered in some detail in Chapter 73.

Mania and mixed states

The treatment of mania aims at managing the core manic symptoms and psychosis, at reducing any behavioural component typically associated with this condition, and at minimizing the risk of side effects in order to improve treatment adherence [11, 12].

A recent meta-analytic review ($N = 13,073$) [13] found that dopamine antagonists/partial agonists are more effective than anticonvulsants for the treatment of manic episodes, making them the most appropriate short-term choice for mania. Haloperidol, risperidone, and olanzapine (OLZ) were ranked as the most effective. Quetiapine (QTP), risperidone, and OLZ showed the best results for tolerability.

Another recent meta-analysis showed the efficacy for mania of aripiprazole (ARP), asenapine (ASN), cariprazine, haloperidol, OLZ, paliperidone (PAL), QTP, risperidone, and ziprasidone (ZIP), in comparison with placebo [14]. A network meta-analysis performed by the same author found that ARP, OLZ, QTP, risperidone, and valproate (VPA) had lower all-cause discontinuation rates than placebo. Moreover, sensitivity analysis by drug class indicated similar efficacy profiles for haloperidol, newer dopamine antagonists/partial agonists, and mood stabilizers [15].

The availability of injectable extended-release formulations (of OLZ, risperidone, ARP, PAL, and ZIP) may also represent a

therapeutic option in mania, with the aim to improve treatment adherence [16].

Combined treatment with lithium or VPA and a dopamine antagonist/partial agonist should be considered when patients show breakthrough mania with the first agent [6–10].

Bipolar depression

In contrast to the treatment of mania, enthusiasm for pharmacological strategies in BD depression is tempered by uncertainty, despite the high burden and prevalence of this phase of BD [17, 18]. Currently, none of the available antidepressants (that is, drugs licensed for the indication of major depression in a unipolar illness course) is officially recognized as monotherapy for the treatment of BD despite their common use in clinical practice. To date, only QTP (approved by the FDA and EMA), OLZ–fluoxetine combination, and lurasidone (LUR) (approved in some countries, but not by EMA) have regulatory approval for BD depression.

OLZ has been found to be effective in BD depression both in monotherapy and in association with fluoxetine [19, 20]. The efficacy of QTP monotherapy for the treatment of BD depression has been demonstrated in two placebo RCTs of similar design [21, 22]. Another two subsequent RCTs showed some superiority of QTP monotherapy over both lithium and paroxetine in BD depressive episodes [23, 24]. Two recent RCTs have demonstrated the efficacy of LUR monotherapy or in combination with lithium or VPA in BD depressed patients [25]. A more recent study of adjunctive LUR found that the significant improvement in depressive symptoms on the Montgomery-Åsberg Depression Rating Scale (MADRS) from weeks 2 to 5 disappeared at week 6 [26].

Despite preliminary evidence suggesting a possible beneficial effect of adjunctive ARP on BD depression [27], two subsequent RCTs failed to find any significant superiority of ARP over placebo [28].

With respect to lithium and anticonvulsants, use of lithium in monotherapy for an episode of BD depression seems to have no support, based on available evidence [23]. Nonetheless, for its proven effectiveness as prophylaxis of BD, as an augmentation strategy of unipolar depression, and for its effect in preventing the risk of suicide [29], lithium continues to be considered as a first-choice

Table 72.1 Pharmacological management of bipolar disorder (BD) in mania, depression, and maintenance phases¹

	Clinical management ¹			Advantages	Disadvantages
	Mania	Depression	Maintenance		
Mood stabilizers					
Valproate	+++	+	++	Useful in BD episodes with mixed features Prophylactic effect in BD Possible effect in bipolar depression	CYP450 inhibitor, not recommended in women at childbearing age Hyponatraemia
Lamotrigine	- - -	++	+++	Predominant depressive polarity, depressive recurrences Possible effect in bipolar depression	Slow titration Risk of rash
Lithium	+++	++	+++	Anti-suicidal properties, prophylaxis in BD, manic-predominant polarity	Not recommended in renal failure
Carbamazepine	+++	+	++	Prophylactic effect in BD, less effective than lithium and valproate, in BD with non-classical features	CYP450 inducer Effects on leucocyte count
Oxcarbazepine	+		+	Fewer adverse effects than carbamazepine. Prophylactic effect in BD, less effective than lithium and valproate, in BD with non-classical features	Hyponatraemia
Antipsychotics					
Aripiprazole	+++	-	++	Manic-predominant polarity, lower rates of discontinuation Intramuscular long-acting formulation available	Akathisia
Asenapine	+++	+	+	Manic-predominant polarity Possible treatment of BD with mixed features	Moderate metabolic syndrome Efficacy related to feeding
Lurasidone		+++		Predominant depressive polarity Approved by FDA for bipolar disorder	Akathisia, sedation
Olanzapine	+++	+++ ²	++	Manic-predominant polarity, manic recurrences Intramuscular long-acting formulation available Olanzapine + fluoxetine approved by FDA in bipolar depression	Severe metabolic syndrome
Paliperidone	++	-	++	Manic-predominant polarity Intramuscular formulation available Minimal liver metabolism	High doses are often needed Hyperprolactinaemia
Quetiapine	+++	+++	+++	The only antipsychotic with indications for both acute episodes and maintenance in BD, for manic- and depressive-predominant polarity. Approved by FDA and EMA for bipolar depression	Sedation
Risperidone	++	-	++	Manic-predominant polarity, prevention of manic relapses, not depressive (risperidone long-acting injectable)	Risk of switch to depression, EPS Hyperprolactinaemia
Ziprasidone	++	-	++	Manic-predominant polarity Intramuscular long-acting formulation available	Good metabolic profile
Antidepressants					
	- -	+	+	Controversial issue. Not in monotherapy in BDI disorder. Applicable in resistant bipolar depression combined with mood stabilizers in individual cases	Risk of switch to mania, mixed states and rapid cycling, mood destabilization

CYP, cytochrome; EPS, extra-pyramidal symptoms.

¹ Reported clinical management reflects our interpretation of available evidence and do not necessarily imply regulatory endorsement. For further information, refer to guidelines [6–10]. The list includes some clinically significant adverse effects which can be experienced by a fraction of patients exposed. This list is by no means exhaustive and is not meant as a comparison between the different drugs.² Olanzapine + fluoxetine.

+++, highly recommended; ++, very recommended; +, recommended; -, not much recommended; --, not recommended; ---, not at all recommended.

strategy in BDI depression by many guidelines on BD, as well as in clinical practice [9].

Use of VPA monotherapy for BD depression was supported in a recent review and meta-analysis of four small studies [30]. The effect of lamotrigine (LTG) on BD depression appeared weak in a first analysis of five double-blind RCTs [31]. However, more recent studies on LTG, mostly as adjunctive treatment to lithium or QTP, found a modest effect in BD depression [32–34]. Some clinical guidelines consider it as a first- or second-choice therapeutic strategy for the treatment of acute depressive phase [7].

One of the most controversial issue in BD is the use of ADs, since it has been associated with the risk of (hypo-) manic or mixed switch, with the risk of suicide or with a rapid cycling course [18, 35–38]. The International Society for Bipolar Disorders (ISBD) has recently assembled an international group of experts to find a clinically and evidence-based consensus on this issue [39]. They concluded that the use of ADs to treat depressive phases of BD should neither be condemned nor endorsed without carefully evaluating individual clinical cases. In general, antidepressant monotherapy should be avoided in BD. If ADs are used, they should be prescribed along with an anti-manic treatment. In BD types I and II depression, with two or more concomitant core manic symptoms and with a history of rapid cycling or mood instability, ADs should be used with caution, due to the risk of worsening of the illness course. Treatment with some ADs in BD type II appears to be otherwise relatively well tolerated. Multi-functional ADs acting on serotonergic and adrenergic systems appear to carry a particularly high risk of inducing pathologically elevated states of mood and behaviour and should be used with caution [39].

During the last years, new therapeutic strategies have been investigated for the treatment of BD depression. Limited evidence of efficacy in BD depression has been found for the dopaminergic drug modafinil and its R-enantiomer armodafinil [40, 41].

Several lines of research have suggested dysfunction of *N*-methyl-*D*-aspartate (NMDA) receptors could play an important role in the pathophysiology of BD [42], and a single intravenous dose of the NMDA receptor antagonist ketamine has been found to be effective in treating severe and resistant acute BD depression. Unfortunately, this effect is relatively short-lasting, so that finding a place in the long-term treatment is problematic [43, 44].

Maintenance phase

The primary objectives of maintenance treatment of BD are preventing new (hypo)manic/mixed or depressive episodes and suicidal behaviour and improving residual symptoms and treatment adherence, but also optimizing functional recovery and quality of life [2].

In considering long-term treatment, the predominant polarity of the individual's illness [45] and the polarity index (PI) of any drug [4, 5] should be taken into account. The PI indicates the relative effectiveness in preventing mania against the efficacy in preventing depression of drugs commonly used for maintenance treatment of BD (Fig. 72.1); it is calculated as the ratio of the number needed to treat (NNT) for the prevention of depression and the NNT for preventing mania, based on the results of relevant RCTs for maintenance treatment of BD.

A PI >1 indicates a greater relative anti-manic prophylactic polarity; a PI <1 indicates a greater relative antidepressant prophylactic polarity, while a PI near to 1 indicates similar relative manic and antidepressant prophylaxis, so a possible ideal 'mood stabilizer'.

A predominantly anti-manic PI was found for PAL, ARP, risperidone (long-acting injectable, RLai), and ZIP, followed by OLZ, ASN, and lithium. Of all the agents tested, QTP presented a PI closest to 1. A predominantly antidepressant PI was found for LTG, oxcarbazepine (OXC), and VPA. From available recent data (not fully published), LUR would represent the first dopamine antagonist with a PI inferior to 1, so predominantly an antidepressant. The PI for VPA and OXC appears <1 but should be interpreted with caution because clinical trials for these two drugs showed no statistical superiority over placebo. In general, anticonvulsants (VPA, OXC, and LTG) appear to be slightly more effective in preventing depressive episodes, while dopamine antagonists/partial agonists (with the exception of QTP and LUR) and lithium are more effective in preventing mania. In maintenance, monotherapy is the goal, but combination treatment is often needed. Typical combinations are lithium or VPA with OLZ, QTP, LTG, or ARP, especially in patients with a depressive-predominant polarity or in the absence of a predominance of polarity. When monotherapy is preferred, in patients with a manic-predominant polarity, lithium, risperidone (RIS), ZIP, ARP, PAL, ASN, and OLZ can be used, while LTG and LUR should be used when depression prevails during the course of the illness.

Fig. 72.1 Long-term relative efficacy according to the polarity index.

RCT data suggest QTP monotherapy should prevent both phases of the illness (Fig. 72.1).

Regarding the efficacy of mood stabilizers and lithium during maintenance, lithium remains the most effective treatment in preventing manic relapses and, less effectively, depressive relapses and in reducing the risk of suicide and hospitalizations [29, 46].

The efficacy of LTG in preventing depression in BD patients with a predominantly depressive polarity is considered the true strength of this drug [47].

VPA monotherapy is considered less effective than lithium in the prevention of relapse and more effective in depressive relapses, and should not usually be considered for women of childbearing potential [48].

Carbamazepine (CBZ) monotherapy is less effective than lithium in preventing recurrences, and the main risk is the unsafe side effect profile and interference with the metabolism of other drugs [17]. OLZ has been studied as a comparator to depot risperidone (RLai) and showed a reduction in manic and depressive relapses [49].

The long-term use of LUR was demonstrated by a recent 28-week study of continued treatment with LUR plus lithium or VPA, with a trend in reduction in time to recurrence of any mood event, compared with placebo, and a significant reduction in time to recurrence of a depressive episode [50]. ARP in monotherapy has shown superiority over placebo for acute and continuation treatment of mania (no depression), with low rates of discontinuation [15, 51]. Similarly, ZIP and PAL have demonstrated a positive effect in preventing manic recurrences [52, 53].

The use of injectable formulations (LAIs) in long-term treatment may be considered in cases of poor adherence (that is, more than 30% of BD patients) [54]. LAIs could be used in BD patients where the treatment plan is continuation with dopamine antagonists, but adherence to oral medication is poor. The available data for LAI risperidone are positive for preventing mania, but not depression [49, 55]. PAL extended-release significantly delayed the time to recurrence of any mood symptoms vs placebo in a randomized study of maintenance treatment in patients with BD after an acute manic or mixed episode [53].

Evidence for the long-term prophylactic effect of antidepressant treatment of patients with BD type I or II remains poorly studied, despite common clinical use of antidepressants; the ideal use is always in combination with an anti-manic drug [39].

Psychosocial management of bipolar disorder

Given the high rates of recurrence among patients with BD when maintained on standard pharmacotherapy [56], effective clinical practice recommends combining pharmacotherapy with targeted psychotherapy. There is currently no agreement on when psychotherapy should be initiated or how long it should last. There is, however, agreement that targeted psychotherapy should be *psychoeducational*, meaning that patients should be given didactic instructions and skill training that will enable them to recognize and manage their mood swings, cope with life stress, and maximize the quality of life. Several forms of psychotherapy have emerged as effective in the stabilization and long-term maintenance of BD in different age groups [57–59].

Psychoeducational approaches

In structured group psychoeducation, between eight and 12 patients with BD meet weekly for a group session led by a mental health clinician and focusing on illness awareness, treatment compliance, early detection of prodromal symptoms and recurrences, and lifestyle regularity. Colom *et al.* [60] assessed the efficacy of group psychoeducation among 120 adult patients with bipolar type I who had been in remission for at least 6 months. All patients received mood-stabilizing medications. One group received 21 weekly sessions of structured group psychoeducation, and the other group 21 non-didactic group support sessions. At the end of 2 years, fewer of the group psychoeducation patients (67%) than the control patients (92%) had relapsed, and fewer had been hospitalized. The group differences remained over a 5-year post-treatment follow-up [61].

A replication study was carried out in Brazil [62]. A total of 55 bipolar type I and II outpatients in remission received 16 sessions of group psychoeducation (using the Colom *et al.* model) or 16 sessions of a ‘matched’ (that is, non-randomized) group placebo treatment. Over 1 year, there were no differential effects of group psychoeducation on recurrence or psychosocial functioning, although patients in group psychoeducation subjectively reported more clinical improvement. Non-randomized selection of the comparison participants may have attenuated treatment effects.

Two large-scale studies examined group psychoeducation within the context of larger care management programmes. Bauer *et al.* [63] compared ‘collaborative care management’ (CCM) for 306 BD patients treated at 11 U.S. Department of Veterans Affairs sites. The core of treatment—the Life Goals programme—emphasized illness management skills. CCM also included enhanced access to care through a nurse co-ordinator and support for physicians to follow medication practice guidelines. Over 3 years, patients in CCM spent fewer weeks in manic episodes and had greater improvements in social functioning and quality of life than patients who received care as usual.

In a group health network, Simon *et al.* [64] randomly assigned 441 patients to a similar care management intervention or to treatment as usual (TAU). Care management consisted of pharmacotherapy, group psychoeducation sessions, telephone-based monitoring, interdisciplinary care planning, and relapse prevention planning. Over 2 years, patients in care management had significantly lower mania scores and spent less time in manic or hypomanic episodes than those in TAU, but there were no effects on depressive symptoms. Both studies strongly support the beneficial effects of psychoeducation about illness management. It was not possible to determine the unique contributions of each treatment component to outcomes.

A 7- to 12-session programme of individual psychoeducation with medication was found to be more effective than routine care and medication [65]. Individual psychoeducation, consisting of instruction on how to identify early warning signs of recurrence and obtain medical intervention, was associated with longer intervals prior to manic recurrences and enhanced social functioning.

There have been recent attempts to test the effects of psychoeducationally oriented clinics on the course of BD. In a randomized trial in Denmark, Kessing *et al.* [66] assigned 158 patients to treatment in a specialized outpatient clinic that integrated

pharmacotherapy with group psychoeducation or to a standard care outpatient clinic. There was an overall beneficial effect of psychoeducationally oriented clinics on rehospitalization, but also a statistical trend for those between the ages of 18 and 25 years to benefit more than those over the age of 25. This study may indicate that younger (or less recurrent) patients may benefit more from psychoeducation than older and more recurrent patients.

In summary, group psychoeducation and individual relapse prevention strategies are effective adjuncts to pharmacotherapy in reducing the risk of mood relapses. Studies that examine treatments at the clinic level, rather than the individual patient level, may be quite informative for community dissemination.

Functional remediation

A multi-site study in Spain has examined the effectiveness of 21 90-minute sessions of functional remediation, in comparison with 21 sessions of structured psychoeducation groups [61] or TAU [67]. All patients received medication management. Functional remediation addresses neurocognitive issues through exercises to enhance memory, attention, problem-solving, reasoning, multitasking, and organization. In 183 euthymic patients who completed 21 weeks of treatment, functional remediation was more effective than TAU and as equally effective as structured psychoeducation in enhancing functioning.

Family intervention approaches

Family interventions for BD first appeared in the 1970s (for example, [68]). Miklowitz and Goldstein [69, 70] developed family-focused treatment (FFT) for patients with BD who had just had an episode of mania or depression. This approach, given in 21 sessions over 9 months, consists of psychoeducation about BD for the patient and family members (parents, siblings, spouse), to assist in identifying and intervening in prodromal symptoms of relapse; communication enhancement training, and problem-solving skills training. The core assumption of FFT is that enhancing knowledge of BD, reducing high expressed emotion (critical, hostile, or overprotective attitudes in caregivers), and enhancing family interactions will promote environments that are protective against relapses.

In the Colorado Treatment/Outcome study [71], BD type I patients who were in the process of recovering from an acute episode ($N = 101$) were randomly assigned to 9 months of FFT with pharmacotherapy or crisis management (CM) (two sessions of family psychoeducation plus crisis intervention sessions) with pharmacotherapy. Over 2 years, patients in FFT were three times more likely to complete the study without relapsing (52% vs 17%) and had longer periods of stability without relapse (73.5 weeks vs 53.2 weeks) than those in CM. They also had greater improvements over time in depression, less severe manic symptoms, and better adherence to medications than patients in CM.

Rea and colleagues [72] compared FFT plus pharmacotherapy to an equally intensive (21 sessions), individually focused psychoeducational treatment plus pharmacotherapy for BD type I patients who had just been hospitalized for a manic episode ($N = 53$). Over a 1- to 2-year post-treatment follow-up, patients in FFT had much lower rates of rehospitalization (12%) and symptomatic relapse (28%) than patients in individual therapy (60% and 60%, respectively). There were no differences between the groups in medication regimens or adherence over 2 years.

Family focused treatment for adolescents with bipolar disorder

In a two-site randomized trial, Miklowitz *et al.* [73] assigned 58 adolescents with BD type I, type II, or not otherwise specified to a developmentally appropriate version of FFT (FFT-A) plus pharmacotherapy or a 3-session 'enhanced care' (EC) family psychoeducational treatment plus pharmacotherapy. Over 2 years, adolescents in FFT-A had more rapid time to recovery from depressive symptoms, less time in depressive episodes, and greater stabilization of depressive symptoms over 2 years than adolescents in EC. Comparable effects were not observed on manic or mixed symptoms. A secondary analysis revealed that adolescents in high expressed emotion families showed greater reductions in both mania and depression if they received FFT-A than if they received EC [74, 75].

A second trial involving three study sites and 145 adolescents with BD type I or II did not replicate these results [76]. Adolescents in FFT-A and the 3-session EC comparator did not differ in time to recovery from their acute episode at study entry or in time to relapse over 2 years. However, the *stage of treatment* had a moderating effect on FFT-A; during the 1-year post-treatment phase, adolescents in FFT-A had significantly lower mania symptom scores than those in EC, and significantly higher quality of life scores. Families may need time to absorb communication, problem-solving, and relapse prevention skills that are the focus of FFT. Once skills are put into use, family environments may become more protective against mood exacerbations in bipolar illness.

Family focused treatment for children at risk for bipolar disorder

FFT has been tested in children and adolescents who are *at risk* for BD—those with a family history of BD type I or II plus a current diagnosis in the child of major depressive disorder (MDD), BD not elsewhere classified (NEC: recurrent manic or hypomanic phases that do not meet the DSM-5 duration criteria), or cyclothymic disorder. In a 1-year RCT, 40 high-risk children (aged 9–17) with MDD or BD-NEC were randomly assigned to either 12 sessions of FFT high-risk version (FFT-HR) or a 1- or 2-session education control [77]. The FFT-HR focused on mood management, sleep/wake rhythm regulation, and communication/problem-solving exercises to reduce family tension. The participants in FFT-HR demonstrated more rapid recovery from their initial mood symptoms, more weeks in remission from mood symptoms, and more improvement in hypomania symptoms over 1 year than participants in the education control. Once again, the largest treatment effect sizes were among children in high expressed emotion families.

FFT is only one approach to family intervention. Reinares *et al.* [78] examined 12 sessions of group psychoeducation for caregivers of adult BD patients (for example, early detection of prodromes, promoting healthy sleep), stress management strategies, and encouraging self-care through expanding one's social network, exercise, and other means. Compared to usual care, caregiver psychoeducation groups were associated with longer time to manic recurrence in patients over 18 months. Caregivers also had increased knowledge of how to manage BD, decreases in subjective feelings of burden, and fewer attributions of blame towards the patients [78].

Other investigators have examined family intervention protocols that are more suited to younger bipolar patients. Multiple family

groups [79] and a 12-session integrated programme of individual CBT and FFT sessions known as the 'Rainbow' programme [80] were both found to be effective in randomized trials for children with bipolar spectrum disorders (aged 12 or under).

Cognitive behavioural therapy

CBT aims to modify maladaptive thoughts through restructuring of patients' self-defeating thoughts or beliefs and behavioural components such as scheduling pleasurable events to improve mood. Therapy usually incorporates problem-solving and interpersonal skills training as well. Several major trials of CBT have been conducted in BD. These trials have tested CBT manuals that differed to some extent (for example, whether or not patients were assumed to be in remission or not), which may, in part, explain the disparate results.

Lam and colleagues [81], compared pharmacotherapy plus 6 months of CBT (12–18 sessions) with pharmacotherapy plus TAU for 103 patients in remission from mood episodes. At 1 year, relapse rates were 44% in CBT and 75% in usual care. Patients in CBT also spent fewer days in illness episodes. One year to 30 months after treatment, CBT no longer prevented relapse, relative to usual care, but continued to show a positive influence on mood symptoms [82]. Unlike the individual psychoeducation study [65], the effects of CBT were stronger on depression than on mania.

A UK trial conducted across five sites [83] compared 22 sessions of CBT plus medication to TAU plus medication for 253 patients who began in various clinical states. No effects of CBT vs TAU were observed on time to recurrence over 18 months. A post hoc analysis revealed that patients with fewer than 12 prior episodes had fewer recurrences if treated with CBT than with TAU, whereas the opposite pattern was apparent among patients with 12 or more episodes. It is not clear whether patients with fewer than 12 episodes were less ill/episodic or younger or had been ill for fewer years than patients with 12 or more episodes.

In a four-site Canadian trial [84], 204 patients were randomly assigned to 20 weekly sessions of CBT or to six group psychoeducation sessions (using Bauer and McBride's Life Goals [63] programme) with pharmacotherapy. There were no differences in relapses or symptom severity over 72 weeks. Group treatment was clearly the more cost-effective alternative in this study.

Meyer and Hautzinger [85] examined 76 patients in a variety of clinical states who were randomly assigned to CBT plus pharmacotherapy (20 therapy sessions over 9 months) or an equally intensive individual supportive therapy plus pharmacotherapy. Over 33 months, there were no differences between the groups in relapse or time to relapse.

Thus, no RCT has shown the superiority of CBT over other forms of therapy matched on duration and the number of sessions. Meta-regression analyses of the psychosocial treatment literature may be able to specify the conditions under which CBT is effective in BD. Trials have varied in the heterogeneity of patient symptomatic states at entry, the number of prior episodes, the intensity of the comparator, or the nature of the outcome variable. It may also be that 'third-wave' approaches, such as dialectical behaviour therapy or mindfulness-based cognitive therapy, will prove effective where CBT was not [86, 87].

Interpersonal and social rhythm therapy

The interpersonal and social rhythm therapy (IPSRT) is based on the assumptions that: (1) symptoms of BD are triggered by disruptions

in daily routines and sleep/wake cycles; and (2) stabilization of these routines is essential to mood stabilization. IPSRT begins during, or shortly following, an acute period of illness and focuses on stabilizing daily and nightly rhythms and resolving interpersonal problems that preceded the acute episode. Patients learn to track their routines and sleep/wake cycles and identify events (for example, job changes) that may provoke changes in these routines.

In the Pittsburgh Maintenance Therapies study [88], 175 acutely ill patients were randomly assigned to IPSRT or active clinical management, both given weekly with medication management. Clinical management emphasized symptom control and medication adherence. Once patients were stabilized, they were randomly reassigned to IPSRT or active clinical management for a 2-year maintenance phase. The findings suggested that IPSRT in the acute phase was associated with longer time before recurrence in the maintenance phase than was clinical management, regardless of what treatment patients were assigned during maintenance care. IPSRT was most effective in delaying recurrences in the maintenance phase when patients succeeded in stabilizing their daily routines and sleep/wake cycles during acute treatment.

A study of IPSRT in New Zealand [89] examined 100 adolescent to young adult patients (aged 15–36) who were randomly assigned to 26–78 weeks of IPSRT or supportive care, both given with medications. There were no differences between groups—over the interval, both groups improved in depressive symptoms, manic symptoms, and social functioning. It is unclear whether the degree of change was attributable to non-specific elements of the two treatments (for example, duration of care or number of sessions), the effects of pharmacotherapy, or the passage of time.

Swartz *et al.* [90] compared IPSRT with placebo vs IPSRT plus QTP in 92 patients with bipolar type II depression, one of the few studies to compare psychotherapy to medications directly. Patients in the two groups had equivalent rates of treatment response over 20 weeks (60% in IPSRT plus placebo vs 74.5% in IPSRT plus QTP). Patients in the IPSRT plus QTP group had greater stabilization of Hamilton depression scores (without evidence of treatment-emergent manic symptoms) but were also more likely to gain weight during the trial. Identification of patients most likely to benefit from psychotherapy as monotherapy is an important direction for research in BD.

The STEP-BD study

In the U.S. NIMH's multi-site study of BD, the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) [91], investigators at 15 sites compared IPSRT, FFT, and CBT (30 sessions over 9 months) to a three-session individual psychoeducational intervention (collaborative care, or CC) on time to recovery from a bipolar type I or II depressive episode. Patients ($N = 293$) received pharmacotherapy with at least one mood stabilizer with or without adjunctive ADs, atypical antipsychotics, or anxiolytics. Over 1 year, patients under intensive therapy conditions were more likely to recover from depression (64%) and recovered more rapidly (mean 169 days) than patients in CC (52%, 279 days, respectively). One-year rates of recovery, which did not statistically differ, were 77% for FFT, 65% for IPSRT, and 60% for CBT [92]. Patients in the intensive therapies were also more likely to remain well in any given month of the 12-month study than patients in CC and had better overall functioning, relationship functioning, and life satisfaction over time [93]. The STEP-BD programme suggests that intensive psychotherapy is a

vital part of the effort to stabilize episodes of depression and enhance functioning in BD, although it did not show that any one of these approaches was better than the others.

Conclusions

The broad emphasis on pharmacological management in BD has sometimes obscured the role of adjunctive psychotherapy in modulating life stressors and enhancing coping mechanisms. Bipolar patients may spend over one-third of their lives in states of depression [94], and mood-stabilizing medications are generally more effective for mania than depression [95]. Thus, integration of pharmacological and psychosocial treatments for bipolar depression seems increasingly important. The use of psychotherapy to enhance compliance with mood-stabilizing medications and to develop a relapse prevention plan may also augment the protective effects of medication maintenance.

There are three interventions with consistent empirical evidence for adults and, in some cases, adolescents: group psychoeducation (often with accompanying care management programmes), FFT, and IPSRT. The evidence for CBT is too mixed at present to list this option as evidence-based for BD. There is beginning evidence for functional remediation treatment for bipolar patients with neurocognitive impairment.

We have a considerable amount to learn about what elements of psychosocial care are most effective in stabilization or long-term treatment. Possibly, strategies like mindfulness meditation, smartphone-based mood reporting, and online psychoeducation programmes will reduce the costs of care without reducing efficacy. However, these programmes are likely to serve as supplements to major psychosocial approaches, rather than as substitutes, until randomized trial data suggest that they are just as effective as the *in vivo* intensive approaches described here.

Use of psychosocial interventions early in the illness course of BD raises the hope that we will one day be able to prevent conversions from subthreshold to threshold versions of this disorder in children. FFT has been examined in a preliminary way in pre-adolescents and adolescents at high risk for BD [77], but participants have not been followed long enough to determine the effects on conversion.

Finally, the subpopulation of patients with BD who respond most consistently to different psychosocial treatments needs to be clarified. Treatments like CBT or group psychoeducation appear to be most effective in patients with few prior episodes [78, 83, 97], although not all studies have shown this (for example, [96]). Ideally, predictive algorithms will be developed to select the type and duration of treatment that is most likely to bring about clinical improvement in patients defined by unique characteristics (personalized medicine).

Perinatal psychiatry

Ian Jones and Arianna Di Florio

Introduction

The links between childbirth and mental disorders have been described for hundreds, if not thousands, of years [1], but post-partum episodes are not merely of historical interest. Perinatal mental illness remains a great health challenge in the twenty-first century, no better illustrated than by the findings of the UK Confidential Enquiries into Maternal Deaths, which have found suicide to be a leading cause of maternal death [2]. The impact of these conditions is wider than merely maternal health, however, with the economic impact of perinatal psychiatric disorders in the UK estimated to be approximately £8.1 billion for each year's birth cohort, with the majority of costs due to consequences on the child [3]. Despite their undoubted clinical importance, perinatal mental illnesses have not received the attention, in terms of clinical practice and research, they deserve.

Terminology and classification

Terminology

A range of terms are used in this area of psychiatry, including perinatal, peripartum, antenatal, prenatal, preconception, pregnancy, puerperal, postnatal, and post-partum. In other branches of medicine, the term perinatal may be used differently, but in the context of 'perinatal psychiatry', it is generally taken to refer to pregnancy and the post-partum—the period following childbirth. Although, as discussed in later sections, the common psychiatric classification systems define the post-partum as 4 or 6 weeks following delivery, in clinical practice, it is common to extend the post-partum period to at least 6 months after childbirth or even up to 1 year. Indeed, the UK National Institute for Health and Care Excellence (NICE)'s *Antenatal and Postnatal Mental Health: Clinical Management and Service Guidance* defined the post-partum period as up to 1 year following childbirth [4]. In this chapter, we will therefore take the perinatal period to be pregnancy and the first post-partum year.

Classification

Before a discussion of individual conditions, it is worth pausing to consider how perinatal episodes are treated by the commonly used classification systems. Unfortunately, the classification of episodes of psychiatric disorder in relationship to childbirth is an area that leads to much confusion, both clinically and in research. The *Diagnostic*

and Statistical Manual of Mental Disorders (DSM) does not include separate categories for perinatal episodes. Rather, DSM-5 allows episodes of some disorders occurring in pregnancy or within 4 weeks of delivery to be given a peripartum-onset specifier [5]. Turning to the International Classification of Diseases (ICD) [6], the way perinatal disorders are dealt with in ICD-10 is also problematic. There is a category for disorders associated with the puerperium (F53), which covers those with onset within 6 weeks of delivery and includes categories for mild and severe episodes under which the terms postnatal depression and puerperal psychosis are used. However, these categories are unique in that ICD-10 states they should only be used for episodes which 'do not meet the criteria for disorders classified elsewhere'. The vast majority of perinatal episodes that would meet criteria for categories such as depression, mania, or psychosis would therefore not be diagnosed as perinatal if the instructions of the classification systems were strictly adhered to. Relying on the ICD-10 F53 diagnostic categories therefore would grossly under-represent the true prevalence of perinatal mental health conditions.

Thus, both DSM and ICD follow the generally accepted position that conditions we will consider in this chapter, such as post-partum psychosis and postnatal depression, are not separate nosological entities but merely represent episodes of psychiatric disorder triggered by childbirth. Despite the post-partum labels not having a place in the classification systems, they remain in common use by professionals, the public, and most importantly women who experience episodes of illness at this time. One further problem with the nosology of perinatal mental health conditions is the ubiquitous use of the term 'post-partum depression' to refer to all forms of psychological distress following pregnancy—from mild and transient mood changes to some of the most severe psychotic conditions seen in psychiatry. This inappropriate usage not only can trivialize severe episodes of illness with an underestimation of risk in future pregnancies, but also supports the inappropriate labelling of a normal mood variation as a psychiatric disorder.

Women can be affected by a range of mental health problems in pregnancy and the post-partum period, including, but not limited to: depression, anxiety, eating disorders, OCD, personality disorders, bipolar disorder, schizophrenia, and other psychotic disorders. In fact, all the conditions discussed in other chapters of this textbook may present in the perinatal period. In this chapter, we will discuss both severe perinatal mental illnesses and more common

mental health conditions. We will discuss disorders with first onset in the perinatal period and the course and management of women with pre-existing illness. We will first consider the presentation, epidemiology, prognosis, and management of a range of conditions presenting in relationship to pregnancy and childbirth, before finishing the chapter discussing what is known about the aetiology of these episodes. However, the most dangerous of the perinatal conditions are associated with a bipolar diagnosis, and for this reason, the chapter belongs in this section of the textbook.

Severe perinatal mental illness

Severe episodes of mental illness occurring in the perinatal period can be a recurrence of an existing condition, such as bipolar disorder or schizophrenia, or may be the first episode of psychiatric illness a woman has experienced.

The perinatal period, as we will see, is a time of high risk for new onset of an episode of severe psychiatric illness. We will therefore also deal with the diagnosis and treatment of severe episodes of affective psychosis with onset in the immediate post-partum period—episodes that have traditionally been referred to as puerperal or post-partum psychosis. In addition, we will consider the management of women with pre-existing severe mental illness, such as bipolar disorder or schizophrenia, who become pregnant. We will examine the impact that pregnancy and childbirth may have on the condition, but also consider the implications that the mental illness may have on the pregnancy.

Post-partum psychosis

The most severe forms of post-partum mood disorder have traditionally been labelled post-partum (or puerperal) psychosis (PP) [7]. These terms are usually used to refer to new onset, although not necessarily the first episode, of severe affective psychosis in the immediate puerperium. Although there is no consensus about what is meant by immediate, it is of note that in 90% of cases, the onset is within 2 weeks of delivery [8]. While the boundaries of this condition are not easy to define, the core concept is the acute post-partum onset of mania or affective psychosis. Accordingly, the continuation of a more chronic psychosis, such as schizophrenia, would not be appropriately labelled as post-partum psychosis. In the majority of cases, in fact, the symptomatology and prognosis of PP resemble those of an affective disorder, rather than those of schizophrenia. Symptoms are those of a severe mood disorder often accompanied by psychotic symptoms such as delusions and hallucinations. The word 'psychosis' in the context of PP can, however, be confusing as some women with severe manic episodes with early post-partum onset may receive the label but not experience actual psychotic symptoms [9]. Mixed episodes, in which manic and depressive symptoms occur simultaneously, are common, and the clinical picture often shows a constantly changing 'kaleidoscopic' picture. The latter point raises an important clinical lesson, in the assessment of women with significant psychiatric symptoms with onset in the immediate post-partum period—one evaluation is usually not enough, as the picture fluctuates over time and can escalate rapidly and severity is sometimes difficult to recognize [7, 10]. In addition,

confusion and perplexity are common symptoms and some women may present in a way typical of the so-called 'polymorphic or cycloid psychosis' [11].

In summary, although, as discussed here, puerperal/post-partum psychosis is not a prominent diagnostic category in the major classification systems, it remains an important concept. It is commonly used in clinical practice and research and, most importantly perhaps, by women who experience these episodes, as illustrated by 'Action on Postpartum Psychosis' being the major third-sector organization in the UK dedicated to helping women and their families with this condition [12]. Although the classification systems appear set on relegating the term 'puerperal psychosis' to the history books, there are advantages in the diagnosis of PP in both research and clinical practice [13].

Differential diagnosis

In addition to other psychiatric disorders, several physical health conditions occurring in the perinatal period can be associated with, or even present with, psychosis and are therefore important in the differential diagnosis. These include: infections, pre-eclampsia and eclampsia, autoimmune, metabolic, encephalitis, and cerebral vascular diseases and syndromes associated with substance abuse and withdrawal [14]. The Confidential Enquiries into Maternal Deaths in the UK has reported a number of maternal deaths that were due to misattribution of psychotic symptoms to PP, rather than the true underlying condition, and therefore emphasize the need to consider physical conditions in the assessment of women who have sudden onset of a severe psychiatric episode in the perinatal period [2]. The Confidential Enquiries into Maternal Deaths have also found that a substantial proportion of women who committed suicide following PP were misdiagnosed as suffering from anxiety, moderate depression, or adjustment disorder and did not receive adequate treatment [2]. Untreated severe post-partum disorders are associated with an increased risk of both suicide [15] and infanticide [16].

Epidemiology

Although, when compared to other conditions occurring in the perinatal period, PP is a less common disorder [13], as a severe and potentially fatal condition, it is important to recognize and manage appropriately. Studies based on hospital admission in the post-partum period have estimated an incidence of 1–2 in 1000 deliveries [17]. This estimate, however, does not account for women with PP who are not admitted and will, of course, also include women admitted for other reasons.

The specific link between childbirth and the triggering of mania or an affective psychosis is well established, with the post-partum a period of very high risk [17–21]. For example, data from Danish population registries have established that the risk of a first lifetime manic episode in the first 4 weeks post-partum is 23 times higher than a comparison period 1 year after childbirth [17]. Further work from Denmark has established that even if admitted for another psychiatric disorder, such as major depression, a first admission within the first month after childbirth increases four times the likelihood of developing bipolar disorder within 15 years, compared to any first psychiatric admission outside the childbearing period [20].

In more than 50% of women experiencing PP, it is their first psychiatric episode and therefore difficult to predict [22]. For women with a psychiatric history, however, there are a number of factors

which identify women who are at a particularly high risk of PP. Women with a history of bipolar disorder have a 1 in 5 chance of PP for each delivery [18], and a previous episode of PP confers an even higher risk in excess of 1 in 2 [23]. A family history of PP has also been identified as doubling the risk of PP in women with a personal history of bipolar disorder [24]. For this reason, establishing a family history of perinatal episodes is clearly important in the assessment of women in pregnancy with existing mental health conditions. In contrast, for women with no personal history that puts them at high risk, the importance of a positive family history is less clear.

Management of post-partum psychosis

PP is a psychiatric emergency, and admission is necessary in the majority of cases [7, 25]. In around 50%, the episode will be the first contact with psychiatric services and therefore could not have been predicted, emphasizing the need for prompt assessment, diagnosis, and treatment [22]. In the UK, NICE guidelines recommend admission to specialized mother and baby units (MBUs) [4], but there remains a postcode lottery in provision; MBU beds are commonly not available, necessitating admission for many women to general adult wards. Although further evidence for the efficacy of MBUs is clearly needed, there is preliminary evidence that MBUs are preferred by women [26] and also lead to better outcomes and shorter duration of admission [25].

The mainstay of the management of PP, in addition to admission, is pharmacological treatment, but there is a paucity of specific evidence to guide us, that is, no RCTs. However, response to medication is good. For example, a study from the Netherlands evaluated the efficacy of an empirical treatment algorithm for PP, consisting sequentially of: (1) a GABA-modulating drug (benzodiazepine); (2) adding a dopamine antagonist/partial agonist; and (3) adding lithium. With adherence to this stepped regime, they observed complete remission in more than 98% of cases, with 80% of women maintaining remission for 9 months [27]. Significantly higher relapse rates were seen in women maintained on a dopamine antagonist/partial agonist alone, compared to those treated with lithium [27].

Despite no RCTs for electroconvulsive therapy in PP, the evidence of its effectiveness is promising [28]. The potential side effects (anterograde amnesia in 18%, prolonged seizures in 11%, according to a recent study [29]) need to be weighed against its efficacy in those resistant to medication and the potentially very rapid response in very severe, life-threatening episodes of illness.

Prognosis

In the modern era, the prognosis for promptly identified and treated PP is good, with over 95% of patients achieving remission within 1 year [27]. The median duration of illness is considerably shorter for women treated with pharmacotherapy (40 days) [27] than for a historical comparison with those treated prior to the era of pharmacotherapy (8 months) [30]. Having an episode of PP has a long-lasting impact beyond the acute episode. Recurrence rates are around 50% for further post-partum episodes and between 50% and 70% for bipolar recurrences not related to childbirth [31, 32]. In addition, there may be an impact on decisions about future pregnancies and on relationships. One retrospective study of 116 women, for example, found that only 58% of women went on to have a further pregnancy and that 18% of relationships ended after the severe post-partum episode [22].

Women with existing severe mental illness

As discussed in the previous section, although an episode of severe perinatal illness may be the first psychiatric presentation, in at least 50% of cases, the episode will be in the context of a history of severe mental illness such as bipolar disorder or schizophrenia.

Bipolar disorder

A considerable body of evidence points to the high risk of post-partum episodes in women with bipolar disorder. In a large retrospective study of 1212 parous women with bipolar disorder, over 70% had experienced at least one episode of mood disorder in the perinatal period and over 1 in 4 had experienced an episode of PP [18]. However, although the relative risk of PP was greatly increased in these women with bipolar disorder, it was non-psychotic depression that was the most commonly reported mood episode in the perinatal period [18]. Regarding the timing of episodes, although over 90% of manic or psychotic episodes occur within the first 4 weeks after childbirth, the pattern of onset is different for non-psychotic depression, with 25% having an onset after the first post-partum month [18].

Management

For women with a history of bipolar disorder, there are difficult decisions to be made around becoming pregnant and about management in pregnancy and the post-partum period. Potential pregnancy should be considered in all women with bipolar disorder in their reproductive years, and women should have access to preconception counselling if they are considering pregnancy [4]. In counselling women about pregnancy, the known or potential risks of taking medication in pregnancy must always be weighed against the high risk of recurrence discussed previously [4, 7, 25, 33].

The evidence base to guide these decisions is admittedly sparse, and more research is clearly needed. However, there are data that can help women and clinicians. For example, it is likely that the recurrence risk in the perinatal period is higher for women who stop mood-stabilizing medication, with one study finding 2-fold higher risk of a recurrence in those who discontinued lithium due to pregnancy [34]. Further guidance on the exact period of risk comes from a naturalistic, longitudinal study which found that women with a history of PP were at high risk in the post-partum period, but not one of the 29 women with a history had a recurrence during a subsequent pregnancy. In contrast, ten of 41 women with a history of bipolar disorder outside the puerperium experienced a recurrence during pregnancy, with the risk doubled in those not taking a drug to stabilize mood (19% vs 40%, respectively) [22]. The results of this study suggest therefore that while prophylactic medication should be considered in all women at high risk in the post-partum period, in pregnancy, it should be considered in women with a history of bipolar disorder not related to childbirth.

Regarding the reproductive safety of specific medications, the evidence base is continuously developing and clinical guidelines, such as from NICE [4] or the British Association of Psychopharmacology [35], may not include the latest research. Advice in individual cases may be sought from perinatal specialist services or from websites, such as that provided by the UK Teratology Information Service (<http://www.uktis.org>). Although we are not able to provide a

detailed consideration of all medications here, there is considerable evidence that children exposed to valproate *in utero* are at high risk of developmental disorders and congenital malformations [36]. In contrast, lithium does not appear to be as problematic in pregnancy as initial studies indicated [37].

Finally, although specific evidence for psychosocial interventions for bipolar disorder in the perinatal period may be lacking, it is vital that these approaches, particularly psychoeducation, are considered [4, 25].

Readers are referred to Chapter 75 for a more detailed account of the treatment options for bipolar disorder.

Schizophrenia

Although a considerable body of evidence points to an aetiological overlap across the mood psychosis spectrum (see Chapter 59), the triggering of episodes by childbirth is an interesting area of distinction. We do not see the same massively increased risk of a new episode of a schizophrenia-like psychosis in the immediate post-partum, as we see for episodes of bipolar disorder [17, 19]. Women with schizophrenia may require admission in the first post-partum year, however, often to deal with issues around becoming a new mother, even in the absence of a severe symptomatic recurrence.

As for bipolar disorder, specific evidence on the management of schizophrenia in the perinatal period is lacking. A preliminary study found that collaboration between services and the women's partner in the care of the baby leads to an improvement in symptomatology [38]. Motherhood can be very challenging for women with schizophrenia, and this diagnosis, together with that of personality disorders and substance abuse or dependence, has been shown to be associated with increased involvement of social services [25]. Tragically, when it does occur, the loss of child custody is a traumatic event that can precipitate a crisis and has been associated with maternal suicide [2, 26].

Common mental disorders

Having considered the presentation of severe perinatal mental illness, we turn now to consideration of other mental disorders that may occur in pregnancy and the post-partum.

Depression

Depression, the leading cause of disability worldwide, is the most common medical complication of maternity [39].

Clinical presentation

The weight of evidence suggests that there is no difference in clinical presentation between post-partum depression and depression occurring at other times [40, 41]. There are, however, issues with some somatic depressive symptoms (that is, fatigue, loss of libido, appetite, and weight, and sleep changes), as these are commonly experienced by all women following childbirth, so they need to be assessed with care [42]. Thoughts of self-harm are common in perinatal depression; an American national survey found 30% of women who screened positive for post-partum depression endorsed thoughts of self-harm [43]. Differences between the presentation of depression in pregnancy and following childbirth have been described, with intrusive violent thoughts and psychosis more common in women with post-partum onset [44].

Differential diagnosis

Episodes of major post-partum depression need to be distinguished from minor mood change, the so-called baby or maternity blues, and from episodes of PP as discussed previously [45]. The blues are characterized by emotional lability in the first post-partum week. This occurs commonly and does not require treatment. Assessment of minor mood change in the post-partum period should ensure that the woman is not, and does not, become more severely depressed. Physical conditions associated with low mood in the perinatal period, such as thyroid dysfunction and anaemia, should also be assessed.

It is important to be aware that post-partum depression can be a manifestation of a bipolar disorder; for example, over 50% of cases of bipolar post-partum depression in one study were initially misdiagnosed as unipolar disorder by clinicians [46], and in another study, over 20% of women who screened positive for post-partum depression were found to have bipolar disorder [43]. Indeed, women with episodes of unipolar depression with post-partum onset have been found to be more likely to develop a future bipolar disorder than women with depression occurring at other times [20]. Episodes of psychotic depression in the immediate post-partum period should raise the possibility of an underlying bipolar diathesis, even in the absence of manic symptoms [47]. Recognition of the bipolar nature of depression is important for management. This is illustrated by a small study of 34 women with bipolar post-partum depression, initially misdiagnosed as unipolar, that showed the discontinuation of antidepressants (that is, drugs licensed for the treatment of unipolar depression) and the introduction of a mood stabilizer (drugs licensed for bipolar disorder) improved symptoms in 88% of cases [46].

Epidemiology

The point prevalence of major depression in the perinatal period varies widely across studies, ranging from 0% to over 30% [42, 48–50], and it is likely that methodological differences, particularly in the assessment of depression, account for this variability. A systematic review estimated the point prevalence of major depressive disorder to be between 3.1% and 4.9% during pregnancy and 4.7% in the first 3 months post-partum [49]. If minor depression is included, these rates are higher—11% in pregnancy and 13% in the post-partum [49]. There has been great debate over the question of whether depression is more common in the perinatal period and the data are not consistent. It does seem clear, however, that pregnancy is not protective against depression, with both a systematic review [49] and a large epidemiological study from the United States finding no significant difference in prevalence or incidence of depression [51]. However, there may be differences for more severe episodes with a Danish registry-based study finding the relative risk of first admission to hospital for major depression is halved during pregnancy, but more than doubled in the first 2 months after childbirth, compared to 1 year post-partum [17].

The risk factors for perinatal depression show considerable overlap with depression occurring at other times. Established risk factors for depression occurring in the post-partum include a history of mood or anxiety disorders, stressful life events, poor social support, and domestic violence [42]. The factors associated with depression in pregnancy are similar (poor social support, adverse life

events, domestic violence, a history of mental illness) but include some additional factors related to the pregnancy (unplanned or unwanted pregnancy, present/past pregnancy complications) [52].

Prognosis

Although women can be reassured that the prognosis of post-partum depression is good, with episodes lasting 3–6 months on average, 30% of women remain depressed beyond the first post-partum year [42]. It should also be discussed with women that they are at an increased risk of further episodes of depression, with recurrence rates of around 40% for both perinatal and non-perinatal episodes [53].

Screening

It is not in doubt that many episodes of perinatal depression go undetected; some estimates suggest this may be up to 50% of cases [3]. However, there is considerable debate over the benefit of screening all women for depression in the perinatal period. The high prevalence and the potentially serious negative consequences of perinatal depression have led many to advocate for universal screening, most recently, for example, by the U.S. Preventative Services Task Force [54]. However, others have pointed to potential negative consequences of universal screening, including misdiagnosis and increasing stigma, and results from economic modelling have suggested that screening may not meet thresholds to be considered cost-effective [55]. Certainly screening tools must not be viewed as comprehensive and clinical guidelines emphasize that the clinical decision about the presence of depression should always be made on the basis of a further comprehensive assessment [4, 56]. A number of self-report measures of depression have been advocated to screen for perinatal depression; the Edinburgh Postnatal Depression scale (EPDS), which has been widely translated, is perhaps most commonly used around the globe. Despite the widespread use of the EPDS, NICE [4] recommends that health care professionals in contact with women in the perinatal period use the Whooley questions:

- During the past month, have you often been bothered by feeling down, depressed, or hopeless?
- During the past month, have you often been bothered by having little interest or pleasure in doing things?

Although formal screening programmes for maternal depression remain controversial, what is not in doubt is that all health professionals should be aware of a woman's mental health in the perinatal period, in addition to her physical well-being.

Treatment

Perinatal depression responds to the same treatments as depression at other times. Given issues around the use of medication in pregnancy and in breastfeeding women (discussed in the following sections), psychological and psychosocial approaches are perhaps of particular relevance. A range of psychosocial interventions have been shown to be effective in a Cochrane meta-analysis, including peer support and non-directive counselling, cognitive behavioural therapy, psychodynamic psychotherapy, and interpersonal therapy [57]. In addition, for some women, further interventions directed at the mother–baby relationship may be appropriate if this remains impaired and has not responded to treatment of maternal depression [4, 56].

For many women, particularly for those with moderate to severe episodes of depression, medication will be required. It is clear that

the use of drugs for depression in pregnancy has increased considerably in recent decades, with rates varying widely from around 3% in Denmark [58] to over 13% in the United States [59]. Pregnancy and breastfeeding are often exclusion criteria in drug trials, and as a result, there is little specific evidence for the pharmacologic management of post-partum or pregnancy depression [60]. Decisions must therefore be extrapolated from evidence for the efficacy of approaches accumulated in the non-perinatal context. Medication trials in women with severe post-partum depression are possible, however, and there may be scope for innovation; a 60-hour hormonal infusion appeared very promising in a small early-stage trial, for example, but obviously requires replication [61, 62].

For women already on drugs for depression, the data are inconsistent regarding the impact of medication being continued or stopped. A longitudinal study of 201 euthymic pregnant women found that 68% of those who discontinued treatment had a relapse during pregnancy, compared with 26% of those who continued medication [63]. In contrast, another study of 778 pregnant women with a history of major depression found that staying on, or stopping, drug treatment had little influence on psychiatric outcome [64]. Differences in the severity of depressive histories probably account for these conflicting findings. We would emphasize the need to take account of the specific history of each woman, the severity of her illness, and the evidence for her response to individual medications, when making these difficult decisions.

Other interventions for perinatal depression have a limited evidence base and include the use of oestrogens and progestins, N-3 fatty acids, exercise, and integrated yoga [65–67].

Just as for pregnancy, decisions regarding medication in breastfeeding women must be made following a full risk–benefit analysis that considers the options available. As new data on medication safety in pregnancy and during lactation are emerging regularly, up-to-date advice from specialist services should be sought in individual cases.

Anxiety disorders

Despite often being overlooked [42] and mislabelled with the pervasive term 'post-partum depression', perinatal anxiety disorders are common [68, 69]. Prevalence rates for anxiety disorders range widely from 6% to 39% in pregnancy [70] and from 16% to 50% in the post-partum period [71]. In addition, both pregnant and post-partum women are at increased risk of developing OCD (risk ratios 1.45 and 2.38, respectively) [72], with 2.5% of women experiencing a clinical episode of OCD in the perinatal period [72]. In making a clinical assessment of women with OCD symptoms, it should be remembered that obsessional thinking is common in the perinatal period, but that some women are much more significantly affected with obsessional thoughts and compulsive behaviours that can often involve the child, and obsessions need to be distinguished from delusions that may pose a risk to the baby.

Perhaps to an even greater extent than for perinatal depression, there is a lack of data to guide the treatment of perinatal anxiety disorders; RCTs are lacking, and even naturalistic studies are rare [42]. Again, management decisions must be made on the basis of evidence obtained in studies of anxiety disorders not related to pregnancy and the post-partum. One group of approaches that have received interest in the perinatal period are the so-called 'mind-body' interventions that encompass a large group of therapies such as hypnosis,

meditation, yoga, biofeedback, t'ai chi, and visual imagery. Although increasingly popular, there is a lack of rigorous evidence to support their effectiveness for the management of perinatal anxiety [73].

Post-traumatic stress disorder

For many years, childbirth was not recognized as a potential trigger for PTSD, and although this has changed, perinatal PTSD still has not perhaps received the attention it deserves. Studies have examined symptoms occurring after a range of pregnancy outcomes, including miscarriage, termination, stillbirth [74], and traumatic birth [75]. The prevalence of perinatal PTSD is estimated to be between 1% and 8% [42, 76], with a higher prevalence in low-income countries and high rates of comorbidity with major depression, anxiety, and substance misuse [42, 77]. Particularly high rates of PTSD have been described in low-income pregnant women exposed to intimate partner violence, with rates as high as 40% according to one study [76]. There is not a large evidence base to guide management, but consistent with data for PTSD more generally, a Cochrane systematic review found little or no evidence to support routine psychological debriefing for women who have experienced a traumatic birth [78].

Eating disorders

Anorexia nervosa impacts a woman's fertility [79], but eating disorders more generally do affect considerable numbers in the perinatal period. One study has reported the prevalence of eating disorders during pregnancy to be 7.5% (compared to 9.2% pre-pregnancy) [80]. For some women with a history of eating disorders, however, pregnancy is associated with symptomatic improvement. A study from Norway, for example, reported remission rates of between 29% and 78%, depending on the specific condition [81]. Eating disorder symptoms have also been reported to increase the risk of post-partum depression [82]. There is no trial evidence for the prevention of recurrence in women at risk. Management should be aimed at maintaining regular eating patterns, supporting realistic goals, and optimizing nutrition for the mother and the fetus [42].

Personality disorders

Despite the potential for personality disorders to cause significant difficulties in pregnancy and the post-partum period, there has been little research conducted to date on their impact and management in the perinatal period. The prevalence of personality disorders in pregnancy, as assessed by self-report, was found to be around 6% in one Scandinavian study [83]. An important point is that personality disorders can occur alongside many of the other disorders discussed previously and are associated with poor prognosis [42, 83].

Substance misuse

Substance misuse in pregnancy is common, with a study in the United States estimating 9.0% of pregnant women aged 18–25 and 3.4% of those aged 26–44 using illicit drugs or misusing prescription drugs. However, these rates were roughly half of those observed in non-pregnant women in the same age group [84]. Substance misuse is often comorbid with other psychiatric conditions and impact negatively on prognosis. In particular, the Confidential Enquiries into Maternal Deaths described a number of cases where substance abuse is a significant feature in those women who died [2]. Women with substance use disorders require intensive and multi-disciplinary care in pregnancy. A harm reduction approach, aimed

at periods of abstinence while recognizing the likelihood of relapse, should be adopted [84].

Aetiology: understanding the puerperal trigger

Given the post-partum is a period of high risk for episodes of psychiatric disorder, particularly for severe illness, it has long been seen as offering potential clues to the mechanisms underlying such illness. PP affects women primarily with a bipolar disorder diathesis, acted on by a specific puerperal trigger [25]. Understanding the nature of this trigger will be of great benefit, allow for the development of novel treatments, and enable the prevention of illness in those women at high risk. There are several hypotheses of puerperal triggering that have been explored.

Changes in medication

Perhaps the simplest explanation could be that the high-risk post-partum is a result of women stopping medication because of concerns over the safety of medication in pregnancy. The illness might be simply a result of acute withdrawal of medication. Evidence against this hypothesis comes from a study that compared the course of 42 women with previous bipolar episodes who stopped lithium due to pregnancy, compared to 59 age-matched non-pregnant lithium discontinuers [33]. Rates of recurrence were very similar for both groups up to 40 weeks, implying that drug withdrawal per se had no effect. However, following delivery, a large and highly significant difference in recurrence rates was observed (70% vs 24% recurrence, respectively). Thus, withdrawal of medication had an important impact on the vulnerability to the puerperal trigger but exerted no discernible effect on the recurrence risk in itself.

Psychosocial factors

Becoming a mother is a complex and often difficult psychosocial transition, but psychosocial factors have not been shown to play a major role in vulnerability to psychosis in the puerperium. A number of studies have found no association between stressful life events and PP in women at high risk [85, 86].

Genetic factors

Studies have suggested both that episodes of PP are a marker for a more familial form of bipolar disorder [87] and that a specific vulnerability to the puerperal triggering of bipolar illness is familial [24]. The relationship between genetic factors influencing puerperal triggering and those for the underlying bipolar disorder is still to be established, however, and is likely only to be clear when the genetic variation underpinning vulnerability to post-partum episodes are identified. Molecular genetic studies of PP have been conducted [88, 89], but in the age of GWAS, no genome-wide associations have been reported to date. Sample sizes available for genetic studies will have to be far bigger than those available at present to achieve the power needed to identify genes of likely small to modest effect (see Chapters 59 and 70).

Hormones

The abrupt onset of illness during a time of major physiological change suggests hormonal factors may play an important role in aetiology. It is increasingly recognized that ovarian sex steroids

have important functions in the central nervous system. Oestrogen and progesterone receptors are widespread in the brain where they modulate neurotransmission and neuroplasticity via both genomic and non-genomic mechanisms and regulate not only maternal behaviour, but also emotion processing, arousal, cognition, and motivation [90–93]. Gonadal steroids have been implicated in a number of neuropsychiatric illnesses, including migraine and neurodegenerative and premenstrual dysphoric disorders [93, 94].

The evidence pointing to reproductive hormones in the aetiology of post-partum episodes is predominantly circumstantial. The study of Bloch and colleagues [95], however, provides more direct evidence for the involvement of oestrogen and progesterone in the post-partum triggering of mood episodes. This study that simulated the supraphysiologic gonadal steroid levels of pregnancy and post-partum withdrawal found five of eight women with a history of post-partum depression and none of eight of the women with no history of post-partum depression developed significant mood symptoms during the withdrawal period. It is possible therefore that women vulnerable to post-partum episodes do not show gross abnormalities in endocrine physiology, but rather an abnormal response to the normal hormonal fluctuations of pregnancy and childbirth.

The role of gonadal steroids in the pathogenesis of perinatal mood disorders is still to be established, and its clinical implications are unclear. At present, however, there is no support for the routine use of hormonal treatments in the prevention or management of perinatal mood disorders [65].

Sleep

It is well established that sleep and circadian rhythm disruption can trigger the onset of manic episodes very rapidly [96]. Sleep loss is also, of course, very common in pregnancy and the post-partum. It is surprising therefore that this potential trigger has not received more attention, with only a few studies addressing this very plausible hypothesis [97].

Other potential factors

Several obstetric-related factors have been explored, but the only robust risk factor identified is primiparity [98, 99], which has held up even in analyses that take account of women with severe post-partum episodes being less likely to go on to have further pregnancies. The effect of primiparity has been hypothesized to be due to the biological differences between first and subsequent pregnancies and has raised the possibility of an aetiological link with other medical conditions showing a similar increase in first pregnancies such as pre-eclampsia [99]. Intriguingly, pre-eclampsia and PP have both been associated with immune dysregulation, for example the observation of a marked increase in the rates of post-partum autoimmune thyroiditis and immune biomarker alterations in women with PP [100]. In addition, pre-eclampsia and PP share other overlaps; for example, both have been found to be inversely correlated with tobacco smoking [101].

Basic mechanisms of, and treatment targets for, depressive disorders

Marcela Pereira, Roberto Andreatini, and Per Svenningsson

Introduction

The diagnosis of major depressive disorder (MDD) relies on the presence of a certain number of signs and symptoms, including feelings of guilt, hopelessness, dysphoria, cognitive dysfunction, persistent sleep, and appetite abnormalities. These signs and symptoms overlap with other conditions such as anxiety, bipolar, and seasonal affective disorders. In this chapter, we provide an overview of the basic neurobiological mechanisms underlying MDD and its treatment. There are several alterations in the molecular pathways and neuronal networks associated with MDD. We focus here on: gene \times environment interactions, dysfunctional brain circuitries, neurotransmitter alterations, maladaptation in neurotrophins and neuroplasticity, hypothalamus–pituitary–adrenal (HPA) axis dysfunction, abnormal immune system responses, circadian arrhythmicity, and sleep disturbances ([Fig. 74.1](#)). We briefly describe the mechanisms of actions for approved antidepressant therapies and also discuss recent insights into the pathophysiology of MDD and future possible therapy targets.

Gene \times environment (G \times E) interactions

There is increasing evidence that MDD is best understood in a lifelong perspective as changes in neuronal circuit function through stressful life events acting in genetically predisposed individuals. The genetic liability of MDD is 30–40% [1, 2]. It is likely that several genes, and their protein products, are involved both in the pathophysiology of the disease and in mediating antidepressant responses. Several genetic polymorphisms have been associated with depression, but in most instances, these studies have not been replicated. According to a large-scale GWAS, 15 loci and 17 independent SNPs were related to depression [3]. GWAS of both MDD and bipolar depression share 11p11.2 and 12p13.33 polymorphisms, including an SNP in *CACNA1C* encoding the $\alpha 1C$ subunit of the voltage-gated L-type calcium channel $Ca_v1.2$ [4, 5]. A recent paper,

which identified genetic determinants associated with personality traits, describes a genetic dimension which relates introversion and neuroticism to MDD [6].

A polymorphism in the 5-HT transporter results in long or short alleles, the short allele being less functional [7]. Influential G \times E studies in humans [8] have reported a positive relationship between the number of self-reported early life stressors (for example, childhood maltreatment) and increased depression risk among individuals who had one or two copies of the short allele, compared with those homozygous for the long allele [8]. Similar results were observed in experimentally stressed non-human primates [9]. However, it should be noted that there have been difficulties in replicating these findings [10].

Epigenetics is an area of research intimately related to G \times E interactions. It is defined as heritable cell characteristics (phenotype), which are not determined in the DNA sequence (genotype), but rather are determined by G \times E interactions [11]. Environmental factors may lead to DNA methylation in cytosine bases and methylation, phosphorylation, or acetylation of histones, resulting in changes of gene expression via activation or inactivation of specific gene promoters [11]. In studies of MDD, most of the epigenetic changes have been experimentally induced by stress, especially early in life. Stressors, among other things, decrease the gene expression of both brain-derived neurotrophic factor (BDNF) and the glucocorticoid receptor [12] ([Fig. 74.1](#)). Epigenetic states might be reversible, even in adulthood. This has important implications for potential pharmacological treatment; for example, drugs that inhibit histone deacetylation (HDAC), such as valproic acid, could be used to reverse epigenetic changes [13, 14]. No human studies have been performed, but preclinical research has demonstrated that local administration of HDAC inhibitors in the nucleus accumbens can reverse depressive behaviour in rodents [13]. In addition, DNA methylation changes (for example, by acetyl-*L*-carnitine) can promote antidepressant-like behaviour in rats [15]. It is important to note, however, that drugs regulating epigenetic mechanisms have pleiotropic actions in different cell types, thus increasing the risk for side effects [12].

Fig. 74.1 Neurobiological mechanisms underlying major depressive disorder. Stress, particularly in early life, causes epigenetic changes which interact with genetic vulnerability, resulting in several pathophysiological processes. Such $G \times E$ interactions affect circadian rhythms, immune activation, cellular arborization, HPA axis activity, and signalling mechanisms. Alterations in these neurobiological mechanisms contribute to the development of depression.

Dysfunctional brain circuitries

Neuroimaging approaches, including volumetric magnetic resonance imaging (MRI), diffusion tensor imaging (DTI), functional MRI, and ^{18}F -fluorodeoxyglucose positron emission tomography (FDG-PET), provide a versatile platform to characterize structural and functional connectomes. Imaging studies have improved neurocircuitry models of mood, emotionality, and behavioural regulation [16, 17].

Studies have reported morphological changes in MDD patients, in both neurons and glia in the hippocampus, amygdala, and prefrontal cortex (PFC) [16, 18]. The decrease in hippocampal volume is directly proportional to the number and duration of depressive episodes, especially in early-onset MDD [19]. The decrease of hippocampal volume seems to be related to prolonged increased levels of cortisol, which may relate to the fact that the hippocampus is the brain region with the highest levels of receptors for glucocorticoids [16, 20]. The hippocampus is critical for learning and memory processes. In depressive patients, memory formation is skewed towards negative events; this is known as negative bias. Negative bias is characterized by an enhanced focus on negative stimulus,

enhanced attention towards potentially threatening stimuli, and the attribution of negative emotional value to environmental stimuli that are considered to have neutral valance by healthy individuals [21]. Negative bias-related memories involve the amygdala, hippocampus, anterior cingulate cortex, PFC, and caudate-putamen [21]. In addition, the lateral habenula (LHb) may be a key subcortical structure in the generation of negative cognitive biases. LHb plays a crucial role in encoding aversive states [21, 22]. Deep brain stimulation (DBS) of the LHb can reverse depressive-like behaviours in rodents [23], reinforcing a role of the LHb in depression. DBS has also been examined in MDD patients. Based on the observation that some brain regions (including the subgenual cingulate cortex or Brodmann area 25) are metabolically overactive in treatment-resistant depression, DBS was applied to Brodmann area 25. This resulted in a striking and sustained remission of depression in some previously treatment-resistant patients in an open study [24, 25]. However, there is no published randomized controlled trial (RCT) to confirm this antidepressant effect. Another observational study showed an antidepressant effect of DBS in the ventral striatum [26], but a subsequent RCT failed to demonstrate an antidepressant effect of DBS in this region [27]. More advanced strategies for directly and

focally altering neural activity, such as gene therapy, chemogenetics, and optogenetics, are successfully being developed in animals. This line of research has revealed that control of projection-specific dynamics is well suited for modulation of behavioural patterns that are relevant to a broad range of psychiatric diseases, including depression. For example, optogenetic targeting of projections from the medial PFC to the dorsal raphe nucleus will control mobility in the forced swim test, while targeting projections from the basolateral amygdala to the nucleus accumbens produces an appetitive or aversive response, depending on the type of stimulus [28].

Neurotransmitter alterations and therapy targets

A critical role of monoamines in depression was initially supported by two independent serendipitous findings in drug discovery. Iproniazid was developed against tuberculosis but was found to exhibit antidepressant properties via monoamine oxidase (MAO) inhibition [29]. Several irreversible and non-selective MAO inhibitors were then developed, but they all have cardiovascular side effects due to the accumulation of tyramine. Accumulation of this trace amine depends upon MAO-B inhibition, and thus more recent antidepressant MAO inhibitors, such as moclobemide, target MAO-A and are reversible. Imipramine was found during efforts to develop an antipsychotic agent. Surprisingly, imipramine showed antidepressant properties and was approved as the first tricyclic drug for depression [30]. Pioneering work showed that imipramine could counteract noradrenaline uptake into presynaptic neurons [31]. It was later found that desipramine, a metabolite of imipramine, is a selective noradrenaline reuptake inhibitor (NRI). This finding, together with data showing lowered activity of noradrenergic neurons in depression, led to the catecholamine hypothesis of depression [32]. It was subsequently found that several tricyclic drugs for depression also inhibit serotonin (5-HT) reuptake, and a serotonin hypothesis of depression was conceived [33]. Currently, agents that selectively inhibit the reuptake of either noradrenaline (that is, reboxetine) or serotonin (SSRIs; for example, fluoxetine, paroxetine, sertraline, and citalopram), or both (that is, venlafaxine and duloxetine) are commonly used as drugs for depression and anxiety [34] (Fig. 74.2).

Several serotonin and noradrenaline receptors are implicated in antidepressant actions and side effects of reuptake inhibitors [34]. Many receptors are now targeted by more recently developed drugs for depression and anxiety. The 5-HT_{1A} somatodendritic autoreceptor, which negatively controls 5-HT release, is an interesting target, since its blockade augments extracellular serotonin levels [34]. Accordingly, vilazodone is a combined 5-HT_{1A} partial agonist and an SSRI, and is used for the treatment of depression [34]. Another compound that both inhibits serotonin reuptake and targets 5-HT receptors is vortioxetine, which binds to 5-HT_{1A} (agonist), 5-HT_{1B} (partial agonist), 5-HT₃ (antagonist), and 5-HT₇ (antagonist) receptors. In addition to these serotonin receptors, antagonism at 5-HT_{2C} receptors plays an important role in the antidepressant actions of mirtazapine and agomelatine [34, 35]. Mirtazapine is also a noradrenergic α_2A autoreceptor antagonist and enhances fronto-cortical serotonergic and noradrenergic transmission to elevate mood. Agomelatine combines 5-HT_{2C} receptor antagonism with melatonin receptor agonism and has antidepressant

properties, along with beneficial effects on sleep, due to the restoration of circadian rhythmicity.

Antidepressant responses can also be obtained by enhancing dopaminergic transmission. Dopamine enhances motivation, reward response, and plays a crucial role in the reinforcement systems, often dysfunctional in MDD [36]. Bupropion, a dopamine and noradrenaline reuptake inhibitor, is an antidepressant drug with energizing and mood-elevating properties [34]. Several studies have also reported that D₂ agonists may present antidepressant actions, some of which (for example, pramipexole) are used in the treatment of Parkinson's disease. A large proportion of patients with Parkinson's disease suffer from depression and, interestingly, depressive symptoms often precede the onset of motor symptoms and diagnosis, suggesting a largely neurochemical cause [37].

An approach to study the role of monoamine transmission in depression and antidepressant effect is monoamine depletion. Serotonin levels can be reduced by para-chlorophenylalanine (PCPA), an inhibitor of tryptophan hydroxylase, the rate-limiting step in 5-HT synthesis, or by acute depletion of tryptophan (an essential amino acid that is the precursor of 5-HT). On the other hand, inhibition of tyrosine hydroxylase by α -methyl-para-tyrosine decreases noradrenaline and dopamine synthesis. These depletion procedures induce a depressive relapse in remitted MDD patients taking drugs for depression, and there is a correlation between the target of the procedure (5-HT or noradrenaline/dopamine) and the site of action of the drug [SSRI or NRI/dopamine reuptake inhibitor (DARI)] [38]. Moreover, while depletion of monoamines lowered mood in normal volunteers with a family history of MDD, it did not affect normal volunteers without a family history of MDD. These results can be interpreted as an indication that monoamines may be related to a biological vulnerability to MDD, rather than to mood state [38, 39].

There is a delay in therapeutic onset after the start of antidepressant treatment, indicating that the antidepressant action is not strictly related to an increase in monoamine levels, but rather to molecular and cellular processes initiated by them [40]. Several molecules, including p11 (also termed S100a10), BDNF, glial cell-derived neurotrophic factor (GDNF), vascular endothelial growth factor (VEGF), insulin-like growth factor-1 (IGF-1), fibroblast growth factor-2 (FGF-2), and glutamate receptors, are induced by monoaminergic antidepressants and mediate beneficial effects on neuronal plasticity, such as increased spine density and neurogenesis, correlating with antidepressant responses [16, 40–42] (Fig. 74.2).

In contrast to monoaminergic drugs, some compounds acting via glutamate receptors possess rapid antidepressant effects. Studies using magnetic resonance spectroscopy (MRS) to measure the concentration of intra- and extracellular glutamate, glutamine, and GABA have shown changes in the glutamate system (for example, reduced levels of glutamine, the precursor of glutamate) in MDD [43–45]. It has been reported that glutamate-reducing agents, such as riluzole and lamotrigine, exert antidepressant actions by lowering extracellular levels of glutamate [46–48] (Fig. 74.2). Moreover, it has been established that blockade of NMDA receptors by a single injection of the non-competitive antagonist ketamine causes a rapid (within hours) and long (weeks) antidepressant effect [45, 49, 50]. However, the psychotomimetic, anaesthetic, amnestic, and addictive properties of ketamine preclude usage on a larger scale, and intense

Fig. 74.2 Cellular mediators altered in depression and by antidepressant agents. Schematic drawing showing cross-talk between neurons, microglia, and astrocytes. Selected neurotransmitters, immune mediators, and glucocorticoid hormones involved in depression are shown. Targets for antidepressant therapies are pointed out. Some intracellular signalling cascades regulating neuronal plasticity are indicated. Red indicates inhibition; black indicates stimulation.

research is focused on finding alternative ways of interfering with glutamate neurotransmission to achieve fast antidepressant actions without severe side effects. Antagonism of the NMDA/NR2B subunit presents antidepressant-like effects in animal models, but has so far failed to show antidepressant actions in clinical trials [51]. Another approach has been to develop antidepressant agents acting at the glycine modulatory site of the NMDA receptor such as the partial agonist GLYX-13 (rapastinel) [45]. Moreover, a metabolite of ketamine—(2R,6R)-hydroxynorketamine—has shown promising antidepressant-like effects in animal models [52]. The mechanism of action of (2R,6R)-hydroxynorketamine remains to be fully understood, but reported data indicate that it is not an NMDA receptor antagonist, but rather an AMPA receptor potentiator [52]. In this context, it is interesting to note that tianeptine, an atypical drug for depression, enhances 5-HT reuptake, potentiates AMPA receptor function, and promotes synaptic plasticity [53]. Moreover, it has also recently been demonstrated that tianeptine acts as a μ opioid receptor

agonist. In addition to targeting ionotropic glutamate receptors, antagonism at metabotropic glutamatergic 2, 3, or 5 receptors have shown antidepressant actions in rodent models [45] (Fig. 74.2).

There is also considerable evidence that depressed patients have reduced GABA levels in the brain and that the subunit composition of GABA(A) receptors are changed following stress and in MDD, particularly in interneurons [54].

Maladaptation in neurotrophins and neuroplasticity

BDNF plays a central role in the neurotrophic theory of depression [20, 55]. BDNF is highly expressed and inducible in the hippocampus and PFC where it critically regulates neurotransmitter release, neurogenesis, neuronal survival, and synapse plasticity [56]. In accordance, peripheral blood markers from both unipolar

and bipolar depression patients and depression-like animals have decreased levels of BDNF [20, 56, 57]. In contrast, treatment with different antidepressant drugs, for example SSRIs and ketamine, increases the levels of BDNF in the PFC and hippocampus [56, 57]. In the nucleus accumbens, low levels of BDNF seem to have antidepressant effects, being therefore the opposite from other areas, which complicates therapy development [16]. In addition to BDNF, other neurotrophins have been implicated in depression. Several studies have shown changes in GDNF and VEGF levels in depression [58]. FGF-2 level is decreased in depression, while treatment with drugs for depression increases FGF-2 levels [59]. Likewise, FGF-2 exerted an antidepressant-like effect in the chronic mild stress model, and furthermore, FGF-2 antagonists blocked the antidepressant effect of imipramine and fluoxetine [60]. Besides pharmacological treatments, cognitive behavioural therapy (CBT), electroconvulsive therapy (ECT), and exercise seem to be effective in the treatment of depression by stimulating neuroplasticity. CBT is effective both in the short and long term [61, 62], although its mechanisms of action are not yet well understood. Regarding ECT, the literature reports different procedures on how to perform it (uni- or bilateral and brief or ultrabrief pulse), and all are effective [63, 64]. The antidepressant action of ECT can be related to 5-HT, noradrenaline, and dopamine neurotransmission potentiation, hippocampal neuroplasticity, glutamate neurotransmission, and rapid eye movement (REM) sleep suppression [65, 66]. These multiple-target actions have been associated with the greater and faster effect of ECT, compared to monoaminergic drugs [63, 64]. Some data suggest that exercise can exert an antidepressant effect and may improve antidepressant drug effects [67, 68]. Exercise has been reported to affect growth hormone, inflammatory cytokines, neurotrophins, and neurogenesis [67].

HPA axis dysfunction

Exposure to prolonged stress can lead to persistently changed responsivity of the HPA axis. Since the pre- and postnatal periods are fundamental to the development of the central nervous system, stress during these periods can promote long-term changes in the brain function, increasing the risk of depression. Accordingly, studies have shown that poor maternal care during early life can induce epigenetic changes in the neuron-specific glucocorticoid receptor NR3C1 promoter [69].

The HPA axis activity is governed by different hormones: corticotropin-releasing hormone (CRH) and vasopressin (AVP) from the hypothalamus; adrenocorticotrophic hormone (ACTH) from the pituitary; and glucocorticoids (cortisol) from the adrenal cortex. Increased levels of CRH and AVP will lead to increased ACTH that will, in turn, increase the secretion of cortisol. Cortisol has a negative feedback action on CRH, AVP, and ACTH release, thereby decreasing the activity of the HPA axis. Cortisol is fundamental to homeostatic and allostatic control of responses to the environment such as cognitive and affective coping mechanisms. Numerous studies have shown that chronic administration of glucocorticoids leads to changes in mood and cognition [70].

A significant number of depressive patients show increased levels of glucocorticoids and glucocorticoid resistance, that is, a lack of feedback suppression of the HPA axis by glucocorticoids [40,

70–72]. Glucocorticoids can activate two distinct types of receptors: mineralocorticoid (MR) and glucocorticoid (GR) receptors; MRs are related to a basal tone of activation of the HPA axis, while GRs play a more important role in the response to stress and in the negative feedback loop of HPA activation [70]. Studies have shown an imbalance in the expression of GRs and MRs in depressive patients, leading to prolonged HPA axis activation, with resistance of the negative feedback loop [70, 72].

Activity of the HPA axis is fundamental to the control of several body functions, including metabolism, the immune system, and several brain functions such as neuronal survival, neurogenesis, and memory acquisition. In rodents, repeated glucocorticoid administration has been shown to reduce hippocampal neurogenesis and volume [73]. Depressed patients with psychotic features showed high evening cortisol levels, which is associated with poor cognitive performance [74]. Moreover, Cai and co-workers [75] showed that early life stress can lead to increased mitochondrial DNA (mtDNA) dysfunction and shortening of telomeric DNA, and that these changes were tissue-specific due to glucocorticoid secretion. Drugs for depression can improve HPA axis abnormalities through modulation of GR function [73]. Several studies in depressive patients have reported increased levels of cortisol in saliva, plasma, and urine, along with hypertrophic pituitary and adrenal glands [70, 76]. Based on the HPA axis dysfunction theory of depression, mifepristone, a GR and progesterone receptor antagonist and an MR receptor agonist, has been studied in patients with bipolar depression, with mixed results (for example, [77]).

Abnormal immune system responses

Glucocorticoids regulate not only the HPA axis, but also metabolism and immunity. There are data suggesting that increased levels of pro-inflammatory cytokines can induce glucocorticoid resistance and promote HPA axis hyperactivity in depressive patients [72, 73, 78] (see also Chapter 15). Cytokines also activate microglia, causing neuroinflammation and amplification in inflammatory signals through release of reactive oxygen and nitrogen species and chemokines [78]. This activation leads to sustained long-lasting brain inflammation that may contribute to depressive-like states and sickness behaviour.

Studies have shown changes in the regulation of both pro- and anti-inflammatory cytokines in depression, and it is proposed that such changes are due to external (for example, family loss) or internal (for example, changes in gut flora) stressors [40, 79]. Preclinical research using administration of lipopolysaccharide (LPS), a major component of the outer membrane of Gram-negative bacteria, showed increased brain levels of tumour necrosis factor alpha (TNF α) up to 10 months after exposure [80]. Moreover, LPS can induce depressive-like behaviours in rodents, which can be attenuated by anti-inflammatory drugs [81]. Increased plasma cytokines (IL-6 and TNF α) and depressed mood are also observed in normal volunteers who received a low dose of this endotoxin [82]. Although there are some discrepancies between studies regarding changes in certain cytokines in depressed patients, elevated IL-6 has been found repeatedly [83, 84]. Increased levels of IL-6 have been linked to an increase in C-reactive protein (CRP), bacterial translocation in the gut, increased oxidative and nitrosative

stress, hyperactivity of the HPA axis, and a shift in the tryptophan pathway to the TRYCAT (tryptophan catabolite) pathway [85]. Due to its many pro-depressive features, antagonism of IL-6 may be a possible target to treat depression. Indeed, addition of the IL-6 receptor (IL-6R) antagonist tocilizumab to drugs for depression could be useful [86]. Recently, a proof-of-concept RCT of infliximab, a TNF α -specific monoclonal antibody, has reported improvements in patients with treatment-resistant depression characterized by high inflammation at baseline [87]. Other promising therapies include antibodies against signal transducer and activator of transcription 3 (STAT3) or soluble glycoprotein 130 (sgp130) [88].

In bipolar depression, a recent meta-analysis indicated that anti-inflammatory drugs exert antidepressant effects and can potentiate the efficacy of monoaminergic antidepressant drugs. Accordingly, *N*-acetylcysteine (NAC) shows an antidepressant effect; NAC also has an antioxidant effect, which may contribute to its effect on bipolar depression. On the other hand, omega-3 fatty acids and ethyl-eicosapentanoate (EPA), which are also antioxidants, have shown mixed results in adjunctive treatment studies [88]. However, not all depressed patients show cytokine changes, and positive results with drugs that target inflammation appear to be restricted to a subset of patients with increased inflammatory biomarkers [78].

Increased oxidative and nitrosative stress is associated with increased inflammation, and studies have reported that even in the absence of a depressive phenotype, long-term stress exposure, especially in early life, can lead to an increase in pro-inflammatory markers in blood [89, 90]. An increase in oxidative and nitrosative stress can also lead to decreased levels of neurotransmitters such as serotonin, noradrenaline, dopamine, and glutamate [91].

Circadian arrhythmicity and sleep disturbances

Circadian rhythms are responsible for our adaptation to a 24-hour day schedule and to keep the homeostasis of the organism. Functions of the brain, peripheral organs (for example, heart and liver), hormone release, and the immune system all present a circadian rhythm. Several findings suggest an association between depression and circadian rhythm changes. For example, sleep change (insomnia or hypersomnia) is one of the criteria for MDD diagnosis, and it is present in 60–90% of depressive patients. Furthermore, depressive symptoms can exhibit a circadian fluctuation, generally being more prominent in the morning than in the evening [92].

Each cell in our body contains a set of circadian genes that are differently expressed along the day. The main pacemaker, responsible for keeping the whole body in synchronicity, is located in the suprachiasmatic nucleus (SCN) in the anterior hypothalamus. The main circadian genes (circadian locomotor output cycles kaput—*Clock*; brain and muscle ARNT-Like 1—*Bmal1*; Period—*Per1,2,3*; Cryptochrome—*Cry1,2*) work in transcriptional/translational feedback loops, that is, a positive and a negative loop that will stimulate and inhibit each other to keep the cycle going [93]. More specifically, increased levels of the heterodimer CLOCK–BMAL1 will increase the transcription of *Per* and *Cry* (that will heterodimerize) and REV-ERBa and RORa (retinoic acid-related orphan nuclear receptors) (another heterodimer). Once the expression of these two heterodimers increases, they will inhibit the expression of *Clock* and

Bmal1. However, during the day, they will be degraded, resulting in increased levels of CLOCK and BMAL1 again [93, 94].

The homeostatic functionality of the circadian system is dependent on the genes that control it, the levels of several neurotransmitters, including serotonin, noradrenaline, dopamine, and acetylcholine, and hormones [95, 96]. In homeostatic conditions, serotonin, that has its synthesis peak in the morning and presents seasonal rhythmicity fluctuations, is the precursor to the synthesis of melatonin, one of the main controllers of rhythms. Serotonergic projections go from the raphe to the SCN, and vice versa. Noradrenaline, in turn, regulates melatonin synthesis, while dopaminergic neurons from the ventral tegmental area play a role in the control of REM sleep and adaptation to light [95–98]. Acetylcholine release is highest during awake time and REM sleep, but reduced during non-REM (NREM) sleep, and consequently loss of cholinergic neurons leads to sleep disturbances [99]. Regarding hormonal regulation, growth-hormone releasing factor (GHRF) (that is predominantly expressed in the first half of the night and is secreted in the hypothalamus and arcuate nucleus) plays a role in the control of NREM sleep [100]. Increasing levels of cortisol and CRH, which build up during the night, increase the frequency of REM sleep in the second half of the night [101, 102]. In MDD, the reduction of REM latency seems to be related to decreased cholinergic and monoaminergic activity, while increased NREM duration appears to be related to low levels of CRH, and shorter sleep episodes are related to decreased cortisol [101, 102]. This could be due to crosstalk between HPA dysfunction and sleep disturbance in depressive patients.

Depressive patients seem to present arrhythmicity or lengthening of the circadian period and disruption in sleep architecture, and it is proposed that part of the effect of drugs for depression, particularly agomelatine, can be due to re-establishment of normal circadian rhythm by shortening of the circadian period [103]. Polysomnographic studies have shown changes in the electroencephalographic profile of individuals with MDD. Depressed patients presented diminished sleep efficiency, shorter sleep period, and increased REM time with shorter REM latency [102].

Regarding the use of circadian rhythm interventions to treat depression, sleep deprivation (SD) is a promising therapy. Several different procedures for SD have been proposed: total SD, partial SD, and selective REM SD [104]. A few hours of SD appear to improve mood in depressive patients. SD appears to potentiate monoaminergic transmission, influence glutamatergic neurotransmission, increase metabolism in specific brain areas (ventral/lateral cingulate cortices and medial PFC), and increase neurogenesis, while resetting the circadian rhythm of the patient [104, 105].

Another non-pharmacological therapy employed to treat depression is light therapy. Light therapy is frequently used to treat seasonal affective disorder (SAD) or MDD with seasonal patterning [106]. A defining characteristic of SAD is its seasonality, with depressive episodes commonly occurring during wintertime [106]. SAD is a complex disease and appears to be polyfactorial and polygenetic and involves circadian arrhythmicity [106]. There is a correlation between latitude and the prevalence of SAD. Indeed SAD is more prevalent in northern latitudes [106, 107]. SAD appears to respond to light therapy, although data are limited [108]. The idea behind light therapy is that exposure to a strong light pulse daily at a specific time will help to keep the circadian rhythm by synchronizing the SCN [109]. The main components of light therapy

are intensity, wavelength, and duration and time of exposure. In patients with SAD, light therapy reduced 5-HT transporter binding in the PFC [110].

Concluding remarks and future perspectives

The discovery of iproniazid and imipramine and its molecular targets resulted in the monoamine hypothesis of depression. Several improvements of monoamine-based drugs have been made, but their efficacy is still limited, with less than 50% of depressed patients remitting. It is therefore crucial to identify relevant targets for novel antidepressant treatment strategies to alleviate this serious, unmet medical need. Fundamental knowledge of the neurobiological systems and molecular targets related to the pathophysiology of depression has improved significantly over the past years. As briefly reviewed in this chapter, abnormal $G \times E$ interactions, dysfunctional brain circuitries and neurotransmitter systems resulting in maladaptive neuroplasticity, and HPA axis dysfunction, along with abnormal immune system responses and circadian arrhythmicity, all play a role in depression. The glutamatergic system, inflammatory pathways, and neuromodulation of specific brain circuitries are all promising new targets for novel therapies. In addition, several preclinical studies suggest that neuropeptides, such as galanin, neuropeptide Y (NPY), and CRH, are targets for drug development. However, there are major species differences in the expression levels and anatomical location of neuropeptides and their receptors, which complicates translation of preclinical data to the clinic.

With the advancement of genetics, epigenetics, and neuroimaging, stratification of patients with distinct diagnostic subtypes, therapy responses, dosing regimens, and likelihood for side effects will develop over the coming years. Moreover, gender is an important and largely ignored factor in depression. Indeed two-thirds of patients with unipolar depression are female, and furthermore, the hormonal status of female patients can impact depression symptomatology [111–113]. Despite the fact that some initial studies suggested that depressed female patients would respond better to SSRIs, while male patients would respond better to tricyclic drugs, the influence of gender in drug treatment response is poorly understood [112, 114, 115].

It is likely that precision medicine utilizing recent neurobiological insights and pharmacogenomic approaches will result in more personalized therapies for a large proportion of depressed patients. This development will also have a major impact on our view of depressive disorder.

Genetic epidemiology of depression in the molecular era

Alison K. Merikangas and Kathleen R. Merikangas

Introduction—genetic epidemiology of depression

The familial nature of major depression has been well established. The results of twin, family, and adoption studies demonstrated that both genetic and environmental factors contribute to the aetiology of depression. More recently, progress in molecular biology has led to greater insight into the specific genetic factors that may underlie depression. This chapter updates information on the genetic epidemiology of depression and reviews results of molecular genetics studies of depression. The sub-discipline of genetic epidemiology focuses on the identification of the role of genetic factors and their joint influence with environmental factors in disease aetiology. Genetic epidemiology employs traditional epidemiologic study designs, including case-control and cohort studies, to evaluate the aggregation in groups as closely related as twins or as loosely related as migrant cohorts.

Prior to the molecular genetics era, study designs in genetic epidemiology were devised to infer genetic causation by controlling for genetic background while letting the environment vary (for example, migrant cohorts, half siblings, separated twins) or, conversely, controlling for the environment while allowing variance in the genetic background (for example, siblings, twins, adoptees, non-biologic siblings). Measures of risk in genetic epidemiology include *familial relative risk* (disease risk in relatives of cases vs controls) and *genetic attributable risk* (the proportion of a particular disease that would be eliminated if a particular gene or genes were not involved in the disease). As described in the next section, sophisticated methods have been developed to compare combinations of genetic markers between cases and controls (for example, polygenic scores) and to estimate the proportion of phenotypic variance explained by genetic variants (typically SNPs) for complex traits [that is, genome-wide complex trait analysis (GCTA)] [1].

Major depressive disorder (MDD) is characterized by low mood and energy, the inability to experience enjoyment, changes to eating and sleep patterns, feelings of guilt or worthlessness, and suicidal thoughts. MDD is the second leading cause of disability worldwide [2]. Depression is highly heterogeneous, and there are eight major subtypes of MDD that are associated with different levels of disability

and different patterns of familiarity (the tendency of a trait to occur among members of a family, usually by heredity), comorbidity, and heritability (the proportion of variability that is genetic in origin, that is, the ratio of the genetic variance of a population to its phenotypic variance).

Genetic epidemiology of depression

There has been a substantial body of research that investigates the familial and genetic factors underlying depression. There are several reviews of family, twin, and adoption studies of depression over the past decade [3–5]. Increased recognition of the role of biologic and genetic vulnerability factors for psychiatric disorders has led to research with increasing methodological sophistication over the past two decades.

Family studies

Familial aggregation is generally the first source of evidence that genetic factors may play a role in the aetiology of a disorder. The most common indicator of familial aggregation is the *relative risk ratio*, computed as the rate of a disorder in families of affected persons divided by the corresponding rate in families of controls. The patterns of genetic factors underlying a disorder can be inferred from the extent to which patterns of familial resemblance adhere to the expectations of Mendelian laws of inheritance. The degree of genetic relatedness among relatives is based on the proportion of shared genes between a particular relative and an index family member or proband.

The familial aggregation of major depression has been examined in numerous controlled studies. Aggregate estimates of the familial associations for major depression, based on reviews and meta-analyses of controlled family study [5] and registry [6] data, are substantially lower than those of bipolar disorder, with familial risk ratios averaging about 2.5–2.8, familial heritability of 0.32, and average twin heritability of 0.3–0.4 [7].

Adoption studies

Adoption studies have been a major source of evidence regarding the joint contribution of genetic and environmental factors to disease

aetiology. However, with recent trends towards selective adoption and the diminishing frequency of adoptions in the United States, adoption studies are becoming less feasible methods for identifying genetic and environmental sources of disease aetiology (<http://www.johnstonsarchive.net/policy/adoptionstats.html>).

As reviewed by Sullivan *et al.* [5], few adoption studies of depressive disorders have been completed and report conflicting findings. These studies are difficult to carry out and often involve indirect sources of diagnostic information, for example using a sick leave registry as the source of clinical information [8] or obtaining only limited data on the biological parents [9]. More recent analyses of Swedish registry data revealed that both genetic and environmental factors had influences on depression in adopted offspring [10]. The most compelling finding from adoption studies, however, is the dramatic increase in completed suicide among biological, as opposed to adoptive, relatives of mood disorder probands [11, 12].

Twin studies

Twin studies that compare concordance rates for monozygotic twins (who share the same genotype) with those of dizygotic twins (who share an average of 50% of their genes) provide estimates of the degree to which genetic factors contribute to the aetiology of a disease phenotype. Path analytic approaches that estimate the proportion of variance attributable to additive genes and common and unique environment have been the standard method of analysis of data from large twin studies. The twin family design is one of the most powerful study designs in genetic epidemiology because it yields estimates of heritability, but also permits evaluation of multigenerational patterns of expression of genetic and environmental risk factors. Finally, twin studies may inform the spectrum of expression of diseases and disease subtypes through identification of the components of the phenotype that are the most heritable.

Twin studies of depression have been conducted on both clinical (for example, [13]) and community (for example, [14–16]) samples, or both (for example, [17]). Regardless of the method of data collection, the heritability point estimates were broadly similar, and the 95% confidence intervals were quite wide; there were no obvious gender differences, and shared environmental influences seemed to have little impact on liability to depression. Instead, the greater proportion of variance was due to individual specific environmental effects [5].

Heritability in twin studies of depression parallels the familial risks, demonstrating the contribution of genetic factors to the aetiology. During the past decade, there has been a shift from small clinical studies to studies with larger samples from registries and population samples, that has increased our ability to identify shared familial risk across these conditions, as well as patterns of familial specificity. The newer generation of family studies has also begun to expand phenotypic assessments to include dimensional measures of phenotypes and biologic measures that may be closer manifestations of the underlying genetic factors [18, 19].

Molecular genetics

The major approaches that have successfully led to gene identification for Mendelian disorders are linkage and association studies. These approaches were highly successful for rare diseases that followed traditional modes of transmission, including autosomal dominant, recessive, or sex-linked patterns in families. With completion

of the human genome project, nearly all of the genes underlying rare Mendelian disorders have been identified.

Linkage

Genetic linkage is the tendency of DNA sequences that are located close together on a chromosome to be inherited together during the meiosis phase of sexual reproduction. This tendency is exploited in linkage analysis, a genetic mapping technique that identifies regions of chromosomes that are likely to contain a risk gene, and is measured by the percentage recombination between loci. The logarithm of the odds (LOD) score is the statistical estimate of whether two genes, or a gene and a disease gene, are likely to be located near each other on a chromosome and are therefore likely to be inherited together. A LOD score of 3 or higher is generally understood to mean that two genes are located close to each other on the chromosome and indicates a statistically significant result. After linkage is established, fine mapping must be completed to attempt to isolate which gene or genes may be driving the linkage signal. Multiple genome-wide linkage studies of depression have been completed and report variable results. Statistically significant or suggestive results have been presented for depression on chromosomes 2, 3, 7, 8, 10, 15, and 17 [20–33], with few replications.

Association

Although there have been dozens of studies of candidate genes in case-control studies of depression, none stood the test of independent replication [34]. These studies were intuitively appealing, but the low a priori probability rate that any particular locus could have a strong association with depression led to high false-positive rates that often misled the field [35]. The lack of identification of these candidate genes in genome-wide association studies (GWAS) was also disappointing. However, few of these studies were adequately powered to identify genes of small effect. A candidate gene approach, based on replicated findings identified in GWAS, may still be a promising future tactic to dissect the genetic architecture of subgroups of depression.

Genome-wide association studies

With advances in molecular biology, there has been a flood of information on the contribution of genetic risk factors to complex diseases. This has transformed the sub-discipline of genetic epidemiology that previously relied solely on inferences based on phenotypic disease manifestations in relatives. These advances are largely attributable to GWAS that identify common genetic variants or SNPs (common DNA variants with >1% population frequency) that are significantly more frequent in cases than in controls [36], with an a priori statistical significance threshold of 5×10^{-8} . Structural variation, such as segmental duplications and deletions, or copy number variants (CNVs) can also be identified in GWAS.

During the past decade, there has been dramatic growth in large-scale case-control studies to identify genetic markers associated with major mental disorders. To date, ten GWAS of MDD have been published [37–46], with only three loci of genome-wide significance reported [41, 46]. It is notable that many of the studies contain overlapping samples, especially since the advent of large international data-sharing initiatives such as the Psychiatric Genomics Consortium (PGC) (<http://www.med.unc.edu/pgc/>) (Table 75.1). The PGC has completed the largest GWAS to date of MDD and found

Table 75.1 Genome-wide association studies of major depressive disorder published through 2016

no statistically significant hits [45]. More recently, however, the PGC presented the results of an analysis that stratified the sample by age at onset (AAO) and identified one replicated genome-wide significant locus associated with adult-onset (>27 years) MDD (rs7647854; odds ratio 1.16; 95% confidence interval 1.11–1.21; $P = 5.2 \times 10^{-11}$) [47]. The technique of subsetting sample cases on the basis of characteristics, such as AAO, recurrence, or episodicity of depressive episodes, and treatment response may help to disentangle the genetic heterogeneity of depression. Also, by examining a broad depression phenotype that included both MDD and depressive symptoms with data from the PGC and the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium, a significant hit was found through a meta-analysis [46], whereas another study

examining depressive symptoms in African American and Latina women found no genome-wide significant hits [48]. Subsequent to the submission of this chapter in March 2016, six additional GWAS studies of depression have been completed and published; details of these are summarized by Ormel *et al.* [48a].

Despite the enthusiasm generated by the positive findings for many of these disorders, the total proportion of variance explained by even the largest international collaborative studies with hundreds of thousands of cases is still quite small (17–29% in cross-disorder analyses and much lower in others) [49]. This has led to substantial discussion regarding the so-called ‘missing heritability’ in GWAS. However, the findings that common genetic variants explain only a limited proportion of the variance is not surprising in light of

growing evidence regarding the role of undetected rare variants, environmental factors, and sources of misclassification of cases and controls in GWAS, including aetiological and clinical heterogeneity within cases, misclassification of controls, and other factors that might reduce the power of these studies. The clinical samples from these studies have been highly heterogeneous in terms of sampling source and diagnostic characteristics, and few of the control samples would meet traditional criteria for controls in epidemiology [50]. Future studies will require large systematic samples that are either directly recruited for a cohort study or existing registries and/or biobanks that have sufficiently large and well-characterized samples of cases, as well as built-in controls without the index conditions.

Sequencing

More recently, international collaborations have focused on genome-wide or exome (protein-coding) sequencing techniques, and this has been proposed as a tool that can be used in risk prediction and lead to a greater understanding of the aetiology, prognosis, and treatment response in psychiatric disorders [51]. Moreover, the analytic challenges will be quite complex, and novel techniques are in development [52]. Success of the sequencing approach has been shown in schizophrenia, where an exome sequencing study of 2536 schizophrenia cases and 2543 controls showed polygenic burden from rare (<1 in 10,000), disruptive mutations distributed across many genes [53]. The first major success of genome sequencing in MDD was reported by the CONVERGE (China, Oxford, and Virginia Commonwealth University Experimental Research on Genetic Epidemiology) Consortium, which used low-coverage whole-genome sequencing of 5303 Chinese women with recurrent MDD and 5337 controls, and reported two loci contributing to risk of MDD on chromosome 10: one near the *SIRT1* gene ($P = 2.53 \times 10^{-10}$), and the other in an intron of the *LHPP* gene ($P = 6.45 \times 10^{-12}$). Additional analyses of 4509 cases with melancholia yielded an increased genetic signal at the *SIRT1* locus [54].

SNP-based polygenic approaches

Several statistical approaches that take advantage of markers identified in GWAS have also advanced our understanding of the genetic architecture of psychiatric disorders, notably genomic profile (or polygenic) risk scores and GCTA.

Genomic profile (or polygenic) risk scores

Polygenic scores summarize the genetic effects in a GWAS by computing a weighted sum of associated 'risk' alleles within each subject. Initially, markers (typically SNPs) are selected based on their evidence for association, typically their P -values, using a 'training' or discovery sample, and the weighted score is then constructed in an independent 'testing' or replication sample. If an association is found between a trait/disorder and the polygenic score, one assumes that a genetic signal is present among the selected markers. Later, this score can then be used for prediction of individual trait values [55]. The original use of polygenic scores has now been extended to include detecting shared genetic aetiology among traits or to infer the genetic architecture of a trait, to establish the presence of a genetic signal in underpowered studies, and can act as a biomarker for a phenotype [56]. Recently, Power *et al.* [47] used polygenic score analyses to show that earlier-onset major depression is genetically

more similar to other major psychiatric disorders, e.g. schizophrenia and bipolar disorder, than later-onset depression is.

Genome-wide complex trait analysis

GCTA is used to estimate the proportion of phenotypic variance explained by genetic variants (typically SNPs) for complex traits, and has been used to better understand the genetic architecture of complex traits [1]. It can be completed genome- or chromosome-wide, and using genomic-relatedness-matrix restricted maximum likelihood (GREML). It provides an estimate of narrow heritability that does not rely on the assumptions defined in standard twin studies. Instead it assumes that environmental factors are uncorrelated, with differences in the degree of genetic similarity for individuals who are not in the same extended families, and estimates genetic relatedness directly from the SNP data. This is contrary to the method used in standard behavioural genetics studies where pedigree-defined relatedness is assumed [57].

In addition to defining the genetic relationship from genome-wide SNPs, GCTA can also be used to predict the genome-wide additive genetic effects for individual subjects and for individual SNPs, to estimate the linkage disequilibrium (LD) structure encompassing a list of target SNPs and to estimate the genetic correlation between two traits or diseases using SNP data (<http://www.complextaitgenomics.com/software/gcta/index.html>). This method was first successfully applied to analyse the genetic contribution to human height [58], but its use has now expanded to psychiatric disorders, including depression. Using this method, Ferentinos *et al.* [59] reported an SNP-based heritability estimate of 0.17 for the presence/absence of early AAO of depression. Slightly higher estimates have been reported in a sample from China where common SNPs explained between 20% and 29% of the variance in MDD risk, and the heritability in MDD explained by each chromosome was proportional to its length ($r = 0.680$; $P = 0.0003$), supporting a common polygenic aetiology [60].

It should be noted that polygenic scoring and GCTA assume additive genetic variance, which does not take into account potential multiplicative gene–gene ($G \times G$) interactions nor do they consider gene–environment ($G \times E$) interactions. Furthermore, polygenic scoring and GCTA estimates are typically derived from SNPs, but other types of genetic variants (CNVs, segmental duplications, etc.) may also underlie disease aetiology.

Pharmacogenetics

Pharmacogenetics is the study of genetic differences in drug metabolic pathways that can affect drug response. Given that treatment response with selective serotonin reuptake inhibitors (SSRIs) and other antidepressant medication varies considerably between patients but demonstrates familial aggregation [61, 62], and with only one-third of patients reaching remission [63], there has been a push to establish more rigorous biological markers of treatment response. The pharmacogenetics of depression has been reviewed by Fabbri *et al.* [64], Hamilton [65], Lin and Lane [66], and others. A number of GWAS [67–73] and meta-analyses [74, 75] have been completed to investigate the genetics of antidepressant response, as well as side effect profiles [76, 77]. Generally, these studies have not yielded positive results, and this has been attributed, in part, to the heterogeneous nature of depressive disorders, the lower rates of heritability

when compared to other psychiatric disorders, and poor medication adherence [78].

Challenges in identifying genetic factors underlying depression

The heterogeneity of depression has been widely documented. The concept of unipolar depression from early therapeutic and genetic research referred to severe cases of depression that led to hospitalization. As the concept was extended to MDD that only required a 2-week episode, depression was characterized by substantially greater heterogeneity in terms of broadened symptom expression, comorbidity with anxiety and other conditions, and stronger association with environmental stressors. Both genetic epidemiologic and molecular genetic studies of depression have systematically investigated these sources of heterogeneity in order to define more homogenous subgroups that may be more likely to reflect common underlying genetic architecture.

Subtypes

The major subtypes of depression in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) system are melancholic and atypical subtypes. There is substantial evidence from twin and family studies that the atypical subtype is more familial and may reflect inflammatory processes that lead to elevated body mass index (BMI) and other cardiovascular risk factors. Other subtypes that have been examined in genetic studies include persistent depressive disorder (dysthymia), bipolar disorder, seasonal affective disorder (SAD), psychotic depression, perinatal/peripartum/post-partum depression, and premenstrual dysphoric disorder (PMDD). The overlap across these subtypes and the lack of specificity in families, however, has not yielded greater specificity of genetic factors underlying these subtypes.

Endophenotypes

Another widely employed approach to reduce the heterogeneity of major depression has been the exploration of endophenotypes, defined as phenotypic traits or markers that may represent intermediate forms of expression between the output of underlying genes and the broader disease phenotype [79–81]. Studies of the role of genetic factors involved in these systems may be more informative than studies of the aggregate psychiatric phenotypes because they may represent more closely the expression of underlying biologic systems. A recent meta-analysis of psychiatric endophenotypes [81] suggests that currently identified endophenotypes are not superior to conventional phenotypic disease definitions.

Incorporation of environmental factors

To date, most of the molecular genetics studies in psychiatry have not incorporated environmental factors as a source of variance in aetiologic models. Most of the evidence for the role of the common and unique environment has been based on residuals from path analytic models employed in twin studies. Stressful life events have been consistently associated with increased risk of mood disorders, but mood disorders also elevate the risk of life events, so the directional links have been complex [82]. More recent research has identified infections [83] and inflammation or immune response [84], which may elevate the risk of depression. However, this association may be related to comorbid conditions or may actually be bi-directional,

as demonstrated in recent prospective studies of large population-based samples [84].

Although intriguing, studies that have examined candidate genes that may interact with stressful life events in the aetiology of depression have generally not been replicated. The widely cited study of Caspi *et al.* [85] has not been replicated in similar prospective studies, even in New Zealand [86], and meta-analyses have demonstrated that the original findings reflected a false-positive report [87, 88], with the most recent meta-analysis of more than 30,000 subjects concluding that there is no interaction between the *5HTTLPR* locus with life events in the aetiology of depression [89]. Duncan and Keller [90] concluded that low power, along with low prior probability that a $G \times E$ hypothesis is true, suggests that most or even all positive candidate gene $G \times E$ findings represent type I errors. Methods to combine genetic susceptibility factors with environmental exposures will be a major challenge in the next phase of psychiatric genetics, as described in the following section.

Combining genetic and environmental factors

The next phase of research in genetic epidemiology will require integration of research on the genetic and environmental risk factors already described. Traditional study designs in genetic epidemiology that can be used to study the joint influence of genetic and environmental factors include case-only studies and cross-sectional cases-control studies, as well as cohort studies on gene–environment interaction [91–93]. These study designs can now be extended to condition upon broad or specific genotypic similarity, based on GWAS, to identify environmental exposures that influence gene expression.

There are a growing number of studies that have incorporated findings from genetic studies to identify the effect of environmental factors for diseases that have well-established genetic risk factors. The large scope of studies that will be required to detect the joint impact of genetic with environmental factors is daunting [94]. Although gene–environment interaction is generally assumed to be a key mechanism for links between genetic susceptibility and environmental exposures in complex diseases, analyses of several of these cohort studies have yielded additive, rather than interactive, influences of genetic and environmental risk factors. Likewise, studies of environmental factors among those with the APOE- ϵ_4 genotype that confers increased risk of cognitive decline and Alzheimer's disease have found additive, rather than interactive, influences of other environmental risk factors [95, 96]. Incorporation of phenotyping that taps the domains underlying broad diagnostic categories, based on knowledge of underlying biologic pathways, coupled with built-in hypothesis-based environmental exposures, will facilitate the integration of advances in molecular genetics and environmental science.

Summary and conclusions

The results of twin, family, and adoption studies demonstrated that both genetic and environmental factors contribute to the aetiology of depression. Depression is highly familial, with familial risk ratios averaging about 2.5–2.8, a familial heritability of 0.32, an average twin heritability of 0.3–0.4, and a SNP-based heritability of 0.17 for the presence/absence of early AAO of depression. To date, no genetic

markers have been associated with aggregate major depression nor its major subtypes in GWAS of tens of thousands of people; however, stratification of the sample by AAO allowed for the identification of one replicated genome-wide significant locus associated with adult-onset MDD. The first major success of genome sequencing was reported by the CONVERGE Consortium, which reported two loci contributing to risk of MDD.

Challenges to studying the genetic underpinnings of depression include its heterogeneity, multifactorial aetiology, and pervasive comorbidity with other conditions. Over time, as the concept of MDD was broadened, depression was characterized by substantially greater heterogeneity in terms of symptom expression, comorbidity with anxiety and other conditions, and stronger association with environmental stressors. Both genetic epidemiologic and molecular genetics studies of depression have systematically investigated these sources of heterogeneity in order to define more homogenous subgroups that may be more likely to reflect a common underlying genetic architecture. Incorporating environmental factors has been a challenge, and though stressful life events have been consistently associated with increased risk of mood disorders, mood disorders also elevate the risk of life events, so establishing the directional links has been complex.

The next phase of research in genetic epidemiology will require integration of research on the genetic and environmental risk factors already described. Building upon traditional study designs in genetic epidemiology that can be used to study the joint influence of genetic and environmental factors include case-only studies and cross-sectional case-control studies, as well as cohort studies on gene-environment interaction, which can now be extended to condition upon broad or specific genotypic similarity, based on GWAS, to identify environmental exposures that influence gene expression. This has led to increased recognition of the role of biologic and genetic vulnerability factors for mood disorders and to research with increasing methodological sophistication over the past two decades. This review also demonstrates the heterogeneity of depression and its multifactorial aetiology that will require future research that embraces sources of complexity, including genetic, biologic, and environmental factors.

Imaging of depressive disorders

Guy M. Goodwin and Michael Browning

Introduction

A range of neuroimaging techniques have the potential and, indeed, are contributing to the understanding of the aetiology, progression, and treatment of affective disorder. In the case of unipolar depression, they have underlined the message that depression is, in some sense, a brain disease. At the same time, they have reinforced the continuity with studies of emotion and cognition in the general population and in other disorders. However, they have also highlighted some of the weaknesses of a biological approach based on small samples and inadequate mechanistic understanding. There are important overlaps between this chapter and Chapter 71 on imaging studies in bipolar disorder (BD).

Study designs used when imaging major depression: what they can and cannot tell us

The majority of imaging studies relevant to major depression have employed case-control designs in which a group of patients with, or at risk of, depression are compared to a control group. These studies report group-level differences in one or more neuroimaging measures, quantifying the significance of their findings using statistical approaches which estimate the probability of the group differences arising by chance. The aim of this approach is to identify features of the brain's structure or function which differ between groups from which inferences about illness mechanism may be drawn. However, as discussed in Chapter 75, it is likely that a number of distinct mechanistic processes lead to the expression of the major depressive phenotype. The ability to determine an imaging signature of a diagnosis is clearly bounded by the degree to which individuals with the diagnosis share common aetiological processes; the absence of the same [1] will make it much more difficult to identify clear neural signatures when comparing groups of depressed and non-depressed individuals. A second limitation to case-control designs is that they provide only weak evidence that the identified neuroimaging processes are causally related to pathology. Group differences in neuroimaging outcomes between patients with depression and controls may arise because: (1) changes in the identified neural system are causally related to the disorder; (2) having the disorder causes changes (for example, taking medication or leaving the house less)

which then leads to the observed neuroimaging effect; or (3) a third factor causes both the expression of the illness and, separately, the observed neuroimaging finding. These limitations are widely acknowledged and can be mitigated by imaging studies using alternative designs, the most prominent of which are briefly summarized in the following sections.

Prospective studies

Prospective cohort studies can demonstrate whether a neural process temporally precedes illness and may have a causal role in outcomes. Studies of increasing ambition have recently begun to be established, with early results relevant to depression already published [2].

Experimental studies

Experimental studies measure the effects of interventions which manipulate neural systems potentially relevant to pathology. They are able to provide strong evidence on the causal role of the system in disease. While the capacity to target and manipulate specific neural circuits is clearly limited in human, compared to animal, models, a degree of anatomical specificity can be achieved in human subjects using electrical or magnetic stimulation, and some biochemical specificity is possible using pharmacological manipulations. For example, increased serotonergic function reduces amygdala activity in response to negative stimuli in both non-depressed control [3] and patient [4] populations, with the degree of this reduction predicting later response in patients [5].

Classification studies

Lastly, there has been increasing recent interest in study designs in which neuroimaging techniques are used to classify patients. Broadly, two procedures have been used. Firstly, unsupervised classification attempts to find structure in the imaging data itself, for example by asking whether the data from depressed patients can be clustered into separate groups (see later in this chapter for detailed examples). A particular advantage of this approach is that it is less a hostage to heterogeneity than case-control designs. Unsupervised classification techniques could conceivably identify the neural signatures of different mechanistic processes which lead to major depression. Secondly, supervised classification uses some sort of ground truth value to determine the group to which a person belongs (for example, has a patient responded or not to their treatment?). The

supervised classification procedure then attempts to uncover a rule by which the neuroimaging data may be used to arrive at this ground truth.

The statistical underpinning of these classification designs is quite different from that of case-control studies. Whereas case-control studies examine the mean differences between groups of patients and controls, asking ‘what is the probability that this group difference occurred by chance?’, classification studies develop a rule to separate individuals into different groups and then ask ‘does my rule work when I apply it to a different set of data?’. Thus, the measure of whether a classification process is meaningful is its capacity to predict the structure of new data (sometimes called ‘out-of-sample data’). The focus on predicting the properties of new data means that there is potential application in clinically relevant situations. For example, a classification rule which accurately predicts response to treatment may, in principle, be used to personalize treatment choice for individual patients.

The neuroimaging literature for major depression is split into studies which have examined genetic risk factors for major depression, those which have examined the broader risk phenotype, and finally those which have examined the phenotype itself. This literature is reviewed later in this chapter, with findings which progress beyond case-control evidence particularly highlighted. Imaging studies in psychiatry have often been too small and have reported effect sizes that are potentially inflated by post hoc statistical methods and publication bias [6]. In addition, cases and controls ought to be recruited using comparable methods, which is a challenge for clinical case series. To allow confidence in what we describe here, we will describe pooled analyses of data from many comparable studies, in preference to single studies, where possible.

Imaging the brain at risk for major depression: ‘imaging genomics’

As Chapters 70, 71, and 72 illustrate, a major depressive episode arises on a background of risk determined by genetics and early experience. The genetic basis of MDD implicates many genes of modest effect, whose identity is only now emerging from the very large samples required for statistical confidence in association studies. Such genes might be operating through anxiety proneness, since the personality trait of neuroticism is a strong predictor of the risk of MDD. Alternatively, new genes may implicate new mechanisms related to decompensation in the face of life stresses or ‘events’. Imaging can identify brain structure and brain function, and both must be, in part, under genetic control and vary accordingly. Historically, there have been two distinct phases of ‘imaging genomics’, as it has been ambitiously named. The first focused on candidate genes that had been suggested might be contributory to genetic risk, based on contemporary understanding of neurobiology. The second, into which we are now emerging, can be described as discovery-based and relies on post hoc associations derived from GWAS.

Of the candidate gene approaches, the serotonin transporter (SERT) has long seemed a potential locus for a genetic effect. Indeed the first putative association between a polymorphism in the regulatory region of the SERT gene and anxiety trait appeared over 20 years ago. It was apparently supported by other very highly cited research [7], which suggested an interaction between the polymorphism and MDD, modulated by exposure to adverse life events. In support of these findings, both functional and structural studies of the brain in healthy volunteers suggested an association between the SERT polymorphism and brain function. The original study suggested that individuals with one or two copies of the short allele of the SERT promoter polymorphism exhibited greater amygdala neuronal activity, as assessed by BOLD, in response to fearful stimuli, compared with individuals homozygous for the long allele [8]. Further studies reported reduced grey matter volumes in the limbic system of healthy volunteers in association with the short allele [9] and that MDD was associated with the polymorphism [10]. The apparent coherence of these findings led to an increasingly optimistic view that imaging provided endophenotypes that were easier to study and more valid than ‘disorders’ for genetic analysis. On this view, an endophenotype could provide a target between the genotype and any disease; this could speed the development of precision medicine and would also be easier to model in animal studies [11].

The subsequent developments around this topic have been highly contested. In essence, the best known findings linking the SERT either with MDD or with abnormal brain function were shown to be at best overstated, and at worst, artefacts of enthusiasm. It has highlighted the general problem of statistical power, excess positive findings, and the problem of reproducibility in such studies. In relation to the BOLD imaging findings, a recent review concluded ‘... there was considerable between-study heterogeneity, which could not be fully accounted for by the study design and sample characteristics that we investigated. In addition, there was evidence of excess statistical significance among published studies. These findings indicate that the association between the 5-HTTLPR and amygdala activation is smaller than originally thought, and that the majority of previous studies have been considerably under powered to reliably demonstrate an effect of this size’ [12]. Moreover, the assumption that endophenotypes will usually turn out to demonstrate larger genetic effect sizes appears to go beyond the evidence from the existing animal models as well [13]. The imaging genomics field continues to struggle with the paradox of a continuing plethora of positive findings from studies that are simply underpowered to detect reliably what is often claimed from post hoc analysis of data.

Discovery-based approaches will inform imaging in two ways. Any GWAS or CNV-based variant showing a strong association with a phenotype of interest is likely to be a better choice of candidate gene than, for example, the SERT (which does not emerge reliably from GWAS). Secondly, pooled imaging data can be directly related to GWAS data in discovery-based designs. For example, the Enhancing NeuroImaging Genetics through Meta-Analysis (ENIGMA) Consortium has identified common genetic variants associated with hippocampal volume. Their philosophy for pooling many data sets promises results for genes with clear effects on brain development [14]. However, a link through this approach to major depression has not yet been reported and the power of even very large genetic studies to detect depression-related genes suggests caution (see Chapter 75).

Imaging the at-risk phenotype in major depression

Imaging young people at risk for depression is an obvious way to relate risk for depression to brain structure and function. Perhaps surprisingly, such studies have not been very numerous, but systematic reviews suggest they have been generally consistent. Being at risk may mean by virtue of familial risk or early adverse experience. The children of a proband with MDD are at risk for MDD. However, they are also at risk for anxiety disorders. Moreover, the child of a parent with BD may also be at risk for MDD and anxiety disorders (and not necessarily BD). Thus, the state of being 'at risk' may not be very specific. As a further complication, some children will prove to be resilient, so not actually at risk at all. These complexities confound all such studies designed on the basis of family history, unless there is a prolonged follow-up to determine actual outcomes. This is not always feasible. Most studies of at-risk offspring are conducted in teenagers.

Being at risk due to early abuse and neglect risks confounding by psychiatric illness in the parent. Thus, the at-risk phenotype may be at risk by virtue of both the early abuse and neglect inflicted by the parent(s) and by virtue of genes inherited from the parent. In practice, it will always be difficult, if not impossible, to control for the latter.

Structural imaging: brain volumes and white matter integrity

Volumetric studies of the developing human brain across adolescence show early cortical grey matter volume (CGMV) increases, followed by decreases, and monotonic increases in cerebral white matter volume (CWMV) [15]. There are no consistent reports of an abnormal growth trajectory for either CGMV or CWMV in young people *at risk* for depression, but the fact that the brain is changing over the critical decades makes such studies additionally difficult. Differences in the brain of adolescent patients with MDD, compared with controls, are seen in the cortex.

Pooling of studies of subjects at risk by virtue of childhood abuse and neglect offers some preliminary findings. In such an analysis, increased exposure to childhood adversity was associated with smaller caudate volumes bilaterally, only in girls. All subcategories of childhood adversity showed the effect, independent of an MDD diagnosis [16]. The absence of the effect in boys is a striking example of sexual dimorphism, but it is not paralleled by different causal pathways to depression in men and women [17]. There was no effect of childhood adversity on hippocampal volume.

Diffusion-weighted MR (magnetic resonance) imaging (diffusion tensor imaging, or DTI) is being used increasingly to determine the integrity of white matter in MDD. DTI resolves the diffusibility of water in different directions to give a measure called fractional anisotropy (FA). If diffusion is highly constrained, as along the axons of a white matter tract, FA values are high. Unconstrained diffusion, as in saline solution or the cerebrospinal fluid, has zero FA. Reduced FA may imply white matter disorganization, either as a developmental or as an acquired property of the brain.

A small, but growing, number of studies have addressed 'at-risk' populations. Participants with a family history of depression have reduced FA in the cingulum and other white matter tracts [18].

Indeed, reduced FA has been a common finding in a range of at-risk studies—for psychosis [19], BD [20], and even antisocial personality disorder [21]. There has been usually a quite surprisingly diffuse effect across the white matter skeleton. Most studies have been individually underpowered, but a substantial overall effect is obvious.

Functional imaging: resting states and brain activation

Functional imaging studies might be predicted to be a sensitive method to distinguish high-risk from low-risk subjects. Resting state connectivity and the patterns of activation in cognitive tasks have provided convincing methodology. However, differences in experimental design often make data pooling difficult. While still preliminary, the published studies have highlighted the insula cortex and its connections and the inferior frontal regions as key components within the networks processing emotional experience. Lesion studies had already suggested that the insula is important for integrating cognitive, affective, sensory, and autonomic information to create a conscious experience of feeling [22]. Frontal areas have been implicated as possible brain regions mediating cognitive control or feedback to brain regions with more reflexive reactions to threat such as the amygdala.

Young relatives of bipolar probands are at risk for both MDD and BD. Those who subsequently developed MDD demonstrated relatively increased activation in the insula cortex in a challenge task, compared to controls and high-risk subjects who remained well. In the latter groups, this region demonstrated reduced engagement with increasing task difficulty. The high-risk subjects who subsequently developed MDD did not demonstrate normal disengagement [23]. Insula involvement may not be specific; young unmedicated participants with BD type II had increased coherence across several brain regions at rest in a temporo-insular network, including the bilateral insula and putamen [24].

Other work has highlighted the inferior frontal cortex as a locus showing weaker connectivity at rest with other regions (including the insula and temporal gyrus in both BD and young people at risk for bipolar and other mood disorder [25]. The same group had shown reduced activation of the inferior frontal lobe when inhibiting response to fearful faces in at-risk subjects [26] and reduced cortical thickness in the left pars orbitalis of the inferior frontal gyrus (IFG), compared with controls [27]. So far, at-risk studies have not differentiated well between bipolar and unipolar risks. Indeed, at a brain systems level, they may be very similar.

The risk for future episodes of depression is increased in patients who have remitted from previous episodes. Thus, remitted patients may also be considered an 'at-risk' group. Interpretation of neuroimaging findings comparing remitted patients and never-depressed control subjects is complicated by the possibility that persistent effects between episodes of the illness may be related to trait-like risk processes or to a scarring effect of previous episodes. Resting connectivity in such patients has been reported to be reduced within cognitive control networks [28], as has default mode activity during effortful tasks [29]. Additionally, activity within reward-related circuitry has been reported to be disordered [30] and amygdala responses to faces increased [31].

There have been also a limited number of functional neuroimaging studies of children and adolescents exposed to early neglect and/or maltreatment (physical, sexual, and emotional). In reviewing

these findings, there have been reports of heightened and reduced amygdala responses to threat in maltreated samples, blunted striatal response to anticipation and receipt of rewards, and increased activation in the anterior cingulate cortex during processing of emotional stimuli and executive control tasks [32].

Imaging the MDD phenotype

Structural imaging: brain volumes and white matter integrity

Patients with MDD are probably a highly heterogeneous group, especially when studied in their maturity with an established pattern of illness. Thus, one may anticipate an impact from the current illness itself, any vulnerability factor as described in the previous paragraphs, and the uncertain effects of physical illness and lifestyle choices. All or any of these cumulative influences may produce acquired brain changes in mature patients. In addition, current or previous drug treatment may contribute to the picture either as an ongoing 'drug effect' or as a consequence of a relatively recent withdrawal. The impact of these confounding factors has been greatly increased by the use of relatively small samples drawn from individual sites. However, this problem has now been well recognized.

Systematic reviews of published data provide one solution. Judicious exclusion criteria can then identify very comparable studies that control for one or more of the obvious confounds. For example, 14 published studies of about 400 *medication-free* cases with MDD showed reduced grey matter in the prefrontal and limbic cortices (including the hippocampus bilaterally) [33]. The alternative to controlling for variables in this piecemeal way is to pool as many individual data sets as possible and allow statistical power to overcome the confounds in a single mega-analysis. This is the principle behind the ENIGMA project (<http://enigma.ini.usc.edu>). Thus, three-dimensional brain imaging data from 1728 MDD patients and 7199 controls (15 research projects worldwide) showed

that patients had significantly lower hippocampal volumes (Cohen's $d = -0.14$; % difference = -1.24). The effect was driven by patients with recurrent MDD (Cohen's $d = -0.17$; % difference = -1.44), so there were no differences between first-episode patients and controls. These effects are, of course, small. They may imply that loss of hippocampal volume is an acquired feature of MDD, related to the illness course. However, no cross-sectional study can prove that. Earlier age of onset was associated with a smaller hippocampus and a trend towards a smaller amygdala and larger lateral ventricles. Current symptoms, use of drugs for depression, and methodology had no effect [34]. The absence of effect in first-episode MDD patients echoes findings in individual, relatively well-powered, and controlled studies [35].

The ENIGMA group's study of cortical volumes in 2148 MDD patients and 7957 controls showed thinner cortical grey matter in the orbitofrontal cortex, anterior and posterior cingulate, insula, and temporal lobes in adults aged over 21 years (effect sizes -0.10 to -0.14) (Fig. 76.1). These effects were *more* pronounced in first-episode and early-onset cases. By contrast, effects in adolescents were larger but occurred as changes in regional brain volume, not cortical thickness. The affected brain areas included medial and superior frontal areas and somatosensory and motor areas (effect sizes -0.26 to -0.57) and were most striking in recurrent MDD [36]. This complex pattern implies different developmental trajectories for the cerebral cortex in early-onset cases, compared with controls.

It is an open question whether improved-quality multimodal imaging can refine methodology to produce more precise results in smaller samples. A pooled analysis from a selection of such studies employing peak co-ordinates for MR structural data showed reduced grey matter in the amygdala, dorsal fronto-medial cortex, and right para-cingulate cortex. In the same patients, PET demonstrated increases in glucose metabolism in the right subgenual and pregenual anterior cingulate [37]. The connectivity of the subgenual region had previously been shown to suggest projections to the nucleus accumbens, amygdala, hypothalamus, and orbitofrontal cortex [38].

Fig. 76.1 (see Colour Plate section) Meta-analysis of magnetic resonance scans from patients with major depression, compared with controls, from the ENIGMA working group [34]. Effect sizes for regions with significant (PFDR <0.05) cortical thinning are shown in red. Negative effect sizes d indicate cortical thinning in MDD, compared to controls.

Functional imaging: resting state and task-based studies

In one sense, resting state data are well suited to aggregation in secondary analyses; the lack of any task for subjects to perform during scanning means that their experience inside the scanner should be reasonably consistent across studies. However, a large variety of statistical approaches are used in the first-level analysis of resting state data; the choice can profoundly influence the connectivity metrics generated. The two common methods for analysing resting state data involve either correlating BOLD signal against a range of seed regions (with different sets of seeds used in different laboratories) or using data-driven independent component analyses of whole brain data. It is difficult to draw firm conclusions from such variable approaches, although increased connectivity in depressed patients within the default mode network is perhaps the most consistently reported finding [39]. While it is an advantage of resting state data that the same networks can be identified with reasonable reliability across studies, it is less clear how differences in these networks relate to cognitive function or why they may be related to symptoms [40]. This explanatory gap means we do not understand what role increased connectivity within the default mode network plays in major depression.

In contrast, task-based fMRI studies in depressed patients have been influenced by dual-process, mechanistic models of emotional and cognitive control. These models suggest two neural systems to be key—firstly, a bottom-up, limbic-based system which responds relatively automatically to salient stimulus features, and secondly, a top-down frontal-based control system which responds more flexibly and is able to modify activity of the limbic system. Published studies have tended to report altered activity of frontal regions during emotional or effortful tasks, which has been interpreted as reflecting reduced or deficient function of the top-down control systems [41, 42]. This goes along with evidence of increased activity of limbic regions, particularly in response to negative affective stimuli [43]. One attraction of this proposal is that it links imaging findings not only to symptoms, but also to cognitive abnormalities observed in patients such as reduced executive function or processing biases for negative information. However, very similar ‘hyperactive limbic system combined with deficient control system’ models have been proposed for a range of psychiatric diagnoses such as anxiety, BD, and attention-deficit/hyperactivity disorder (ADHD). Whether this explanatory overlap between diagnoses is a result of common neural mechanisms across disorders, a reflection of the current technical limitations of neuroimaging modalities, or of a relatively underdeveloped imaging literature is not clear. Whatever the explanation, current imaging-based mechanistic models of major depression do not have the specificity to distinguish between different illness phenotypes.

Classification studies in major depression

The RDoC project has exemplified the search for objective measures, such as those from neuroimaging, to inform novel categorical schemes in mental health and disease (see Chapter 8). It has led to an increased focus on studies which recruit patients with a range of difficulties and diagnoses in order to identify common processes across conventional symptom-based diagnoses. A slightly less ambitious approach attempts to identify subcategories within existing diagnoses. The common observation that patients with major depression show heterogeneous illness courses, response to treatment,

and risk factors has prompted a number of early attempts to identify subgroups of depressed patients such as those with a melancholic vs a reactive illness course. Historically, it proved challenging to demonstrate that such subgroups were clinically meaningful, for example that they provide useful information on prognosis or response to treatment. A recent influential study provides a first hint that neuroimaging measures may be useful in this project. In the study illustrated in Fig. 76.2, Drysdale and colleagues amassed over 1000 resting state scans from depressed patients and controls [44]. Using an unsupervised classification approach, based on resting state connectivity measures and symptom score measures, the authors claim to have identified four distinct subgroups of patients. The groups displayed a reasonably specific pattern of resting state connectivity and associated cluster of symptoms. They then demonstrated that they were able to identify patients with these symptom clusters using just the connectivity data, in a sample of 400 new participants. However, the validity of the reported clustering of patients has been questioned in recent work [44a] and, even if the clusters do turn out to be reliable, this does not not guarantee that they will be clinically useful. The authors provided important initial reassuring evidence on this point. The four clusters of patients responded differently to repeated transcranial magnetic stimulation (rTMS). Further assessment of the utility of this clustering technique will require replication of the cluster identification process by other research groups and confirmation that cluster assignment is associated with response to more mainstream treatments or to general illness course. However, the study demonstrates a potentially exciting development beyond symptoms; this has been long anticipated, but not hitherto delivered.

Supervised learning, the second approach to classification, has most commonly been employed to classify depressed patients into responders vs non-responders to treatment. The majority of pharmacological and psychological treatments for depression take weeks to fully influence subjective symptom measures. A significant proportion of patients do not respond to the initial treatment regime. As a result, there is often a long delay before patients are started on effective therapy. A number of studies have looked at whether an individual will respond to a specific treatment, based on structural and/or functional neuroimaging data collected before treatment is initiated or over the first few days of treatment. The rationale is that such measures could pave the way to personalized therapy in which the neuroimaging outcomes would be used to select the treatment that is most likely to help an individual patient. Published studies to date have employed modest sample sizes and have been unable to test the performance of the classifiers using a fully held-out sample [45]; within-sample accuracies (that is usually estimated using ‘leave-one-out’ procedures) have tended to range between 60% and 70%. Response rates to antidepressants in unstratified clinical trials are often around 50%, so a 10–20% improvement appears promising for clinical settings. Ongoing projects are collecting larger sample sizes, which will allow more robust out-of-sample validation of classifier performance.

Improvements in methodology may well identify reliable subgroups of patients or classifiers which identify treatment responders vs non-responders. The next stage will be to test the use of these classifiers in RCTs. Imaging is still both unwieldy and relatively expensive, and other methods of objectifying behavioural phenotypes will be developed from self-rating and wearable devices, which may

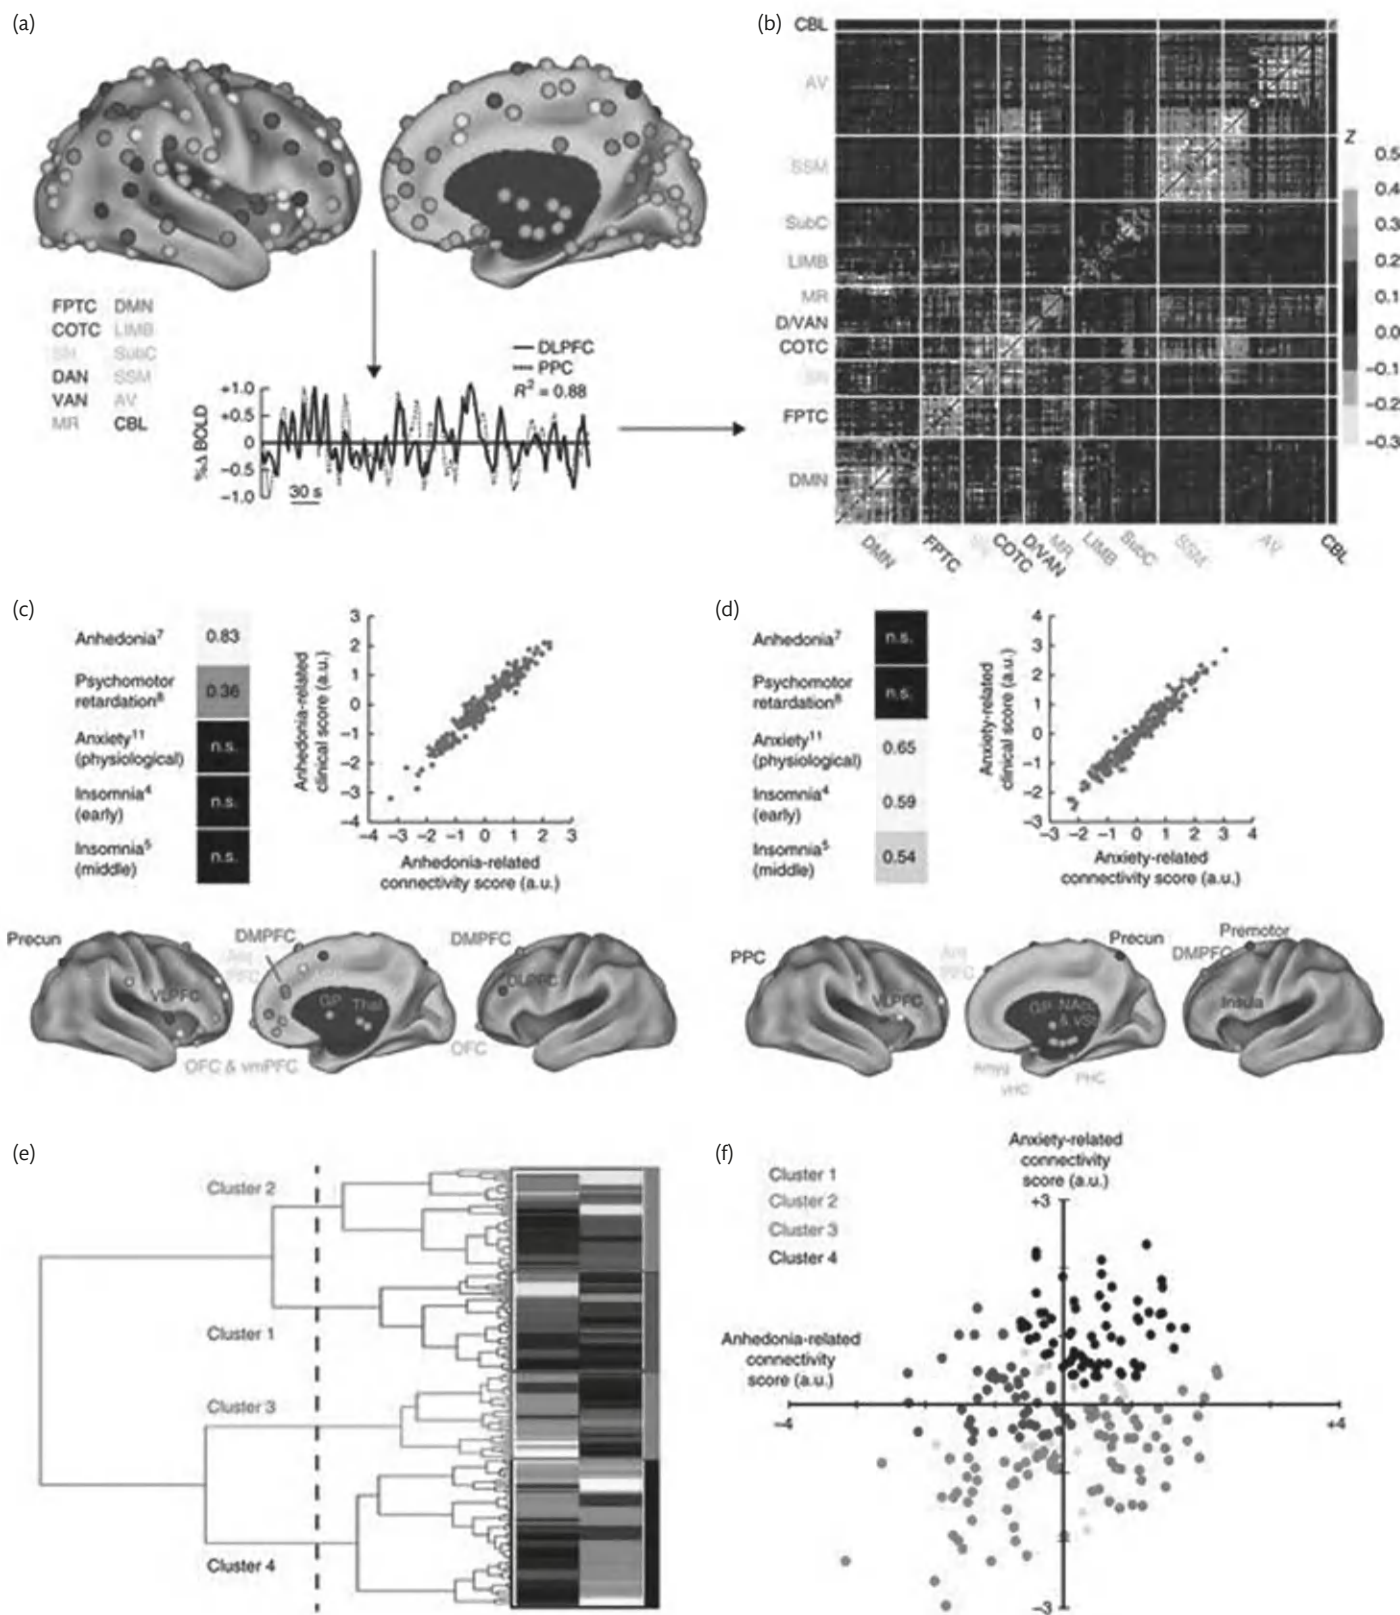

Fig. 76.2 (see Colour Plate section) Definition of subtypes of depression using resting state fMRI data taken from [44]. Resting state data from depressed patients and control subjects were collected. (a) Regions of interest were defined across the brain, and the mean BOLD time series from each of these regions was extracted for each subject. (b) For each subject, the correlation between all pairs of time series was calculated as a measure of connectivity. The figure illustrates the correlation between the regions of interest which are arranged depending on the neural system of which they are a member. (c) and (d) A data reduction method (canonical correlation; CC) was then used to find simple relationships between the imaging data shown in (b) and patient depression scores measured using the Hamilton Depression Rating Scale. CC looks for common factors in the imaging and symptom score data sets; here two were found: (c) an ‘anhedonia’-related scale and (d) an ‘anxiety’-related scale. The brain images display the regions of interest

provide cheaper means of patient stratification. Whether imaging will find a role generating classifiers in clinical practice is still uncertain. Its widespread adoption will require evidence for meaningful and cost-effective improvement in outcomes.

White matter integrity and neurodevelopment

As already noted, diffusion-weighted MR imaging (DTI) offers a sensitive way to determine the integrity of white matter. Apparent abnormalities are seen in at-risk samples. A quantitative voxel-based pooled meta-analysis of FA of almost 400 first-episode, drug-naïve MDD revealed reductions in the corpus callosum, bilateral anterior internal capsule, and right inferior temporal and right superior frontal gyri. FA reductions in some of these areas correlated with symptom scores and duration of depression [46]. In a similar large pooled analysis comparing over 500 more heterogeneous MDD patients and controls, there were trends to reduced FA in the corpus callosum (CC) and inferior fronto-occipital fasciculus (effect sizes -0.19 and -0.20 , respectively) [47].

These findings in people early in the illness course suggest decreased fibre coherence or glial distribution [48] to be associated with MDD. Given similar findings in at-risk populations and first-episode cases, the abnormality appears likely to be neurodevelopmental, rather than acquired, as a result of illness course or medication. FA increases monotonically during adolescence, but at different rates in different brain structures; thus, the splenium appears to stabilize by age 15, while the uncinate fasciculus appears still to be changing at age 30 [49]. Therefore, development of the splenium would be complete by age 20 and the difference in FA would then be enduring. Some prospective longitudinal data in young people with first-degree relatives with BD suggest no catch-up of the decreased FA when first seen, over the next 2 years [50]. This finding clearly complements, and must partly explain, the findings of reduced FA in mature patients. Studies of twins and siblings suggest that FA in multiple cortical regions is under genetic control [51]. Therefore, diffuse FA abnormalities in white matter appear to be a neurodevelopmental marker of vulnerability to MDD and other psychiatric disorders, including BD (see Chapter 71), ADHD (see Chapter 35), schizophrenia (see Chapter 60), and impulse control disorders (see Chapter 123). How alterations in white matter microstructure can be such a general marker of neurodevelopmental abnormality is not established. White matter investigation using more advanced MR methods will clearly be increasingly possible.

Given the findings in young people at risk of MDD or with early-onset psychiatric disorder, it is unsurprising that mature patients show the same pattern of diffuse reductions in white matter FA. It could be an enduring mark of their early vulnerability. A preliminary description of DTI data from the pooled ENIGMA MDD cohort showed the largest differences in white matter between cases

and controls in the body and genu of the CC [52]. The effect sizes for different areas varied up to a maximum of -0.34 in the body of the CC. Such effects for the white matter microstructure are stronger than those reported in their similar meta-analysis of subcortical grey matter volume in MDD described previously. The sample size is still modest, and moderating factors remain to be studied in larger samples.

In an early study of patients with *onset* of MDD over 60 years, FA reductions were marked, even when grey matter volume changes were undetectable [53]. In addition, these patients performed worse than appropriate controls in tests of executive function, processing speed, episodic memory, and language. There were meaningful correlations between FA in individual brain areas and cognitive impairments: reduced FA of the anterior thalamic radiation and uncinate fasciculus with executive function; the genu of the CC with processing speed and anterior thalamic radiation; and the genu and body of the CC and the fornix with episodic memory. While exploratory, these findings supported the internal validity of the findings in a small study. Moreover, they predicted a closer link between acquired or progressive white matter disruption and cognitive deficits than for the superficially similar reductions seen in younger patients with MDD.

For the late-onset group, acquired white matter disruption may be a particular risk factor. This is supported firstly by the observation that DTI changes are more striking in late-onset patients, compared with age-matched early-onset patients [54]. Secondly, there was an association between *subthreshold* depressive symptoms and FA reductions in an intensively studied cohort of now ex-civil servants aged almost 70 years (effect size -0.2) [55]. This group gave no history of depressive episodes. In this study, there was no association with grey matter volume, and the sample size was 350. However, only 10% of the total sample had excess depressive symptoms. The anatomy of the largest effects was diffuse, involving particularly the CC and the inferior and superior longitudinal fasciculi. Vascular risk factors are believed to contribute to the development of DTI changes in the elderly. Scores for vascular risk (Framingham Stroke Risk Profile) correlated with DTI measures in late-life MDD [56].

Reduced FA has been a highly consistent finding in studies of more heterogeneous groups of older patients. In a review of nine such studies, the dorsolateral prefrontal cortex and uncinate fasciculus in patients with MDD had lower FA than controls (effect sizes 0.7 and 0.23 , respectively), although heterogeneity and publication bias were evident for the dorsolateral prefrontal cortex [57].

White matter integrity, neurodegeneration, and cerebral lesions

White matter abnormalities were originally described in mood disorder patients in the earliest studies with CT and MR imaging

Fig. 76.2 Continued

between which resting state correlations were most closely related to the specific factor. (e) The strength of these two factors was estimated for each patient, and then an unsupervised classification procedure—hierarchical clustering—was used to try and find clusters of patients who differed on the two measures. (f) Four clusters of patients were found, with each cluster defined by a different combination of the two factors. The scatter plot shows data from patients colour-coded by the cluster to which they are assigned; grey dots represent patients who could not be confidently classified. The authors next demonstrated that these clusters could be reliably detected in a second data set and that cluster membership could be assigned using just the neuroimaging data. Lastly, it was shown that the clusters predicted treatment response to transcranial magnetic stimulation (TMS) therapy—a greater proportion of patients in clusters 1 and 3 responded to TMS than those in clusters 2 and 4.

as 'white matter hyperintensities' [58, 59] and are most often seen in older patients [60] (see Chapter 66). They are clearly correlated with vascular disease [53]. They do not, in themselves, explain any of the findings already described for older patient samples, because white matter changes appear to be so diffuse. Notwithstanding the foregoing emphasis on *neurodevelopmental* abnormality in young people and stable FA reductions in mature patients with MDD, white matter disruption appears also to be a manifestation of progressive brain changes in ageing. Correlates of microstructure abnormality with cognitive function are more evident in a healthy ageing population; progressive reduction in FA was seen with age and correlated selectively with working memory among several tests of executive function and processing speed [61].

Brain diseases or injury and depression

Post-stroke depression (PSD) is a common complication of rehabilitation after stroke. The location of brain injury predisposing to depression is of obvious interest, although not without controversy [62, 63]. A recent systematic meta-analysis aimed to determine the mapping between PSD and lesion location. Forty-three studies involving 5507 patients suffering from stroke were included [64]. Only studies with 1–6 months post-stroke group showed a statistical association between right hemisphere stroke and risk of depression (OR 0.79, 95% CI 0.66–0.93). This contrasts with earlier claims that lesions of the *left* hemisphere were associated with an increased risk of depression after stroke [63].

Rather differently, mood and anxiety disorders may be presenting symptoms of brain tumours or other brain disease. Imaging can be highly relevant to neurological diagnosis. Depressive illness may be the only complaint in the presentation of meningioma for as many as 20% of the cases occurring in the fifth decade of life. As many as 75% of some series of patients with multiple sclerosis experience a delay in multiple sclerosis diagnosis due to symptoms of MDD. A missed or delayed diagnosis is clinically significant if it postpones effective intervention, increases the burden of disease/disability, and reduces the quality of life. Rather similarly, major depression may precede the diagnosis of Parkinson's disease in as many as 37% of younger, especially female, patients presenting with motor signs [65].

Traumatic brain injury (TBI) is receiving increasing attention because of the impact on survivors of head trauma in civilian and military life and in contact sports. In a review of almost 100 publications, 27% of cases of TBI were diagnosed with MDD/dysthymia using formal criteria and 38% reported clinically significant depression with self-report scales, which makes it a common complication of TBI [66]. Interestingly, DTI investigations of white matter integrity can effectively differentiate patients with TBI from controls [67]. There also appears to be a relationship between DTI measures and TBI outcomes. However, a specific relationship with depression in this patient group, perhaps mediated by white matter damage, has not yet been described, even if it can be anticipated from what has been foregoing in this chapter.

As with other MR measures, DTI may prove useful in patient stratification and prediction of treatment response. Lower FA has been related to treatment resistance [68] and reduced resilience to MDD after early-life adversity [69].

Isotope-based imaging

Isotope-based imaging (PET and SPET or SPECT) has assumed marginal importance in recent years. PET and SPECT provide the initial evidence, based on cerebral blood flow, for functional abnormality in the brain in depression [70, 71]. These methods remain the only way in which specific binding to brain receptors can be measured in the living human. We do not propose to review here the literature relating to the 5-HT₁ receptor [72], the D₂ receptor [73], or the serotonin transporter [74], all of which are relevant to depression.

The findings in isotope imaging studies are limited by the costs of such studies (which result in small samples) and the complicated context for their interpretation (provided by genotype, development, early experience, previous exposure to medication or drug/alcohol use, data from post-mortem studies, and our understanding of animal experiments on the same receptors).

Conclusions

MR measures have an obvious direct appeal for neuroscience, and the biology of MDD has proved no exception. To date, definitive advances that change practice have not been made. As a marker of neurodevelopmental abnormality, the white matter may prove to be an important tissue for understanding behavioural pathology; as such, it provides a candidate target for understanding gene and gene × environment interactions on the one hand and impairment of emotional control and cognition on the other.

Management and treatment of depressive disorders

Philip J. Cowen

Introduction

'But one need not sound the false or inspirational note to stress the truth that depression is not the soul's annihilation; men and women who have recovered from the disease—and they are countless—bear witness to probably what is probably its only saving grace: it is conquerable.' [1]. William Styron here elegantly expresses the notion that the prognosis of most depressive episodes is eventually favourable, and indeed much depression in the community resolves without specific treatment. However, depression can be persistent and disabling, and in these circumstances, the use of effective therapies is appropriate and important.

This chapter will first examine evidence for the efficacy of the wide range of treatments employed in depression. The subsequent section (see Management of depressive disorders, p. 810) will deal with the way in which these treatments are best integrated into specific clinical management plans. It should be noted that controlled trials of treatment usually involve patients with a depressive episode diagnosed according to DSM or ICD criteria and in the moderate range of clinical severity. There are less controlled data available about the treatment of milder depressions or those that are particularly severe.

Evidence for efficacy of treatment

Antidepressant medication

Treatment of acute major depression

The first widely used drugs for depression were tricyclic antidepressants (TCAs) such as imipramine and amitriptyline. Their mechanism of action in depression was eventually shown to be due to blockade of the reuptake of noradrenaline (NA) and serotonin [5-hydroxytryptamine (5-HT)] at nerve terminals, thus prolonging the action of these monoamines in the synapse. The majority of drugs developed subsequently for depression share this therapeutic mechanism [2] (Table 77.1). Despite their efficacy, TCAs have significant safety problems, particularly potential lethality in overdose through cardiotoxicity. In addition, their anticholinergic properties can

make tolerance of a therapeutic dose challenging and, for example, place older male patients at risk of urinary retention [2].

Newer drugs, in particular selective serotonin reuptake inhibitors (SSRIs), have replaced TCAs as first line [3]. SSRIs are better tolerated and much safer in overdose than TCAs, but commonly cause gastrointestinal and CNS adverse effects (Box 77.1). Serotonin and noradrenaline reuptake inhibitors (SNRIs), such as venlafaxine and duloxetine, are primarily 5-HT reuptake blockers but also have some modest effects to inhibit the reuptake of NA. Their side effect profile is similar to that of SSRIs, but venlafaxine appears less safe in overdose [2]. A number of other antidepressant drugs are available, including mirtazapine, which has antagonist properties at 5-HT_{2/3} and NA α_2 -adrenoceptors, and trazodone, which is a weak 5-HT reuptake inhibitor and is metabolized to a 5-HT receptor agonist. Both latter drugs have a sedating profile [2]. Agomelatine is licensed for depression in Europe; its main action is stimulation of melatonin receptors, but it may also antagonize 5-HT_{2C} receptors [4].

Other recent developments have led to drugs that block 5-HT reuptake, while having additional effects on a variety of 5-HT receptor subtypes. For example, vilazodone has partial agonist activity at the 5-HT_{1A} receptor, while vortioxetine binds to several other 5-HT receptor subtypes (5-HT_{1A/1B/1D}, 5-HT₃, 5-HT₇). Whether these agents have advantages over SSRI treatment is not fully clear, though vilazodone is claimed to produce less sexual dysfunction and vortioxetine to have particular benefits in depression-related cognitive impairment [5, 6].

All the drugs listed in Table 77.1 are efficacious in the acute treatment of major depression, with the largest effects, relative to placebo, being seen in patients with major depression whose symptoms are of at least moderate severity. Short-term response rates in controlled trials are about 50% for patients on active treatment, and about 30% for those on placebo, with the number needed to treat (NNT) being between 5 and 6 [3]. Several meta-analyses have assessed the differences in efficacy and general tolerability between the newer agents. There are suggestions that, among the SSRIs, sertraline and escitalopram are the most effective, while venlafaxine is slightly more efficacious than SSRIs, though less well tolerated [7]. Whether these differences are clinically important has been disputed [8]. In

Box 77.1 Some side effects of SSRIs

Gastrointestinal	Common: nausea, appetite loss, dry mouth, diarrhoea, constipation, dyspepsia Uncommon: vomiting, weight loss
Central nervous system	Common: headache, insomnia, dizziness, anxiety, agitation, fatigue, tremor, somnolence Uncommon: extra-pyramidal reaction, seizures, mania
Other	Common: sweating, delayed orgasm, anorgasmia Uncommon: rash, bleeding, pharyngitis, dyspnoea, serum sickness, hyponatraemia, alopecia
Drug interactions	NSAIDs, aspirin, anticoagulants (bleeding), lithium, triptans, MAOIs (including selegiline), tryptophan, linezolid, pethidine, St John's Wort (5-HT toxicity). Some SSRIs (fluoxetine, fluvoxamine, and paroxetine) strongly inhibit hepatic metabolizing enzymes and increase levels of other drugs; numerous examples reported, including antipsychotic drugs, anticonvulsants, and antiarrhythmics

Adapted from Cowen P, Harrison P, Burns T, *Shorter Oxford Textbook of Psychiatry*, Sixth Edition, Copyright (2012), with permission from Oxford University Press.

some meta-analyses, the selective NA reuptake inhibitor reboxetine performs poorly in terms of tolerability and efficacy [7].

Monoamine oxidase inhibitors (MAOIs) were among the first drugs discovered that treat depression, but they are little used nowadays because of their liability to cause dangerous reactions with other drugs and tyramine-containing foods. However, controlled trials have shown that MAOIs can be effective in depressed patients who have not responded to numerous other pharmacological and non-pharmacological treatments, and for this reason, they retain some specialist use [9]. The reversible type A MAOI moclobemide has the advantage of not requiring adherence to a special diet. However, it can still produce hazardous interactions with other

drugs, and it is doubtful whether moclobemide at standard doses is as effective as conventional MAOIs for patients with resistant depression.

Other depressive conditions

Drugs for major depression, in particular SSRIs, have been shown to be effective in dysthymia, with an NNT of 3–4 [10]. This suggests that medication can be effective in milder depressive conditions of lengthy duration. However, for milder depressions of more recent onset, antidepressant medication does not seem specifically useful [11].

Longer-term treatment

By convention, the term 'relapse' is used to describe the worsening of depressive symptoms after an initial improvement, following the acute treatment of a depressive episode. 'Recurrence', on the other hand, refers to a new episode of depression that develops after a sustained period (of at least several months) of complete recovery. Treatment to prevent relapse is called 'continuation treatment', while that employed to prevent recurrence is known as 'prophylactic' or 'maintenance' therapy [3].

It is well established that stopping antidepressant treatment soon after an acute treatment response is associated with a high risk of relapse. Placebo-controlled studies indicated that continuing effective acute phase treatment for 6 months halves relapse rates [3]. For patients at high risk of recurrence (for example, those with three or more previous depressive episodes), extending antidepressant medication after this period is highly effective in lowering recurrence rates. A systematic review found that prescription of maintenance medication, relative to placebo, diminished the recurrence rate over the next 1–2 years from 40% to 18% (NNT = 4.5) [12]. Maintaining the dose at the level which was required to achieve acute symptomatic remission, if tolerability permits, appears the most effective strategy.

Electroconvulsive therapy

Controlled trials indicate that electroconvulsive therapy (ECT) is more effective than simulated ECT (anaesthesia with electrode

Table 77.1 Pharmacological properties of some antidepressants

Drug	5-HT reuptake	NA reuptake	Anticholinergic	Sedating	Overdose toxicity	Sexual dysfunction	Weight gain

Trazodone	+	0	0	+++	+	+ ⁴	+

0, minimal effect; +, some effect; ++, moderate effect; +++, marked effect.

¹ Indirect anticholinergic effects through NA potentiation.

² Also blocks dopamine reuptake to some extent.

³ Increases NA through α_2 -adrenoceptor blockade.

⁴ Rarely causes priapism.

application, but no passage of current) in patients with major depression. The overall response rate is about 70% for ECT, and 40% for simulated treatment (NNT = 3.5) [13]. Randomized trials also suggest that ECT is slightly more effective and more rapid-acting than antidepressant medication, at least in the short term [13]. Generally, ECT is employed in patients who have not responded to other antidepressant therapies, and it may often prove effective in these circumstances; however, relapse rates in the months following treatment are high [14, 15].

ECT is generally a safe treatment. However, there is concern about its deleterious effects on memories for more remote personal events (autobiographical memory loss). While objective measures suggest that this loss largely resolves within 6 months, subjective reports by patients indicate that the loss can extend for longer and might sometimes be permanent [2].

Other neurostimulatory treatments

A number of other neurostimulatory treatments have been tested in depressed patients, often where conventional therapies have not been helpful. Deep brain stimulation is discussed in Chapter 20. Other neurostimulatory approaches include vagal nerve stimulation (VNS) and transcranial magnetic stimulation (TMS), both of which have been approved for the treatment of depression in the United States. TMS has also been approved in several other countries for the management of resistant depression.

VNS has a slow onset of antidepressant action, over many months, which means that long-term follow-up studies are needed to assess its effectiveness. A meta-analysis of six outpatient multi-centre trials involving patients with refractory depression showed higher response rates in the VNS group at 96 weeks than a matched group of patients receiving standard treatment (32% vs 14%, respectively; NNT = 5.5). However, most of the studies were not randomized [16].

TMS uses a powerful magnetic field to produce a current flow in neural tissue. The use of appropriately shaped coils allows localization of stimulation to the main cortical regions. TMS has been used successfully to relieve depressive states, but there are still uncertainties about the best coil placement and stimulus parameters. The usual mode of administration is to administer stimulation to the left prefrontal cortex, with treatments being given 5 days a week for 2 weeks.

In a meta-analysis of trials involving about 1300 depressed patients randomized to either active or sham TMS, there was a greater clinical response in patients receiving active treatment (36% vs 15%, respectively; NNT = 9) [17]. However TMS appeared less effective than ECT in producing remission in severely depressed patients (34% vs 52%, respectively; NNT = 5.5) [18]. Nevertheless, TMS would be expected to be relatively free of the personal memory deficits induced in some patients by ECT.

Bright light treatment

The use of phototherapy, or artificial bright light, as a treatment for depression was first studied systematically by Rosenthal and colleagues who used morning bright light to treat patients with the newly identified syndrome of 'seasonal affective disorder' [19]. Since then, phototherapy has become the mainstay of treatment of 'winter depression', particularly in patients whose clinical features include hyperphagia, hypersomnia, and diminished energy.

A meta-analysis of eight randomized studies found that morning bright light was significantly superior to a dim light control in reducing symptomatology in patients with winter depression, with an effect size of about 0.5 [20]. In winter depression, the therapeutic effects of bright light, fluoxetine, and cognitive behavioural therapy (CBT) appear generally equivalent, although cognitive therapy may have a better long-term outcome [3].

Psychotherapy

Treatment of acute depression

Individual CBT is the most studied psychological treatment in the management of acute depression, and there is strong evidence for its efficacy. Not surprisingly, the effect size of CBT is greatest in studies that compare it to a wait-list control or 'treatment as usual' (TAU). Direct comparisons of CBT to other structured psychological treatments, such as interpersonal psychotherapy (IPT) and behavioural activation, tend not to show important differences in outcome. Similarly, most studies show similar efficacy when CBT is compared to antidepressant medication in the treatment of acute depression. However, the combination of CBT with antidepressant medication is probably better than drug treatment alone [21, 22].

Many psychiatrists do not consider that CBT is effective for patients with severe depression, but this view does not have support from randomized trials. However, defining 'severity' by means of a score on a rating scale may not capture specific factors that could compromise the efficacy of psychological treatment such as significant cognitive impairment and psychomotor retardation. Also the expertise of the therapist and their adherence to treatment protocols significantly influences outcome in CBT trials [23].

Systematic reviews indicate that other individual structured psychological treatments, such as IPT, behavioural activation, and problem-solving therapy, are effective in treating depression, in comparison to both placebo treatment and TAU [22]. However, the efficacy of short-term psychodynamic therapy is less certain [24]. The utility of behavioural activation and problem-solving therapy is important because such therapies require less therapist training and are easier to implement than CBT. Because of the high prevalence of depression in primary care and the preference of many patients for psychological treatments, there has been much interest in developing ways of increasing the availability of psychological therapies. Approaches range from group CBT formats to self-help booklets and therapy delivered via the Internet. Generally, in mild to moderate depression, all these treatments have some efficacy, relative to wait-list control, and there are no clear-cut differences between them [25].

This is also a convenient place to discuss the efficacy of exercise in treating depression. While there has been some controversy, the more recent systematic reviews suggest large effects of supervised, moderate-intensity aerobic exercise to decrease depressive symptomatology, compared to no treatment, and a moderate effect in comparison to TAU [26]. Again such treatment is likely to be most beneficial for patients with mild to moderate depression.

Other depressive conditions

Where depression has persisted for a considerable period, and particularly in dysthymia, CBT appears less effective than antidepressant medication [27]. There are few trials of other psychological treatments in chronic depression, but psychodynamic therapy

may be superior to TAU in patients with long-term resistant depression [28].

Continuation and maintenance treatment

There is evidence that in patients randomized to CBT during the acute phase of depression, there is sustained improvement in depressive symptomatology over the next few months, even after the end of treatment. The risk of relapse after CBT is significantly less than that of patients withdrawn from pharmacotherapy (NNT = 5). There is also good evidence that CBT given in the continuation phase lowers relapse rates, compared to CBT given in the acute phase only (10% vs 31%, respectively; NNT = 5) [29].

Mindfulness-based cognitive therapy (MBCT) integrates CBT with meditation techniques designed to lower stress by facilitating acceptance and self-compassion. There is evidence that MBCT lowers the risk of recurrence in patients with a history of frequent episodes of depression and is as effective as maintenance antidepressant treatment in this respect [29, 30]. However, reliable identification of the specific elements of treatment and patient characteristics that may be linked to therapeutic response has proved difficult.

Combining IPT with medication in the treatment of acute episodes decreases relapse rates over the following 12 months [29]. In patients who achieve remission from depression, with IPT as sole treatment, maintenance therapy is also helpful in preventing recurrence. In a 3-year follow-up of elderly depressed patients, the combination of nortriptyline and IPT was more effective in preventing relapse (20% relapse rate) than nortriptyline alone (43% relapse rate), which itself was more effective than IPT alone (64% relapse rate) [31].

Management of depressive disorders

Assessment

The key aspects of the assessment of depression are summarized in [Box 77.2](#). The critical factors that facilitate assessment are careful history taking and mental state examination. These also provide an invaluable opportunity to build a rapport with the patient, which is essential if constructive management plans are to be mutually agreed. The availability of a close friend or relative, able to provide collateral information, can be very helpful.

In the history, particular attention should be paid to previous episodes of mood disturbance, which can offer important clues to the likely prognosis of the present disorder. A careful search for symptoms of hypomania and mania should be made, as the presence of bipolar disorder indicates that a different kind of management of

the depressive episode is likely to be necessary (see Chapter 72). The severity of the depressive disorder will have important implications for the kind of treatment that might be suggested first. Here, it is necessary to gauge both the intensity and the range of current symptoms, as well their duration. Identification of melancholic depression or depressive psychosis will also influence treatment selection. The risk of suicide should be assessed in every patient presenting with depression.

Coming to an understanding with the patient about the aetiology of the depressive episode is important in management. As pointed out by Aubrey Lewis [32], in most patients, the depressive episode appears to be the result of a combination of personal predisposition and current life difficulties, though, with the latter, it is important to try to establish which problems have arisen as a result of the depressive condition—often a difficult task. It is important to remember that depressive symptoms may be secondary to another psychiatric disorder or an underlying general medical condition—or its treatment.

Another important part of the assessment is learning about the patient's current social resources, for example how well they are supported in their home and work life and whether they have an understanding confidant. It is also important to consider the effects of the depressive condition on other people, both those close to the patient, such as dependent children, or others who might be affected by the patient's occupation, for example coach drivers or medical workers.

Treatment setting

The majority of patients with depression are treated in primary care, and many continue to work and carry out family and social activities, albeit with reduced efficiency and enjoyment. Patients with more severe depressive disorders are often quite unable to function and may be in states of considerable anguish and distress, with significant suicidal ideation. An early treatment consideration therefore is how far patients need additional support and what form this should take. A few patients, perhaps because of poor self-care and worrying levels of suicidal thinking, will require inpatient admission. However, if sufficient family support is available, even very ill patients may be managed at home, in conjunction with frequent home visiting and monitoring by a community psychiatric team.

The next question is whether the patient should continue to work. If the disorder is of mild to moderate severity, work can provide a valuable distraction from depressive thoughts and be a source of companionship. If the disorder is more severe, slowness, poor concentration, and low energy are likely to impair work performance, which can increase feelings of hopelessness and may pose risks to others. If patients are not engaged in work, it is important to plan day-to-day activities because depressed patients often give up activities and withdraw from other people. As a result, they become deprived of social stimulation and potentially rewarding experiences, which increases feelings of depression. It is therefore important to make sure that the patient is occupied adequately, although they should not be pushed into activities which will be too demanding.

The appropriate kind of psychological treatment should also be decided in each case. All depressed patients require support, encouragement, and an explanation that they are suffering from an illness, and not some form of moral or other personal failure. Similar counselling of partners and other family members is often useful. It is also important to try and tackle any psychosocial problems that

Box 77.2 Assessment of a depressive condition

- Is the diagnosis major depression (DSM-5) or depressive episode (ICD-10)?
- How severe is this episode, and what is its duration?
- What is the past history of mood disturbance?
- What is the risk of suicide?
- What are the important causal factors?
- What are the patient's social resources?
- How is the depression affecting others?

Box 77.3 Stepped-care management of depression

1. Patients with short-lived mild depression who may recover quickly without treatment should be offered an early review ('active monitoring').
2. Antidepressants are not recommended for the treatment of mild depression.
3. Patients with persistent mild depression should be recommended a guided self-help programme, based on cognitive behavioural therapy. Group cognitive behavioural therapy is an alternative. An exercise programme can also be recommended.
4. For patients with persistent mild depressive symptoms who do not respond to these measures, consider drug treatment with an SSRI or higher-intensity psychological treatment.
5. Patients who present with moderate or severe depression should be treated with a combination of antidepressant medication and a high-intensity psychological intervention.
6. Patients who respond to antidepressant medication should continue treatment for at least 6 months. Patients at high risk of relapse should be advised to continue antidepressant treatment for 2 years.
7. Consider cognitive behavioural therapy for patients who have relapsed despite antidepressant treatment, or mindfulness-based cognitive therapy for patients who are well but who have experienced three or more previous episodes of depression.

are making an important contribution to the depression. For example, couple therapy can be a helpful addition in depressed patients where problems with a partner are playing a role in maintaining the disorder. Other more specific psychological treatments will be indicated for some (see [Box 77.3](#)).

The stepped-care approach

The majority of patients with depression present in primary care with mild to moderate symptoms. It is generally agreed that depressive symptomatology in the community follows a dimensional distribution, with no clear cut-off between the mild and transient depressive feelings common in everyday life and the more severe depressive states that are an indication for some form of medical

intervention. In practice, the latter judgement is made on the basis of the number and severity of clinical symptoms, the subjective level of distress, the level of functional impairment, and the length of time for which the symptoms have persisted [33].

Current guidance from the National Institute for Health and Care Excellence (NICE) advises a stepped-care approach, so that depressed patients are treated with the least intrusive approaches first, with more intensive treatments being introduced where improvement does not occur [25, 34] ([Box 77.2](#)). Patients with milder symptoms can be helped by the less intensive approaches described earlier, including self-help treatment, group CBT, or exercise. It should be noted, however, that in people with a history of recurrent depressive episodes, even mild symptoms may be a sign of an impending relapse and more active treatment may be indicated.

For patients with moderate levels of depression or greater, NICE recommends a combination of high-intensity psychological treatment (which generally would be individual CBT) and antidepressant medication. This treatment is suggested because systematic reviews indicate that a combination of CBT and medication is superior to medication given alone. However, in practice, it may be difficult to access expert CBT in a timely way, in which case starting treatment with antidepressant medication is appropriate. If, however, individual CBT or IPT are available from a suitably experienced therapist, it is reasonable to use psychotherapy as sole first-line treatment in moderate depression, if the patient prefers.

Antidepressant medication

Antidepressant medication can be considered for most patients with a major depressive syndrome of at least moderate severity, and particularly those with features of melancholic depression in DSM-5 or somatic depression in ICD-10. Dysthymia is also an indication for antidepressant medication [10, 27].

Most guidelines recommend initial treatment with an SSRI [3, 34]. Several preparations are available, and the differences between them relate largely to the pharmacokinetic profile and the risk of drug interaction ([Table 77.2](#)). There have been concerns that early in treatment, SSRI use may be associated with an increased risk of hostile and suicidal behaviour, but meta-analyses of placebo-controlled trials in adults suggest no increase in fatal suicide outcomes. SSRIs may be associated with a small increased risk of non-fatal self-harm,

Table 77.2 SSRIs available to treat depression

Drug (daily dose range)	Half-life (hours)	Withdrawal syndrome	CYP inhibition ¹	Cardiotoxicity
Citalopram (20–40mg)	36	+	0	Prolongation of QTc at higher doses
Escitalopram (10–20mg)	30	+	0	Prolongation of QTc at higher doses
Fluoxetine (20–60mg)	90 (plus long-acting metabolite)	0	2D6/2C9	0
Fluvoxamine (100–300mg)	20	+++	1A2/2C9/2C19/3A4	0
Paroxetine (20–50mg)	24	+++	2D6	0
Sertraline (50–200mg)	26	++	2D6 (modest)	0

¹ Hepatic metabolizing enzymes.

but the number need to harm (759) is much greater than the NNT (about 5) [35]. However, the first few weeks in the clinical management of depression do seem to be a time of increased risk of suicidal behaviour across a range of treatment modalities [36]. Careful and frequent monitoring of patients over this period is therefore prudent.

Patients should be warned about the delayed onset of action of SSRI, as well likely side effects, including nausea and some restlessness during sleep—a forewarned patient is more likely to continue with medication. A number of patients become more anxious and agitated early during SSRI treatment; therefore, it is important to explain that such effects are sometimes experienced during treatment but do not mean that the underlying depression is worsening. If the patient persists with treatment, such anxiety and agitation usually diminish, but short-term treatment with a benzodiazepine may be helpful, particularly if sleep disturbance is a problem. Patients should be reviewed frequently during the first few weeks of treatment, when support and advice are helpful both to maintain morale and to ensure compliance with medication.

If the use of SSRI medication is not suitable or not well tolerated (Box 77.1), a number of other options are available. Mirtazapine has a sedating profile. Less sedating alternatives include the NA and dopamine reuptake inhibitor bupropion, which is licensed for treating major depression in the United States, but not in Europe. In Europe, it is possible to use lofepramine, a tricyclic drug which is predominantly an NA reuptake inhibitor and appears relatively safe in overdose [2].

Special situations

Depression in pregnancy

The management of depression in pregnancy involves careful assessment, together with the provision of accurate information about the risks of depression to the mother and baby and the risks and benefits of different forms of treatment. If a woman has a history of recurrent moderate to severe depression and has been effectively maintained on antidepressant medication, it is generally better to continue this treatment during pregnancy because the risk of relapse is high if medication is withdrawn and there are risks to the fetus of untreated maternal depression. However, women with a history of less severe depression can often withdraw antidepressant medication successfully [37, 38].

Women not taking antidepressant medication who become depressed during pregnancy should be provided with psychoeducation and psychological treatment in a stepped-care manner, depending on the severity of their condition (Box 77.3). If the depression is severe, or if a moderate depressive episode fails to respond to psychological management, antidepressant medication should be offered, usually an SSRI [38]. Generally, the risks of SSRI treatment in pregnancy are low and are outweighed by those of untreated depression. However, self-limiting neonatal withdrawal syndromes have been described, although the incidence across studies varies widely. SSRI use in later pregnancy may also be associated with a small increase (1–2 per 1000 live births) in the risk of pulmonary hypertension of the newborn, a potentially fatal condition [39]. Paroxetine has been associated with cardiac defects and should therefore be avoided in pregnancy; other SSRIs appear to be safe in this respect [38]. There may also be an increased risk of autism in offspring born to mothers

taking SSRIs in pregnancy, but whether this is a causal effect of SSRI treatment has yet to be determined.

Antidepressant drugs should also be prescribed cautiously to women who are breastfeeding. The amount of drug that enters breast milk varies according to the individual agent. In terms of SSRI treatment, sertraline is present in milk in only small amounts and breastfeeding may continue while the baby is observed for effects such as sedation and feeding difficulties [2].

Depression in childhood and adolescence

For children and young people with persistent depressive disorders that have not responded to simple supportive measures, psychological treatment is regarded as the first-line approach. A systematic review found that both CBT and IPT were superior to wait-list control, whereas psychodynamic therapy was not. IPT and CBT were also superior to problem-solving therapy, but IPT had fewer all-cause discontinuations than CBT [40].

Antidepressant medication seems less effective in child and adolescent depression than in adults, and there is greater evidence for an increased risk of self-harm with SSRIs. A network meta-analysis of several drugs, including TCAs, SSRIs, venlafaxine, and mirtazapine, found that only fluoxetine was reliably better than placebo [41]. Another meta-analysis of 27 placebo-controlled trials of SSRI therapy in young people found no completed suicides, but a small significant increase in suicidal ideation and self-harm attempts in association with SSRI treatment (number needed to harm = 143) [42].

There have been few direct comparisons of medication and psychological treatment in adolescent depression, but the Treatment for Adolescents with Depression Study (TADS), sponsored by the United States National Institute for Mental Health (NIMH), found that after 12 weeks of treatment, response rates for pill placebo (34%) and CBT (43%) were significantly less than for fluoxetine alone (61%) and the combination of CBT and fluoxetine (71%). By 18 weeks, the response to CBT was similar to that found with fluoxetine alone, while the response to combination treatment was still superior. Fluoxetine treatment alone was associated with an increased risk of suicidal ideation and self-harm relative to placebo; however, this increase was not seen in patients in whom fluoxetine was combined with CBT [43]. TADS suggests that the best current treatment for moderate to severe depression in adolescence is a combination of fluoxetine and CBT.

Psychotic depression

Determining when the negative thinking of a severely depressed patient has reached delusional intensity is not easy. However, recognizing patients suffering from psychotic depression is important because antidepressant medication is unlikely to be effective as sole treatment. There is a long-held clinical view that pharmacological treatment of depressive psychosis requires combination therapy with antidepressant medication and a dopamine antagonist drug—the latter given at antipsychotic doses. A meta-analysis of nine trials confirmed that such combination treatment was superior to either treatment alone (NNT = 7 vs antidepressant monotherapy; NNT = 5 vs antipsychotic monotherapy) [44]. It is also worth noting that TCAs may be more effective than the newer more pharmacologically selective drugs in the treatment of depressive psychosis [45].

Use of electroconvulsive therapy

ECT will, very rarely, be part of the first-line treatment of depression and, in such circumstances, will usually be considered only where there is a need to bring about improvement as rapidly as possible. In practice, this applies mainly to patients who are unable to drink enough fluid to maintain an adequate output of urine, including the rare cases of depressive stupor. In depressive psychosis, ECT is considerably more effective than an antidepressant given alone, but probably about the same therapeutic effect can be achieved, albeit more slowly, if a combination of an antidepressant drug and an antipsychotic drug is used [46].

The main use of ECT is in severely depressed patients who have failed to respond to other antidepressant treatments. In these circumstances, a response rate of at least 50% can be expected, though the relapse rate over the next 6 months is high, emphasizing the importance of continuation of pharmacological and psychological treatment [9].

Failure to respond to first-line antidepressant treatment

If a moderate to severe depressive condition does not respond within a number of weeks to psychological treatment or antidepressant medication, the diagnosis should be reviewed carefully and further assessment made as to whether continuing psychosocial difficulties are perpetuating the disorder. Substance misuse, which is commonly comorbid with depression, may also hinder the response to treatment and may need to be separately addressed (Box 77.2).

If a patient has failed to respond to appropriately delivered psychological treatment, then a trial of medication can be considered. Where there has been a lack of response to antidepressant treatment, it is important to check that the patient has been taking medication as prescribed. If not, the reasons for this should be sought. The patient may be convinced that no treatment can help or may find the side effects unpleasant. If this enquiry is unrevealing, antidepressants should be continued at an increased dose, if possible. In general, SSRIs do not have well-described dose–response relationships, although some patients respond to higher doses, particularly if a partial response has been observed at a standard dose. If psychotherapy has not been offered at this point, a structured psychological treatment, such as CBT or IPT, should be considered if it is available in a timely way.

The large pragmatic Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study found similar response rates when SSRI-non-responsive patients were randomized to CBT or to pharmacological augmentation; however, the pharmacological approach worked more quickly [47]. A study of primary care patients who had failed to respond adequately to antidepressant medication found that CBT (a median of 11 sessions given over 6 months) was markedly superior to TAU in terms of response rate at 6 months (46% vs 22%, respectively; NNT = 4) [48].

If it becomes clear that the patient is not getting better, a number of further steps can be taken to improve pharmacological treatment (Box 77.4). There is not a fixed order in which treatments should be offered. Prescribing decisions should be made in collaboration with the individual patient, taking into account factors such as specific symptomatology, how far the condition may have shown a partial response, and the side effect profile of the various treatment options [46].

Box 77.4 Some pharmacological treatments for resistant depression

- Increase antidepressant to the maximum dose, if tolerance permits; if the patient has depressive psychosis, add an antipsychotic drug; try a different class of antidepressant drug, including venlafaxine and tricyclic antidepressants.
- Try an antidepressant combination (for example, an SSRI or venlafaxine with mirtazapine).
- Add an atypical antipsychotic drug to an SSRI or venlafaxine.
- Add lithium to antidepressant drug treatment.
- MAOIs (can be usefully combined with lithium).
- ECT.

Switching antidepressants

If a patient does not respond to one antidepressant, the first step is usually to stop the first medication and try another. If a patient has not responded to one kind of antidepressant, it would seem sensible to switch to an antidepressant that has different pharmacological properties. However, a meta-analysis showed that switching from an ineffective SSRI to a different class of antidepressant (mirtazapine, venlafaxine, or bupropion) was only marginally better in terms of remission rate than switching to a second SSRI (28% vs 23.5%, respectively; NNT = 22) [49]. Overall, however, around 30% of patients unresponsive to a first antidepressant medication will show some benefit from a switch to a second compound.

Both amitriptyline and venlafaxine appear somewhat more effective than SSRIs in patients with severe depression; these drugs are therefore worth trying at some point in the management of patients who are unresponsive to initial medication trials [9]. While MAOIs are also clearly beneficial in some patients with resistant depression, the food and drug restrictions required mean that these drugs are likely to be used as something of a last resort, unless a patient has responded well to them in the past [9].

Combination/augmentation of antidepressants

When switching antidepressant preparations, withdrawal of the first compound may not be straightforward. For example, patients may have gained some small symptomatic benefit from the treatment and this may be lost. Also, if the first medication is stopped quickly, withdrawal symptoms can result. On the other hand, a protracted changeover in medication may be distressing for a patient who is in despair about ever feeling better.

For this reason, in patients who are unresponsive or partly responsive to first-line medication, it may be more appropriate to add a second compound to the antidepressant. This is called ‘combination therapy’ where the second compound is itself considered to be an antidepressant. The term ‘augmentation’ refers to the addition of a drug that is not by itself regarded as an effective antidepressant but is nevertheless able to produce a therapeutic response when added to ineffective antidepressant medication.

Combination therapy is widely used in patients who have failed to respond to first-line antidepressant treatments, with drugs such as mirtazapine and bupropion commonly being added to ineffective

SSRI and SNRI treatment. However, the evidence that these are efficacious strategies is not well supported by large randomized trials [9]. There is more evidence for the benefit of augmentation therapy, particularly using low-dose atypical antipsychotic drugs. A meta-analysis involving about 3500 patients found that, relative to placebo, the addition of antipsychotics such as aripiprazole and quetiapine to SSRI treatment was significantly more likely to result in clinical remission (NNT = 9) [50]. However, atypical antipsychotics are not well tolerated because of sedation and weight gain in the case of quetiapine, and restlessness and agitation with aripiprazole.

Lithium also appears effective in augmentation treatment when added to ineffective antidepressant medication. Meta-analyses of randomized studies suggest an NNT of around 5, but overall the total number of patients studied is relatively small [51]. In addition, many lithium augmentation studies involved a primary TCA treatment and the efficacy of lithium in augmentation of newer antidepressants is less firmly established. Because of the potential for serotonin toxicity, the addition of lithium to SSRIs and SNRIs should be carried out cautiously, starting at low lithium doses.

Ketamine

Ketamine is a dissociative anaesthetic that blocks the *N*-methyl-D-aspartate (NMDA) subtype of the glutamate receptor. Recent controlled studies have shown that ketamine, given intravenously at a sub-anaesthetic dose, produces a striking and rapid remission of depressive symptoms in patients resistant to conventional pharmacotherapy. The improvement in depression begins about 1 hour after ketamine administration, as dissociative symptoms wane, and can last up to 7 days. A systematic review of controlled studies involving 180 patients with depression found higher rates of clinical response to ketamine than to intravenous saline or intravenous midazolam at 1, 3, and 7 days, with an NNT of 3–5 [52].

The rapid and striking antidepressant effect of ketamine in resistant depression is of great interest. However, it has not proved possible in most patients to maintain the antidepressant effect with the use of oral glutamatergic agents such as riluzole or memantine, which means that repeated administration of intravenous ketamine is often necessary to maintain the therapeutic response. A form of intranasal ketamine has been developed that appears to have acute antidepressant effects and that might be feasible to use for repeated treatment. However, there are concerns about possible ketamine toxicity after repeated use, including bladder changes, as well as adverse psychological effects such as dependence [9]. Nevertheless, the antidepressant effect of ketamine has focused attention on the role of glutamate in antidepressant action and might conceivably lead to novel classes of agents for the common clinical problem of resistant depression.

Continuation and maintenance treatment

Continuation treatment

After symptomatic remission, follow-up for several months is usually recommended. If the improvement in depression appears to have been brought about by an antidepressant drug, that drug should usually be continued for about 6 months and then gradually withdrawn over a period of several weeks, provided longer-term maintenance treatment is not indicated. If residual depressive symptoms are still present, it is safer not to withdraw medication [3]. At follow-up interviews, a careful watch should be kept for signs of

discontinuation reactions or relapse. It is helpful to discuss with the patient the possible early signs of relapse and to develop a plan of action, should any of these signs appear. Involving relatives in this plan can be helpful.

If a patient has responded to CBT or IPT, having some additional sessions during the continuation phase lessens the risk of relapse. It is known that patients with residual depressive symptoms are at greater risk of relapse, and the use of CBT, whatever the primary treatment, can have a useful prophylactic effect in this situation [29]. As noted earlier, there is a high risk of relapse in the 6 months after the use of ECT for resistant depression, and the best continuation therapy is not yet determined. Some benefit has been claimed for a continuation regime of lithium and nortriptyline [15]. The STAR*D study showed that, in general, depressed patients who required several treatment steps to achieve remission had high relapse rates over the next year [53]. In such patients, additional psychological treatment may have a useful role in improving outcome [9].

Maintenance treatment

Major depression is often recurrent, and long-term maintenance treatment may need to be considered. It is estimated that, among patients who have had three episodes of major depression, the likelihood of another episode is 90%. The usual recommendation is that maintenance drug treatment should be considered if a patient has had two previous episodes of depression within a 5-year period, particularly if there is a family history of recurrent major depression or personal and social factors predictive of recurrence [3]. In addition, the clinician will need to take into account factors such as the likely impact of a recurrence on the patient's life and the previous response to drug treatment, as well as the patient's view of long-term drug therapy [46].

For patients taking antidepressant medication, the longer-term treatment choice is most readily based on the response to acute phase therapy. If, however, a change needs to be made because of adverse effects (for example, sexual dysfunction with SSRIs), an alternative choice can be decided on the basis of the side effect profile. Lithium is not generally employed as monotherapy in longer-maintenance treatment of depression but can be added to antidepressant treatment if the response is inadequate or there is a high risk of suicide [3].

For patients who do not do well with these measures or where a patient at high risk of relapse wishes to discontinue antidepressant medication, there is growing evidence for a role of mindfulness CBT [29, 30]. Sometimes, it appears that the depressive disorder is related to continuing life stressors such as overwork, complicated social relationships, or substance misuse. In this case, various forms of psychotherapy may help adjustment to a lifestyle that is less likely to lead to further illness.

Another important aspect of longer-term follow-up is attention to the physical health of the patient, bearing in mind that people with depression are at substantially increased risk of medical comorbidities, particularly cardiovascular disease and metabolic syndrome [54]. Regular monitoring of relevant aspects of physical health is therefore an important part of overall management.

Classification and descriptive psychopathology of post-traumatic stress disorder and other stressor-related disorders

Dean G. Kilpatrick, Matthew J. Friedman, and Amanda K. Gilmore

Introduction

Exposure to stressful adverse events has always been an important part of human life, and the notion that exposure to such events can have a profound impact on our emotions and behaviour was described by philosophers, writers, and artists long before it became the focus of mental health professionals and researchers. Prior to the introduction of the post-traumatic stress disorder (PTSD) diagnosis into the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) [1], there was widespread recognition that experiencing stressful life events could have numerous negative effects on physical and mental health [2, 3], but there was little to no focus on distinguishing between potentially traumatic vs other stressor events. The PTSD Criterion A (the stressor criterion) serves an important gatekeeping function by distinguishing between stressor events that are and are not considered to be potentially traumatic and capable of producing PTSD. Thus, it is not surprising that one of the most controversial and challenging aspects of the PTSD diagnosis has been defining potentially traumatic events (PTEs) and distinguishing PTEs from other stressor events (OSEs) [4].

PTSD was initially categorized as an anxiety disorder, whereas other disorders that are clearly precipitated by exposure to adverse stressor events [for example, adjustment disorders (ADs) and reactive attachment disorder (RAD)] were placed elsewhere in the DSM. An unintended consequence of this distinction between PTEs and OSEs and the placement of PTSD and other stressor-related disorders in different chapters of prior additions of the DSM was that it obscured the extent to which exposure to stressor events can produce a broad range of mental disorders and health problems. Perhaps the most important change regarding PTSD in DSM-5 [5] was its removal from the 'Anxiety disorders' category and reclassification within a new diagnostic category that captures problems that emerge following exposure to PTEs and OSEs. Although PTSD

may be expressed as a fear-based anxiety disorder, as defined in both DSM-III [1] and DSM-IV [6], it may be expressed also as an anhedonic/dysphoric, externalizing, or dissociative disorder [7].

Given abundant evidence that post-traumatic psychopathology is characterized by a wider range of cognitions, emotions, and behaviour than seen in an anxiety disorder, DSM-5 created a new classification for PTSD and related disorders—'Trauma- and stressor-related disorders'. All diagnoses included in this new chapter have two things in common: (1) a discrete traumatic/adverse event or experience that preceded the onset or aggravation of symptoms; and (2) a wide range of cognitions, emotions, and behaviours embedded within DSM-5 diagnostic criteria for each disorder. This new category includes five specific disorders: PTSD, ASD, AD, RAD, and disinhibited social engagement disorder (DSED). This chapter reviews each of these disorders with respect to DSM-5 diagnostic criteria, separated into adult- and child-specific disorders, describes notable changes from DSM-IV, and discusses theoretical and clinical implications of these changes.

The DSM-5 revision process adopted a very conservative approach and required very strong evidence to modify, delete, or add any symptoms to any diagnostic disorder [8]. As detailed later in this chapter and elsewhere [8, 9], major changes for PTSD were revisions of the stressor criterion (Criterion A1), deletion of Criterion A2, reconceptualizing PTSD's symptom meta-structure as a four-factor model (rather than three factors, as in DSM-IV and DSM-III), revising specific diagnostic criteria, addition of a pre-school subtype, and addition of a dissociative subtype. As with PTSD, ASD diagnostic criteria were modified to recognize the variability of post-traumatic distress responses. Further, the DSM-IV stipulation that three dissociative symptoms were required to meet diagnostic criteria was eliminated from ASD. AD, previously a residual diagnostic category in a class by itself in DSM-IV, was moved into the 'Trauma- and stress-related disorders' category because onset is preceded by

an adverse event (PTE or OSE). Finally, the absence of adequate caregiving (for example, extreme insufficient care) is a prerequisite for two childhood disorders—RAD and DSED.

Recognition of the heterogeneity of post-traumatic distress in both PTSD and ASD, with consequent removal of these diagnoses from the 'Anxiety disorders' category raised a number of important theoretical issues. This is highlighted by the very different PTSD conceptualization offered by DSM-5's broad construct, in contrast to the WHO's forthcoming ICD-11 [10], which proposes a very narrow construct of PTSD. The broad DSM-5 approach seeks to 'provide clinicians with a menu of symptoms and symptom clusters that would adequately cover the most typical clinical presentations' [8, p. 550], but ICD-11's narrow approach restricts PTSD diagnostic criteria to symptoms that are unique to PTSD, and not found in other anxiety or mood disorders [10]. Therefore, symptoms, such as insomnia, irritability, cognitive impairment, dysphoria, alienation, and detachment, which occur in DSM-5's PTSD, as well as in other DSM-5 disorders, are eliminated in ICD-11's PTSD criteria. There are 20 PTSD symptoms in DSM-5, with a minimum of six symptoms needed to meet the diagnostic threshold, whereas ICD-11 only has six PTSD symptoms and requires a minimum of three symptoms to meet the diagnostic threshold. As stated elsewhere, to extend the ICD-11 approach to medical diagnoses, 'one would eliminate symptoms such as fever, pain, and edema from the diagnostic criteria of a specific disease because they are found in so many other diseases' [8, p. 550].

Categorical vs dimensional diagnostic approaches

Both the DSM and ICD systems take categorical approaches towards PTSD and other diagnoses (for more information, see Chapter 7). That is, a person either has a diagnosis based on meeting symptoms and functional impairment thresholds or they do not have a diagnosis because they do not meet these thresholds. This categorical approach has the advantage of simplicity by making it easier to study groups of individuals with and without diagnoses and to determine eligibility for services or compensation based on diagnosis. However, categorical diagnostic approaches have disadvantages and have been criticized on theoretical, empirical, and practical grounds.

The case can be made that the latent construct of PTSD is more dimensional than categorical. Two lines of evidence support this contention. Firstly, a series of studies examined the latent structure of PTSD, using a sophisticated set of statistical procedures called taxometric analysis which used national probability samples of adult women and adolescents in the United States [11], randomly selected combat veterans in Australia [12], and United States combat veterans [13]. Taxometrics is a branch of applied mathematics that determines whether the latent structure of a phenomenon is a taxon (that is, a latent category whose members are qualitatively different from non-members of that category) or non-taxonic (that is, the latent structure is continuous in nature and the differences are quantitative, not qualitative). Analysis of the latent structure of PTSD in these three studies obtained indicators of PTSD symptomatology from individuals that were subjected to taxometric analyses to determine whether the data fit a categorical or a continuous solution. All studies found that the latent structure of PTSD is continuous in nature, not a taxon or distinct category. Secondly, studies of individuals

with PTE exposure with several PTSD symptoms, but not enough to meet diagnostic criteria, still have elevated rates of suicidal behaviours and other problems in functioning [14, 15]. This suggests that it may be more useful to think about people having degrees of PTSD, as opposed to either having PTSD or not.

Although the DSM-5 planning process recognized some of the limitations of its current categorical approach to diagnosis and conducted preliminary work investigating the feasibility of adopting a more dimensional approach, a decision was made that this was premature for DSM-5. Therefore, PTSD remained a categorical diagnosis in DSM-5 and will remain so in ICD-11.

Post-traumatic stress disorder

DSM-5 PTSD description and revisions from DSM-IV

The PTSD diagnostic criteria have evolved incrementally with each DSM revision. However, the core features of PTSD have remained similar throughout these evolutionary changes. The underlying assumption of this diagnosis is that exposure to PTEs has the potential to produce a characteristic set of symptoms, resulting in substantial psychological distress and/or functional impairment. Many individuals exposed to PTEs are resilient and do not develop PTSD [16], confirming that PTE exposure is a necessary, but not sufficient, condition for PTSD development and highlighting the importance of understanding factors associated with PTSD. DSM-5 contains PTSD diagnostic criteria, as well as detailed text that describes and elaborates upon these criteria and symptoms.

In DSM-5, Criterion A defines eligible PTEs as an event or events that involve exposure to: (1) death (either actual death or threats of being killed); (2) serious injury; or (3) sexual violence. Exposure to PTEs can happen in one or more of the following four ways: (1) experiencing the event directly; (2) witnessing the PTE happening to someone else in real time, in person, and not via electronic media; (3) learning that the PTE happened to a family member or close friend (note: if the PTE involved the death of a family member or close friend, the cause of death must have been violent or accidental); and (4) experiencing extreme or repeated exposure to disturbing details or aspects of PTEs experienced by other people, usually in a work-related context (for example, collecting human remains following combat, crime, or disasters; law enforcement personnel viewing photos of, or hearing, depictions of child murders or child pornography cases; military drone operators viewing death, destruction precipitated by drone attacks, and psychotherapists exposed to details of their patients' traumatic experiences). In the latter type of exposure, there is exclusion of cases in which exposure occurs through electronic media, television, movies, or pictures, unless the exposure is work-related.

The DSM-5 text gives numerous examples of the types of PTEs that are included in Criterion A. These include serious accidents and natural and man-made disasters, including terrorist attacks; combat or war zone exposure; physical or sexual assault; exposure to hazardous chemicals; torture; witnessing dead bodies or parts of dead bodies; witnessing physical or sexual assaults; threats of injury or death to family members or close friends; deaths of family members or close friends due to violence, accidents, or disasters; and the types of extreme or repeated exposure to disturbing aspects of PTEs experienced by others described previously. Medical procedures can

also qualify as PTEs if they ‘involve sudden, catastrophic events (for example, waking during surgery, anaphylactic shock)’ [5, p. 274].

Four points are important to note about PTEs described in DSM-5. Firstly, the text indicates that the list of PTEs described in the text is not inclusive, so other events can qualify as PTEs, even if they are not specifically listed. Secondly, the Criterion A text and accompanying explanation clearly acknowledge the possibility that many individuals have experienced more than one PTE. Thirdly, the DSM-IV Criterion A (for example, A2) requirement that an event must produce fear, helplessness, or horror to qualify as a PTE was removed from DSM-5, which would likely result in an increase in the number of events qualifying as PTEs in DSM-5 vs in DSM-IV. However, DSM-5 also excluded some events that were included as PTEs in DSM-IV (for example, non-violent deaths of family members or close friends; observing violent events such as mass shootings or terrorist attacks exclusively via electronic media, unless the viewing was work-related), which would reduce the number of events qualifying as PTEs in DSM-5, as compared to DSM-IV. One study with a national sample of United States adults compared the prevalence of lifetime exposure to PTEs using DSM-5 vs DSM-IV Criterion A definition and found that lifetime prevalence was high using both definitions, but that lifetime prevalence of exposure was slightly lower using the DSM-5 Criterion A definition [16]. This suggests that the DSM-5 revisions of Criterion A had largely offsetting effects on the proportion of individuals with a qualifying PTE. However, this study did find that the biggest reason individuals had PTSD with DSM-IV, but not DSM-5, criteria, was exclusion in DSM-5 of deaths that were not violent or accidental. Finally, it is extremely important to understand that defining an event as a qualifying PTE does not mean that everyone exposed to that event will develop PTSD or that all qualifying PTEs have an equal probability of producing PTSD if they are experienced. Some PTEs have a much higher probability of increasing the risk of PTSD than others, as is described in the DSM-5 text.

Criterion B symptoms are: (1) recurrent memories of the PTE that are involuntary, intrusive, and distressing; (2) distressing dreams of the PTE or something that is closely related to the PTE; (3) flashbacks or other dissociative reactions in which the person feels as if the PTE is happening again (note: these dissociative reactions are on a continuum, ranging from feelings that are reliving the PTE all over again to experiencing fragmentary sensory or perceptual sensations that occurred during the PTE); (4) intense or prolonged psychological distress that occurs when someone encounters an internal or external cue that reminds them of the PTE or something that is closely associated with it; and (5) physiological reactions of an extreme nature that occur when a person encounters internal or external cues that remind them of the PTE or something closely associated to it. Criterion B is met if an individual has one or more of these symptoms. Criterion B in DSM-IV was revised in very minor ways, so this criterion is virtually the same as in DSM-5, with the exception of minor changes in language.

Criterion C has two symptoms that measure persistent avoidance of stimuli that are associated with a PTE: (1) avoiding, or attempts to avoid, distressing memories, thoughts, or feelings about a PTE or something that is closely associated with a PTE; and (2) avoiding or attempting to avoid external reminders of the PTE that arouse distressing memories, thoughts, or feelings about the PTE or things that are closely associated with it. Examples of such external

reminders include people, places, conversations, activities, objects, or situations. Criterion C is met if an individual has at least one of these symptoms.

One of the biggest revisions of DSM-IV criteria in DSM-5 was constructing a new Criterion C that contains only two active avoidance symptoms by pulling these symptoms out of DSM-IV Criterion C that included both avoidance and numbing symptoms. DSM-IV Criterion C had two avoidance symptoms and five numbing symptoms, and three Criterion C symptoms were required to meet the threshold. This meant that someone could meet the DSM-IV Criterion C threshold of three symptoms without having any active avoidance symptoms. Numerous factor-analytic studies found that DSM-IV Criterion C symptoms were split into an avoidance symptom factor and a numbing symptom factor. This provided ample justification for creating a separate criterion for active avoidance symptoms [7]. Some critics of DSM-5 have expressed concern that requiring the presence of at least one active avoidance symptom to obtain a PTSD diagnosis in DSM-5 will result in some people not having PTSD using DSM-5 criteria who would have PTSD using DSM-IV criteria [17]. Others argue that avoidance has always been an important part of the PTSD construct and clinical picture [16] and that the presence of active avoidance distinguishes PTSD from other disorders, including major depression [12]. The Kilpatrick *et al.* study [16] did find that failure to have at least one active avoidance symptom was the second biggest reason for persons meeting DSM-IV but failing to meet DSM-5 criteria for PTSD, but this occurred in a very small number of cases. Taking all of this into consideration, the DSM-5 revision requiring active avoidance is well justified because avoidance has always been a key component of the PTSD construct.

Criterion D has seven symptoms measuring negative alterations in cognition and mood. These symptoms must be associated with the PTE and must have either begun after, or been aggravated by exposure to, the PTE. Criterion D symptoms are: (D1) inability to recall important aspects of the PTE, typically due to dissociative amnesia and not due to other factors such as head injury or heavy alcohol or drug use; (D2) negative beliefs and/or expectations about others or the world that are persistent and exaggerated; (D3) distorted cognitions about the cause or consequences of the PTE that result in the person unreasonably blaming themselves or others for what happened; (D4) negative emotional states such as feelings of fear, horror, anger, guilt, or shame; (D5) diminished interest or participation in important life activities; (D6) feeling detached or estranged from other people; and (D7) inability to experience positive emotions such as happiness, satisfaction, or loving feelings. At least two of these symptoms are required to meet Criterion D.

ICD-11 proposed criteria for PTSD have no negative cognition or mood symptoms [10, 18]. However, there is substantial evidence that exposure to PTEs can produce these alterations and that exposed individuals who develop PTSD are significantly more likely to have negative alterations in cognition and mood. Two papers using data from a large national sample of United States adults addressed this issue. The first paper compared the prevalence of D2 and D3 symptoms among individuals with no PTE exposure, PTE exposure that did not result in PTSD, and PTE exposure that did result in PTSD [19]. Participants identified the type of cognitive distortion experienced if D2 or D3 was endorsed. No significant differences were found between groups with no PTE exposure or PTE exposure

that did not result in PTSD. However, those with PTSD were significantly more likely to believe that they were a bad person; that they could not trust anyone; that nothing good would ever occur; that they had no chance for a career, relationship, marriage, or children; that their soul or spirit was permanently damaged; and that the world was completely dangerous. The group with PTSD was also significantly more likely to exhibit beliefs that the PTE happened because of something they did wrong; that they should have been able to prevent it; that the event happened because of something about them; and that they blamed themselves for not being able to recover and get on with their lives.

The second paper examined associations between specific negative emotions in symptom D4 and a DSM-5 PTSD diagnosis among adults who had experienced a PTE involving a physical or sexual assault [20]. Compared to individuals with assault histories who did not develop PTSD, individuals with assault-related PTSD were significantly more likely to have several negative emotions, including anger, guilt, shame, and horror, as well as fear. This study also found that the emotion of anger among those with PTSD was more prevalent than the emotion of fear.

Criterion E consists of major alterations in arousal and reactivity associated with the PTE. There are six symptoms, two or more of which are required and most of which are identical to those in DSM-IV Criterion D. However, two symptoms are new or substantially modified. Symptom E1 is irritable behaviour and angry outbursts that are expressed as verbal or physical aggression towards other people or objects. This symptom requires some behavioural manifestation of anger and aggression, not just an angry mood, and there is considerable evidence that individuals with PTSD have a substantially higher prevalence of the symptom than those without PTSD [20, 21]. Symptom E2 is reckless or self-destructive behaviour such as dangerous driving, excessive alcohol or drug abuse, or risky sexual behaviour. The behaviours described in E1 and E2 have long been a part of the clinical picture of many patients with PTSD and have also been an important focus of clinical treatment efforts. The remaining Criterion E symptoms are hypervigilance, exaggerated startle response, problems with concentration, and sleep difficulties.

As was the case with DSM-IV, PTSD in DSM-5 cannot be diagnosed unless the symptoms persist for at least 1 month (Criterion F). Likewise, PTSD cannot be diagnosed unless symptoms produce significant distress and/or functional impairment (Criterion G).

PTSD in DSM-5 has two other additions of note. Firstly, there is a new explicit set of PTSD criteria for children aged 6 years or younger. Child trauma professionals had observed that young children had extremely low rates of PTSD, using DSM-IV criteria, primarily due to adult-centric phrasing of symptoms and the requirement to have an inappropriately high number of symptoms within the DSM-IV Criteria C and D to meet the diagnostic threshold. Consequently, the DSM-5 child PTSD diagnostic criteria use a more child-centric language focus on observable behaviours, while eliminating subjective symptoms, and reduce the number of symptoms per criterion to meet the diagnosis. Secondly, there is a new dissociative subtype of PTSD, defined on the basis of repeated experiencing of either depersonalization or derealization. This addition was based on evidence of neurobiological differences among individuals with PTSD with and without these dissociative symptoms [22], as well as evidence that treatment outcome is worse among PTSD-positive patients with dissociative symptoms [7, 23].

PTSD prevalence

Obtaining accurate estimates of PTSD prevalence requires the use of a probability sample of the population in question, comprehensive assessment of PTE exposure, and thorough assessment of PTSD symptoms and symptom-related distress/functional impairment [24, 25]. Several good studies provide information about PTSD prevalence using DSM-IV criteria. The National Comorbidity Survey-Replication (NCS-R) [26] found that the lifetime prevalence of PTSD among a national probability sample of United States adults was 6.8% overall, 7.9% among women, and 3.6% among men. The National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) [27] reported that the lifetime prevalence PTSD was 7.3%. A study of PTSD among a national household probability sample of United States adolescents found that the past 6-month prevalence of PTSD was 6.3% among female adolescents and 3.7% among male adolescents [28].

Limited data are available about the impact of the DSM-5 revisions on PTSD prevalence. However, one study that compared PTSD prevalence using DSM-IV and DSM-5 criteria in a large national sample of United States adults found slightly lower prevalence using DSM-5 vs DSM-IV criteria for lifetime (8.3% vs 9.8%, respectively), the past 12 months (4.7% vs 6.3%, respectively), and the past 6 months (3.8% vs 4.7%, respectively) PTSD [16]. Another major study with a large national probability sample of United States adults reported that the lifetime and past-year prevalence of PTSD using DSM-5 criteria were, respectively, 6.1% and 4.7% [29], but this is clearly an underestimate of DSM-5 PTSD prevalence due to the use of an incorrect diagnostic algorithm requiring three symptoms each for Criteria D and E, instead of the two symptoms in each that are actually required. Another study of United States Army soldiers by Hoge and colleagues [30] confirmed that PTSD prevalence using DSM-5 vs DSM-IV criteria was slightly lower (11.5% and 12.3, respectively). In summary, the data are clear that DSM-5 PTSD is a prevalent disorder, with a prevalence that appears to be slightly lower overall than when using DSM-IV criteria.

PTSD in ICD-11

The ICD-11 revision is scheduled for completion in 2019, so no proposed changes have been finalized. However, it is apparent from a draft of the proposed criteria and descriptions of the proposed approach that the ICD-11 version of PTSD is likely to be a radical departure from the DSM-5 version of PTSD, as well as from the DSM-IV and ICD-10 version of PTSD [10, 18]. The most radical proposed change separates PTSD into two disorders: PTSD and complex PTSD. The stated rationale is to narrow the scope of the PTSD construct, reduce the number of symptoms from 20 in DSM-5 to six in the ICD-11 proposal, increase diagnostic reliability, and eliminate a large number of symptoms that overlap with other disorders such as depression [10, 18].

The ICD-11 proposed definition of Criterion A describes exposure to an extremely threatening or horrific event or a series of events which is substantially less specific than the DSM-5 definition. The ICD-11 PTSD proposal focuses on three core elements: (1) re-experiencing of the trauma; (2) avoidance of reminders of the event; and (3) a heightened perception of threat and arousal. This ICD-11 proposal for PTSD is operationalized by requiring at least one (of two) re-experiencing symptom (that is, flashbacks or nightmares),

one (of two) avoidance symptom (that is, avoidance of internal or external reminders), and one (of two) hyperarousal symptom (that is, hypervigilance or exaggerated startle response) [10, 18, 31]. The ICD-11 proposal omits the entire DSM-5 Criterion D and omits four of the DSM-5 Criterion E hyperarousal symptoms (that is, E1 irritable behaviour and angry outbursts; E2 reckless and self-destructive behaviour; E5 concentration difficulties; and E5 sleep difficulties). This PTSD proposal, like DSM-5, but unlike ICD-10, requires the symptoms to produce distress and/or functional impairment.

Complex PTSD is a controversial diagnosis which has been criticized on conceptual and empirical grounds [27, 31]. Under the ICD-11 proposal, the first requirement for complex PTSD is to have the diagnosis of PTSD. Complex PTSD, as defined by ICD-11 proposal [10, 18], requires at least one symptom in each of three complex PTSD symptom clusters: (1) affect dysregulation (that is, emotional reactivity, dissociation, anger, aggression, and emotional numbing); (2) negative self-concept (that is, negative beliefs about the core value of the self, along with feelings of guilt and shame); and (3) interpersonal disturbances (that is, avoidance of relationships, estrangement, and lack of emotional intimacy in relationships). Complex PTSD was not included in DSM-5 due to a lack of supporting evidence [7].

An obvious question is the effect these extensive revisions might have on PTSD prevalence and whether there is an impact on the percentage of those exposed to a PTE who meet diagnostic criteria for PTSD, because having a diagnosis is often required to qualify for treatment services or other benefits. The few head-to-head comparisons of ICD-11 vs DSM-5 prevalence and caseness indicate that the ICD-11 proposal may produce a dramatic reduction in PTSD prevalence and caseness. Wisco and colleagues [32] compared past-month PTSD prevalence using DSM-5 and ICD-11 criteria in a national sample of United States adults and a sample of United States military veterans. The prevalence of past-month PTSD prevalence using ICD-11 criteria was lower than when using DSM-5 criteria in both national adult and veteran samples. O'Donnell and colleagues [33] also reported the same pattern of findings in a probability sample of injury patients from four hospitals. A study from Denmark [34] also found that PTSD prevalence was lower using ICD-11, as opposed to DSM-5, criteria. An international study conducted in 13 countries [15] did not actually assess PTSD using DSM-5 and ICD-11 criteria but approximated these diagnoses using data from DSM-IV assessments. This study reported a slightly higher PTSD prevalence estimate when using the ICD-11 approximation (3.2% vs 3.0% for DSM-5), but the DSM-5 estimate was clearly lower than it should have been due to the three new symptoms not having been measured. Although more research on this topic is needed, findings suggest that the proposed ICD-11 PTSD criteria are likely to have the unintended consequence of reducing the prevalence of PTSD and the number of people with a PTSD diagnosis that could qualify them for treatment and other services.

Acute stress disorder

Acute stress disorder (ASD) was first introduced in DSM-IV and significantly updated in DSM-5. The DSM-5 definition includes exposure to a Criterion A PTE, as described previously in the PTSD criteria. The key difference between PTSD and ASD is time and

markers of distress. ASD is defined as distress occurring after 3 days, but within 1 month of a Criterion A PTE. Further, ASD requires nine or more symptoms in the five major categories of intrusion, negative mood, dissociative, avoidance, and arousal symptoms (DSM-5). Consistent with other mental health disorders, the symptoms must cause clinically significant distress or functional impairment.

DSM-III [1] did not permit a trauma-related diagnosis prior to 1-month post-traumatic event exposure, perhaps due to the normative symptoms associated with experiencing traumatic events. The introduction of ASD as a mental health disorder within DSM-IV [6] allowed for individuals who have marked distress due to a PTE within 1 month of the PTE to receive clinical services that may potentially decrease distress and the development of PTSD. However, the DSM-IV definition of ASD gave excessive weight to dissociative symptoms. Although other symptoms, including anxiety and arousal, were part of the diagnosis, individuals needed three or more dissociative symptoms in order to meet the criteria. In fact, several other acute symptoms are associated with the development of PTSD, rather than only peritraumatic dissociation [35]. When developing DSM-5, several critiques regarding DSM-IV definitions of ASD were considered, including questioning the predictive value of ASD in predicting the development of PTSD, differentiating ASD from other mental health disorders, the utility of ASD to enhance early intervention, and the general utility of the ASD diagnosis. These critiques have been described elsewhere in more detail [35–37], but recommendations for DSM-5 primarily focused on the broadening of symptoms to remove DSM-IV's unjustified emphasis on dissociative symptoms.

The DSM-5 definition of ASD differs from that of the DSM-IV definition in several ways. Firstly, the definition of a PTE was updated to be consistent with the new definition of a PTE, as described in PTSD. The most marked change in symptom presentation was the elimination of DSM-IV's requirement of three or more dissociative symptoms, while giving greater weight to a broader set of symptoms in DSM-5. Although DSM-5 does recognize that some people may experience dissociative symptoms, others may now meet ASD criteria without a single dissociative symptom. In other words, there has been a shift in our understanding of ASD from a predominantly dissociative disorder to one that includes a greater variability in symptom presentation.

Preliminary evidence suggests that both DSM-IV and DSM-5 criteria have equal predictive value related to the development of PTSD, but DSM-5 criteria have greater specificity, compared to DSM-IV criteria [35]. According to DSM-5, there are higher rates of ASD among individuals who have experienced interpersonal PTEs (20–50%), compared to non-interpersonal PTE (<20%) [5, p. 284]. Therefore, ASD is quite common and should be regularly assessed for among populations who have experienced recent PTEs. Although ASD is not always predictive of PTSD, individuals with ASD (and those without) should also be assessed for PTSD if they continue (or develop) significant symptoms of distress or impairment 1 month following a PTE.

Adjustment disorders

Until DSM-5, ADs constituted a cluster of residual diagnoses that occupied their own space in DSM-III or DSM-IV. Divided into

anxiety and depressed and disturbed conduct subtypes (or some combination of these), ADs were perhaps the most poorly characterized set of diagnoses within DSM. There were no specific symptoms needed to make the diagnoses. Indeed, all that was necessary was prior exposure to an adverse event (PTE or OSE) and a clinician's judgement that 'significant distress or functional impairment' had its onset because the exposure took place. In many cases, ADs have been considered subthreshold anxiety or mood disorders, although it has never been clear how disturbed conduct relates to better explained DSM diagnoses.

The AD diagnosis seems to be relatively common. According to DSM-5, 'prevalence may vary widely as a function of the population studied and the assessment methods used' [5, p. 287]. In outpatient cohorts, the prevalence ranges from 5% to 20%. In hospital psychiatric consultation settings, the prevalence may reach 50% [5].

When considering ADs, the DSM-5 workgroup was faced with various definitions of AD—was it a bona fide diagnosis in its own right, a subthreshold anxiety/mood disorder (like dysthymia and cyclothymia), or something else? Given the lack of rigorous research and poor validation for the various AD subtypes, it was unclear how and whether they related to one another [38]. Some investigators formulated the diagnosis as a subthreshold PTSD syndrome [39], but again, evidence was lacking. Finally, given the DSM-5 ground rules that no diagnostic criterion could be added, deleted, or modified without strong empirical evidence and given the almost complete lack of such evidence (because of the lack of published research) when it came to ADs, it is not surprising that the DSM-5 version of ADs resembles the DSM-IV version very closely.

There were two important decisions regarding ADs that should promote research, which should usefully guide future revisions of DSM-5. Firstly, ADs were removed from their own category and moved into the 'Trauma and stressor-related disorders' chapter of DSM-5. Secondly, ADs were reconceptualized as a stress-related disorder that might share a common pathophysiology with PTSD and ASD, since failure to cope with an overwhelming stressor appears to characterize all of these disorders.

Child-specific symptoms and disorders

In addition to the mental health disorders described, there are specific disorders for children within the trauma- and stressor-related disorders section of DSM-5. This includes PTSD, RAD, and DSED.

PTSD can be diagnosed among children; however, as discussed, DSM-5 outlines several modifications for children under the age of 6 (the preschool subtype). These child-specific symptoms were suggested after compiling 15 years of research suggesting that there may be specific developmental manifestations of symptoms [13]. Specifically, intrusive memories may manifest as re-enactment of the traumatic event; children may not be able to connect the content of nightmares to the traumatic event, and irritable behaviour may manifest as extreme temper tantrums. It is important to consider these child-specific manifestations of symptomology related to traumatic event exposure, as they differ from adults.

RAD and DSED are both diagnoses for young children older than 9 months. Both RAD and DSED are thought to be caused by social neglect, defined by DSM-5 as 'the absence of adequate caregiving during childhood' [5, p. 265]; therefore, this is a requirement for

both diagnoses. DSM-IV included only one disorder—RAD—with two subtypes (inhibited and disinhibited), but now the two subtypes are considered separate disorders in DSM-5. RAD includes predominantly internalizing symptoms, while DSED includes predominantly externalizing symptoms. Both disorders are considered to be rare, and the prevalence, even among severely neglected children, ranges from 10% for RAD to 20% for DSED [5].

Diagnostic criteria for RAD include symptoms of emotional withdrawal towards an adult caregiver and marked social and emotional disturbance, both presumably caused by social neglect. Children who meet criteria for RAD must engage in both minimal comfort-seeking and minimal responding to comfort from the caregiver when distressed. Further, children must exhibit two of the following: social withdrawal prior to the age of 2, persistent lack of positive mood, and 'episodes of unexplained irritability, sadness, or fearfulness' with their caregivers [5, p. 265]. Children are eligible for this diagnosis between the ages of 9 months and 5 years.

In contrast, DSED occurs when a child regularly interacts with unfamiliar adults in a disinhibited manner. Children who meet criteria for DSED must engage in two behaviours related to interacting with unfamiliar adults, including: (1) approaching unfamiliar adults; (2) in a disinhibited manner, including being overfamiliar with the unfamiliar adults; (3) without checking in with the caregiver; and (4) leaving with the unfamiliar adults. Similar to RAD, there must be a pattern of social neglect from the caregiver. Although both child-specific disorders are rare, they have the potential to have a significant impact on the children's lives if left untreated.

Other specified trauma- and stressor-related disorders

In addition to the disorders described, there are several disorders that are considered to be trauma- and stressor-related but did not fit the previously referenced diagnoses. These disorders cause significant distress and functional impairment but are either not specified within the already described disorders, are culturally specific disorders, or require further study in order to determine their existence as separate disorders. These include adjustment-like disorders with delayed onset or prolonged duration, *ataque de nervios* and other culturally specific disorders, and unspecified trauma- and stressor-related disorders. Persistent complex bereavement disorder (PCBD) embodies symptoms otherwise categorized as complicated grief or prolonged grief disorder. Because it has not been established which symptoms best characterize pathological grief reactions, PCBD now only appears only in the DSM-5 appendix as a presumptive disorder that requires future research (for more information, see Chapter 84).

Although there is currently not a specific diagnosis for those who have PTSD symptoms but fail to meet all of the diagnostic criteria of PTSD, this 'diagnosis' is currently best captured within the 'Other trauma-related disorder' category. This is sometimes referred to as subthreshold, subsyndromal, subclinical, or partial PTSD, but the term partial PTSD has achieved the most widespread usage [15]. Partial PTSD has been operationally defined several ways, but they all require individuals to have several PTSD symptoms. Unfortunately, there is no current consensus on a case definition for partial PTSD in DSM-5, since different investigators have used different criteria in their research. Achievement of such a case definition should be a

high priority for research in this field. As noted in Schnurr's recent review [15], partial PTSD is prevalent, and individuals with partial PTSD often have lower rates of functional impairment/distress than those with full PTSD, but higher rates than their counterparts who were exposed to PTEs but who had no PTSD symptoms.

Such findings are strikingly similar to what would be predicted if PTSD is continuous, as opposed to categorical. Also, many individuals with partial PTSD seek clinical services or attempt to enrol in PTSD research studies. Lacking one PTSD symptom can sometimes make the difference between having PTSD and having partial PTSD, and the former would be eligible for treatment services or research studies recruiting individuals with PTSD, whereas the latter would not.

Co-occurring disorders

Trauma- and stressor-related disorders often have several key co-occurring disorders. Many disorders may co-occur partially due to overlapping symptomology (that is, which include both depressive and anxiety disorders). Other disorders co-occur possibly as a means to cope with the symptoms associated with experiencing stress and trauma (that is, substance use disorders). Other disorders may also be related to PTE exposure (that is, borderline personality disorder and dissociative identity disorder). When the psychological trauma is accompanied by head injury (for example, combat and motor vehicle accidents), traumatic brain injury is often a co-occurring condition. Although a thorough discussion of co-occurring disorders is beyond the scope of the current chapter, it is important to mention that co-occurring disorders can significantly complicate treatment and therefore should be thoroughly assessed. Historically, it was thought that disorders like PTSD should not be treated if there are other disorders that may complicate treatment (that is, substance use disorders or borderline personality disorder). However, recent treatment outcome research indicates that concurrent treatment of trauma-related disorders and other disorders should be strongly considered due to its efficaciousness [27, 40, 41].

What is needed to move the science forward in understanding trauma- and stressor-related disorders?

For a better understanding of how to best classify, assess, and treat trauma- and stressor-related disorders, more research is needed in several areas. More work is needed to integrate the dimensional approach into the current categorical diagnostic criteria. With respect to PTSD, there are three major ways to accomplish this. Firstly, it is important to conduct taxometric analyses with DSM-5 PTSD symptoms to confirm the continuous nature of PTSD latent structure using the new criteria. Secondly, there is great merit to utilize continuous, as well as categorical, measures of PTSD symptoms/symptom frequency/symptom intensity in research and clinical practice. Thirdly, both research and clinical practice should make more use of the partial PTSD construct, because it is clear that individuals not meeting full diagnostic criteria still have significant problems that could benefit from increased research and clinical attention. Moreover, increased use of the partial PTSD construct might also be useful in

addressing discrepancies in PTSD caseness using DSM-5 vs DSM-IV criteria. To the best of our knowledge, no research has been done to date, in which comparisons of the overlap between PTSD cases using DSM-IV and DSM-5 criteria also included individuals with partial PTSD. Our hypothesis is that the inclusion of partial PTSD cases would substantially increase the diagnostic concordance and reduce discrepancies.

PTSD assessment

There is a substantial literature on specific structured interview and self-report measures that have been used to assess PTSD [42, 43], so we will make three general points, rather than provide a detailed discussion of assessment measures. Firstly, an accurate assessment cannot be conducted without a thorough assessment of PTE exposure across the lifespan. In clinical, as well as research, settings, this requires asking a series of behaviourally specific questions about all types of relevant PTE exposure.

Secondly, you cannot accurately assess for PTSD or partial PTSD unless your assessment asks about all 20 DSM PTSD symptoms. It is relatively common for some PTSD assessment instruments to use screening questions or skip-outs in which individuals are not asked about all PTSD symptoms once it becomes clear that they cannot meet the full diagnostic criteria. However, these skip-outs make it impossible to determine whether someone has partial PTSD, and we believe that a strong case can be made that skip-outs should never be used in PTSD assessment.

Thirdly, the typical approach to PTSD assessment in multiple PTE exposure cases is to assess PTSD symptoms in reference to one index PTE (for example, the most recent PTE, the most serious or worse PTE, a PTE of particular interest such as rape or military combat, or a randomly selected PTE). However, exposure to multiple PTEs can result in composite PTSD, defined as meeting PTSD diagnostic criteria in which the PTSD symptoms incorporate content related to more than one PTE [16]. This requires a different assessment approach that first determines whether individuals have each PTSD symptom and then determines which PTE or PTEs caused or aggravated the symptom. Not surprisingly, composite PTSD was more prevalent than PTSD to a single event, and its prevalence increased as a function of the number of PTEs that were experienced [16]. We believe that a challenge to PTSD researchers and clinicians will be to develop assessment strategies that better address the issue of how multiple PTE exposure relates to PTSD symptomatology. Further, more research concerning the other trauma- and stressor-related disorders, specifically with respect to PCBD and ADs. Research is needed regarding the diagnostic criteria of ADs and PCBD and how these disorders may or may not overlap with other disorders within this diagnostic cluster.

It remains to be seen whether there are similar or overlapping psychobiological consequences of traumatic event exposure in PTSD and ASD, adverse experiences in ADs, and insufficient care in RAD and DSED. Research on biomarkers and underlying pathophysiological abnormalities promises to improve our understanding of how effective psychobiological mechanisms for stress and adaptation are dysregulated in the five trauma- and stressor-related disorders.

Are there different PTSD phenotypes?

By the time DSM-6 is published, it is possible that there will be no longer a PTSD diagnosis, as we have known it since DSM-III. When

first introduced in 1980, PTSD was revolutionary because it validated the notion that an overwhelming stressor can produce stable alterations in cognitions, emotions, and behaviours that result in recognizable symptom clusters. The explosion of research, since that time, has made it abundantly clear that there are a variety of post-traumatic clinical presentations that meet diagnostic criteria for PTSD. Currently, this is best exemplified in DSM-5 ASD, as discussed previously. Indeed, DSM-5 PTSD has been criticized because it has so many different symptoms, in contrast to most other psychiatric disorders such as major depressive disorder and most anxiety disorders [17, 44].

To us, the best explanation for such complexity is that we have tried to sweep all significant post-traumatic symptomatology under a single PTSD rug. Indeed, based on clinical phenomenology alone, there appear to be four different PTSD phenotypes: (1) an adrenergic fear-based anxiety disorder; (2) an anhedonic/dysphoric disorder; (3) an externalizing disorder; and (4) a dissociative disorder [45]. It is likely that the ongoing Research Domain Criteria (RDoC) approach will identify different genetic or other biomarkers that may be more strongly associated with one phenotype than another (see Chapter 8 for more on RDoC). For example, the dissociative phenotype (currently categorized as PTSD's dissociative subtype) is characterized by unique brain imagery patterns and treatment responsivity [22]. Evidence for an adrenergic subtype is indicated by selective responsivity to the adrenergic antagonist prazosin among soldiers with PTSD who recorded the highest blood pressure [46]. A specific biological marker dopamine-beta-hydroxylase (DBH), which catalyses the conversion of dopamine to noradrenaline, is uniquely associated with Criterion B intrusion symptoms; indeed, preliminary data have shown that plasma DBH levels appear to be causally related to the development of PTSD intrusion symptoms [44]. We expect that progress along these fronts may eventually result in explication of a number of more specific post-traumatic syndromes, rather than the very complex array of clinical presentations currently embodied in the solitary DSM-5 PTSD diagnosis. A list of potential phenotypes might include: post-traumatic hyperarousal/hyperadrenergic, post-traumatic anhedonic/serotonin-deficient, post-traumatic dissociative, etc. syndromes. If and when we can confidently identify different PTSD phenotypes, it is likely to have two major implications for diagnosis and treatment. Firstly, it may result in a spectrum of post-traumatic syndromes differentiated by a more concise set of diagnostic criteria that will include phenotype-specific biomarkers. Secondly, it may facilitate treatment matching, so that individuals with a certain phenotype will receive treatments best suited for their specific post-traumatic phenotype.

In short, DSM-5 has opened the way for considering PTSD as a spectrum disorder, in which research on phenotypes is the inevitable next step. We look forward to the future identification of distinct post-traumatic diagnoses with different underlying pathophysiologies that will respond best to different optimal treatments.

Conclusions

The diagnostic criteria and classification for trauma- and stressor-related disorders have undergone significant changes with DSM-5 and are proposed to include even more drastic changes within ICD-11. The iterative changes in diagnostic criteria and classification

highlights not only the extensive research that has gone into understanding these phenomena, but also the challenges that arise when examining disorders that stem from PTEs and OSEs. Given the current knowledge, there are several needed next steps to understand how to best classify trauma- and stressor-related disorders which includes, but is not limited to: (1) further clarifying partial PTSD and deciding whether classification under a dimensional vs a categorical approach would be beneficial; (2) continuing to refine assessments to ensure that PTEs and OSEs are thoroughly assessed and symptoms after these experiences are best captured; and (3) continuing to examine potential phenotypes of trauma- and stressor-related disorders.

Basic mechanisms of, and treatment targets for, stress-related disorders

Bruce S. McEwen

Introduction

'Stress' is a commonly used word that generally refers to experiences that cause feelings of anxiety and frustration, because they push us beyond our ability to successfully cope. 'Stress' has become a major focus of modern life, but what do we mean by 'stress'? Besides time pressures and daily hassles at work and home, there are stressors related to economic insecurity, loneliness, poor health, and interpersonal conflict. More rarely, there are situations that are life-threatening—accidents, natural disasters, violence—and these evoke the classical 'fight-or-flight' response and can cause traumatic memories and post-traumatic stress disorder (PTSD).

The most common stressors are the ones that operate chronically, often at a low level, and that cause us to behave in certain ways. For example, being 'stressed out' may cause us to be anxious and/or

depressed, to lose sleep at night, to eat comfort foods and take in more calories than our bodies need, and to smoke or drink alcohol excessively. Being 'stressed out' may also cause us to neglect seeing friends, or to take time off from our work, or to reduce our engagement in regular physical activity as we, for example, sit at a computer and try to get out from under the burden of too much to do. Often we are tempted to take medications—anxiolytics, sleep-promoting agents—to help us cope, and, with time, our bodies may increase in weight and develop other symptoms of an unhealthy lifestyle. Thus, health-promoting and health-damaging behaviours must be included when we discuss 'stress', and this leads us to the concepts of 'allostasis' and 'allostatic load and overload' that will be discussed in this chapter.

The brain is the organ that determines what is stressful and the behavioural and physiological responses, whether health-promoting or health-damaging (Fig. 79.1). And the brain is a biological organ

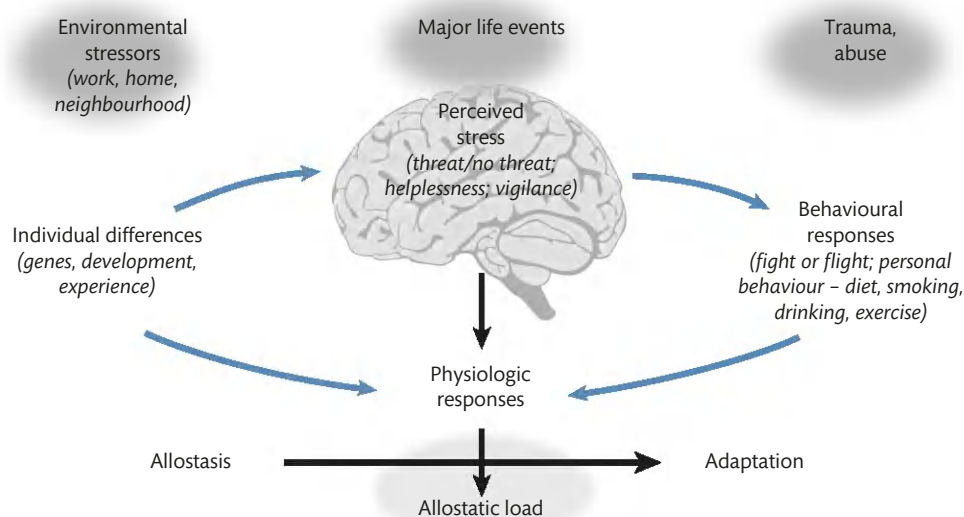

Fig. 79.1 Central role of the brain in allostasis and the behavioural and physiological response to stressors [122].

that changes in its architecture, molecular profile, and neurochemistry under acute and chronic stress and directs many systems of the body—metabolic, cardiovascular, immune—that are involved in the short- and long-term consequences of being ‘stressed out’ and the consequent health-damaging behaviours. This chapter summarizes some of the current information, placing emphasis on how the stress hormones and other hormones can play both protective and damaging roles in the brain and body, depending on how tightly their release is regulated and how harmoniously the network of stress mediators functions. The chapter discusses implications for mental, as well as physical, health and describes some of the approaches for dealing with stress in our complex world.

Types of stress

This chapter will use the following classifications of the types of stress: good stress, tolerable stress, and toxic stress (**Box 79.1**). See (http://developingchild.harvard.edu/library/reports_and_working_papers/policy_framework/) for paper related to toxic stress.

Good stress is a term used in popular language to refer to the experience of rising to a challenge, taking a risk, and feeling rewarded by an often positive outcome. A related term is ‘eustress’. Good self-esteem and good impulse control and decision-making capability, all functions of a healthy architecture of the brain, are important here! Even adverse outcomes can be ‘growth experiences’ for individuals with such positive, adaptive characteristics that promote resilience in the face of adversity.

‘Tolerable stress’ refers to those situations where bad things happen, but the individual with a healthy brain architecture is able to cope, often with the aid of family, friends, and other individuals who provide support. These adverse outcomes can be ‘growth experiences’ for individuals with such positive, adaptive characteristics and support systems that promote resilience. Here, ‘distress’ refers to the uncomfortable feeling related to the nature of the stressor and the degree to which the individual feels a lack of ability to influence or control the stressor [1–3].

Finally, ‘toxic stress’ refers to the situation in which bad things happen to an individual who has limited support and who may also

have a brain architecture that reflects the effects of adverse early life events that have impaired the development of good impulse control and judgement and adequate self esteem. Here, the degree and/or duration of ‘distress’ may be greater. With toxic stress, the inability to cope is likely to have adverse effects on behaviour and physiology, and this will result in a higher degree of allostatic overload, as will be explained later in this chapter.

Definition of stress, allostasis, and allostatic load

In spite of the further definitions of the types of stress, the word ‘stress’ is still an ambiguous term and has connotations that make it less useful in understanding how the body handles the events that are stressful. Insight into these processes can lead to a better understanding of how best to intervene, a topic that will be discussed at the end of this article. There are two sides to this story—on the one hand, the body responds to almost any event or challenge, whether or not we call it ‘stress’, by releasing chemical mediators, for example catecholamines that increase the heart rate and blood pressure, that help us cope with the situation; on the other hand, chronic elevation of these same mediators, for example chronically increased heart rate and blood pressure, produces chronic wear-and-tear on the cardiovascular system that can result, over time, in disorders such as strokes and heart attacks. For this reason, the term ‘allostasis’ was introduced by Sterling and Eyer in 1988 to refer to the active process by which the body responds to daily events and maintains homeostasis (allostasis literally means ‘achieving stability through change’). Because chronically increased allostasis can lead to disease, we introduced the term ‘allostatic load or overload’ to refer to the wear-and-tear that results from either too much stress or from the inefficient management of allostasis, for example not turning off the response when it is no longer needed. Other forms of allostatic load are summarized in **Fig. 79.2** and involve not turning on an adequate response in the first place or not habituating to the recurrence of the same stressor and thus dampening the allostatic response.

Protection and damage as the two sides of the response to experiences

Protection via allostasis and wear-and-tear on the body and brain via allostatic load/overload are the two contrasting sides of the physiology involved in defending the body against the challenges of daily life. Besides adrenaline and noradrenaline, there are many mediators that participate in allostasis, and they are linked together in a network of regulation that is non-linear, meaning that each mediator has the ability to regulate the activity of the other mediators, sometimes in a biphasic manner [4]. Glucocorticoids, produced by the adrenal cortex in response to ACTH from the pituitary gland, is the other major ‘stress hormone’. Pro- and anti-inflammatory cytokines are produced by many cells in the body, and they regulate each other and are, in turn, regulated by glucocorticoids and catecholamines. Whereas catecholamines can increase pro-inflammatory cytokine production, glucocorticoids are known to inhibit this production. And yet, there are exceptions—pro-inflammatory effects of glucocorticoids that depend on the dose and cell or tissue type [5, 6]. The parasympathetic nervous system also plays an important regulatory

Box 79.1 Levels of stressful experiences: their causes, consequences, and why we experience them!

- Result: sense of mastery and control
- HEALTHY BRAIN ARCHITECTURE
 - Good self-esteem, judgement, and impulse control

Tolerable stress

- Adverse life events buffered by supportive relationships
- Result: coping and recovery
- HEALTHY BRAIN ARCHITECTURE
 - Good self-esteem, judgement, and impulse control

Toxic stress

- Unbuffered adverse events of greater duration and magnitude
- Result: poor coping and compromised recovery
- Result: increased life-long risk for physical and mental disorders
- COMPROMISED BRAIN ARCHITECTURE
 - Dysregulated physiological systems

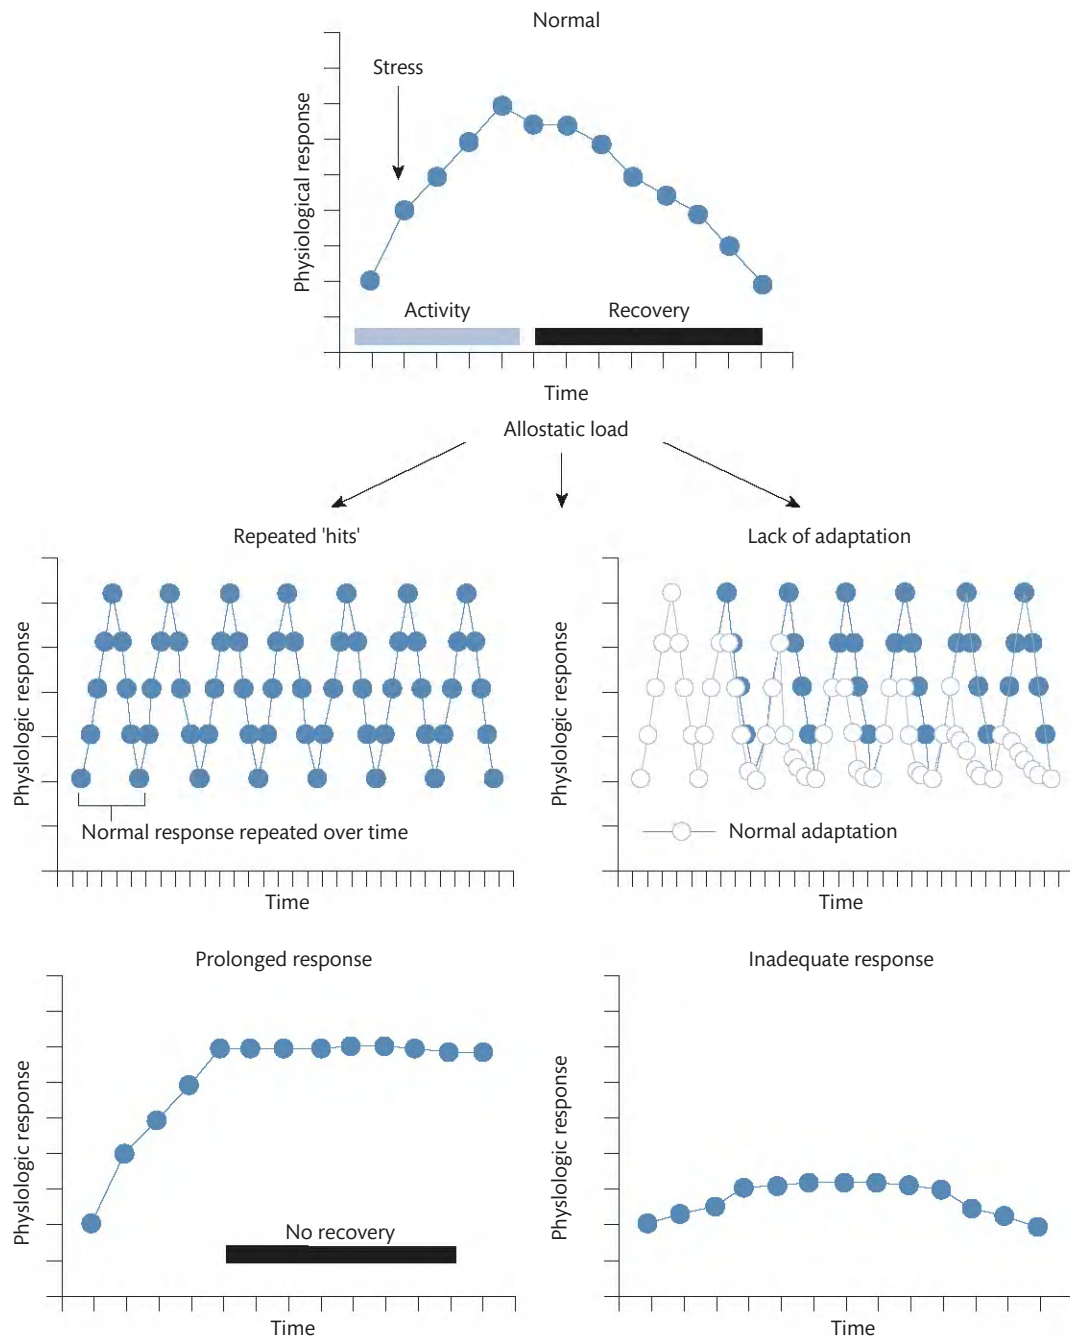

Fig. 79.2 Four types of allostatic load. The top panel illustrates the normal allostatic response, in which a response is initiated by a stressor, sustained for an appropriate interval, and then turned off. The remaining panels illustrate four conditions that lead to allostatic load: top left, *repeated 'hits'* from multiple stressors; top right, *lack of adaptation*; bottom left, *prolonged response* due to delayed shutdown; and bottom right, *inadequate response* that leads to compensatory hyperactivity of other mediators (for example, inadequate secretion of glucocorticoid, resulting in increased levels of cytokines that are normally counter-regulated by glucocorticoids) [122].

Reproduced from *New Eng J Med*, 338(3), McEwen BS, Protective and Damaging Effects of Stress Mediators, pp. 171–9, Copyright (1998), with permission from Massachusetts Medical Society.

role in this non-linear network of allostasis, since it generally opposes the sympathetic nervous system and, for example, slows the heart and also has anti-inflammatory effects [7, 8].

What this non-linearity and interaction among mediators mean is that when any one mediator is increased or decreased, there are compensatory changes in the other mediators that depend on the time course and level of change of each of the mediators. Unfortunately,

we cannot measure all components of this system simultaneously, and we must therefore rely on measurements of only a few of them in any one study. Yet the non-linearity must be kept in mind in interpreting the results.

A good example of the biphasic actions of stress, that is, 'protection vs damage', is in the immune system, in which an acute stressor activates an acquired immune response via mediation by

catecholamines and glucocorticoids and locally produced immune mediators; and yet a chronic exposure to the same stressor over several weeks has the opposite effect and results in immune suppression [9, 10]. Acute stress-induced immune enhancement is good for enhancing immunization, fighting an infection, or repairing a wound, but it is deleterious to health for autoimmune conditions such as psoriasis or Crohn's disease. On the other hand, immune suppression is good in the case of an autoimmune disorder and deleterious for fighting an infection or repairing a wound. In immune-sensitive skin cancer, acute stress is effective in inhibiting tumour progression, while chronic stress exacerbates progression [11, 12].

Stress and disease

Cardiovascular disease and depression are recognized as consequences of 'toxic psychological stress', using the definition of toxic stress discussed earlier [13]. There are conditions that lead to allostatic load and overload and exacerbate pathophysiology, besides the well-known factors associated with diet, alcohol consumption, and smoking and other unhealthy behaviours (**Box 79.2**). We shall discuss physical activity and lack thereof below, in connection with interventions. In particular, the social and physical environments are huge factors. Human beings are social creatures, and loneliness is a contributor to allostatic overload. Likewise, neighbourhoods matter and living in ugly, noisy, and dangerous neighbourhoods with a lack of green space contribute to allostatic overload.

Circadian disruption

One of the key systems in the brain and body that regulate homeostasis of these varied physiological and behavioural variables is the circadian system. Based in the suprachiasmatic nucleus (SCN) of the hypothalamus, the brain's clock controls the rhythms in the rest of the brain and body through both neural and diffusible signals. Disruption of these key homeostatic systems contributes to allostatic overload [14]. Reduced sleep duration is associated with increased body mass and obesity, and sleep restriction to 4 hours per night increases blood pressure, decreases parasympathetic tone, increases evening cortisol and insulin levels, and promotes increased appetite, possibly through the elevation of ghrelin, a pro-appetitive hormone, along with decreased levels of leptin. Moreover, pro-inflammatory cytokine levels are increased with sleep deprivation, along with decreased performance in tests of psychomotor vigilance, and this has been reported to result even from a modest sleep restriction to 6 hours per night [14, 15].

Circadian disruption has sometimes been overlooked as a separate, yet related, phenomenon to sleep deprivation. In modern

industrialized societies, circadian disruption can be induced in numerous ways, the most common of which are shift work and jet lag that contribute to weight gain and obesity (reviewed in [14]). Animal models have provided additional insights; for example, normal C57Bl/6 mice housed in a disrupted 10-hour light:10-hour dark cycle showed accelerated weight gain and disruptions in metabolic hormones and also showed cognitive inflexibility and shrinkage of dendrites in the medial prefrontal cortex [16], similar to reports of long-recovery vs short-recovery flight crews where short-recovery crews had impaired performance in a psychomotor task, reacting more slowly and with more errors [17].

Key role of the brain in response to stress

The brain is the key organ of the stress response because it determines what is threatening, and therefore stressful, and also controls the behavioural and physiological responses (**Fig. 79.1**). There are enormous individual differences in the response to stress, based upon the experience of the individual early in life and in adult life. Positive or negative experiences in school, at work, or in romantic and family interpersonal relationships can bias an individual towards either a positive or a negative response in a new situation.

Early life experiences carry an even greater weight in terms of how an individual reacts to new situations. Early life physical and sexual abuse carry with it a life-long burden of behavioural and pathophysiological problems [18]. Cold and uncaring families produce long-lasting emotional problems in children [19]. Some of these effects are seen on the brain structure and function and in the risk for later depression and PTSD [20]. One of the biological consequences of early life adversity is prolonged elevation of inflammatory cytokines, as well as poor dental health, obesity, and elevated blood pressure, in children and young adults [21]. Harsh language is among the components of early life adversity and has been shown to increase inflammatory markers [22].

And the physical environment makes a huge difference, with crowding, noise, and ugliness, along with physical danger, being major contributors to allostatic overload both during development and throughout adult life [2, 23, 24].

Animal models have been useful in providing insights into behavioural and physiological mechanisms. Individual differences in anxiety-like behaviours are evident [25, 26]. Early life maternal care in rodents is a powerful determinant of life-long emotional reactivity and stress hormone reactivity, and increases in both are associated with earlier cognitive decline and a shorter lifespan [27]. Effects of early maternal care are transmitted across generations by the subsequent behaviour of the female offspring as they become mothers, and methylation of DNA in key genes appears to play a role in this epigenetic transmission [28, 29]. Yet, the mother is not the sole determinant of offspring emotional and physical development, but rather modulates it by her behaviour towards the infant, particularly in the immediate aftermath of infant experiences of novelty inside or outside of the home cage [30].

Furthermore, in rodents, abuse of the young is associated with an attachment, rather than an avoidance, of the abusive mother, an effect that increases the chances that the infant can continue to obtain food and other support until weaning [31]. Moreover, other conditions that affect the rearing process can also affect emotionality

Box 79.2 Causes of allostatic load/overload [122]

- Loneliness [123]
- Circadian disruption: jet lag, shift work, sleep deprivation [14, 15, 17, 82]
- Lack of physical activity [124]
- Ugly, noisy, dangerous living environment and lack of green space [2, 23, 24]
- Health behaviours: type and quantity of food, alcohol consumption, smoking

in offspring. For example, uncertainty in the food supply for rhesus monkey mothers leads to increased emotionality in offspring and possibly an earlier onset of obesity and diabetes [32, 33].

Besides the important role of the social and physical environment and experiences of individuals in health outcomes, genetic factors also play an important role. Different alleles of commonly occurring genes determine how individuals will respond to experiences. For example, the short form of the serotonin transporter is associated with a number of conditions such as alcoholism, and individuals who have this allele are more vulnerable to respond to stressful experiences by developing depressive illness [34, 35]. In childhood, individuals with an allele of the monoamine oxidase A gene are more vulnerable to abuse in childhood and more likely to themselves become abusers and to show antisocial behaviours, compared to individuals with another commonly occurring allele [36]. Nevertheless, in a positive, nurturing environment, as formulated by Suomi and by Tom Boyce and colleagues [37–39], these same alleles may lead to successful outcomes, which has led them to be called ‘reactive or context-sensitive alleles’, rather than ‘bad genes’.

Brain as a target of stress

The hippocampus

One of the ways that stress hormones modulate function within the brain is by changing the structure of neurons. The hippocampus is one of the most sensitive and malleable regions of the brain and is also very important in cognitive function and mood regulation [40]. The dentate gyrus (DG)-CA3 system, which is delicately balanced anatomically, and thus vulnerable to overstimulation, as in seizures, is believed to play a role in the memory of sequences of events, although long-term storage of memory occurs in other brain regions [41]. Moreover, the anterior part of the hippocampus has strong connections to the amygdala and prefrontal cortex and is a nexus of vulnerability to depression. But, because the DG-CA3 system is so delicately balanced in its function and vulnerability to damage, there is also adaptive structural plasticity, in that new neurons continue to be produced in the dentate gyrus throughout adult life [42], and CA3 pyramidal cells undergo reversible remodelling of their dendrites in conditions such as hibernation and chronic stress [43, 44]. The role of this plasticity may be to protect against permanent damage. As a result, the hippocampus undergoes a number of adaptive changes in response to acute and chronic stress via a host of cellular and molecular mechanisms [45] and also shows positive effects of regular physical activity on hippocampal volume and memory [46].

Prefrontal cortex and amygdala

Repeated stress also causes changes in other brain regions such as the prefrontal cortex and amygdala. Repeated stress causes dendritic shortening in the medial prefrontal cortex [47] but produces dendritic growth in neurons in the amygdala, as well as in the orbitofrontal cortex. Excitatory amino acids and BDNF are involved [47–49].

Contrasting effects

Acute stress induces spine synapses in the CA1 region of the hippocampus, and both acute and chronic stress also increases spine

synapse formation in the amygdala, but chronic stress decreases it in the hippocampus. Moreover, chronic stress for 21 days or longer impairs hippocampal-dependent cognitive function and enhances amygdala-dependent unlearned fear and fear conditioning, which are consistent with the opposite effects of stress on hippocampal and amygdala structure [49]. Chronic stress also increases aggression between animals living in the same cage, and this is likely to reflect another aspect of hyperactivity of the amygdala [50]. Behavioural correlates of remodelling in the prefrontal cortex include impairment in attention set shifting, possibly reflecting structural remodelling in the medial prefrontal cortex [51].

Sex differences

Animal models of stress effects on the brain show that females and males respond differently to acute and chronic stressors because of developmental factors involving both epigenetic effects of hormones along with genes in the sex chromosomes themselves [52]. Sex differences in the brain are subtle but widespread [53], and yet males and females do many things equally well; for example, in human subjects taking tests on empathy, men and women do equally well, but the brain activation patterns during the tests show different brain regions are activated [54]. This is reminiscent of an animal model study in which, despite no overall sex differences in fear conditioning freezing behaviour, the neural processes underlying successful or failed extinction maintenance are sex-specific [55]. Given other work showing sex differences in stress-induced structural plasticity in prefrontal cortex projections to the amygdala and other cortical areas [56], these findings are relevant not only to sex differences in fear conditioning and extinction, but, according to Gruene *et al.* ‘also to exposure-based clinical therapies, which are similar in premise to fear extinction and which are primarily used to treat disorders that are more common in women than in men’ [55].

Translation to the human brain

MRI and fMRI imaging studies of stress, depression, and Cushing’s disease

Much of the impetus for studying the effects of stress on the structure of the human brain has come from the animal studies summarized thus far. Although there is very little evidence regarding the effects of ordinary life stressors on brain structure, there are indications from functional imaging of individuals undergoing ordinary stressors, such as counting backwards, that there are lasting changes in neural activity [57], and a 20-year history of chronic perceived stress has been linked to smaller hippocampal volume [58]. Moreover, the study of depressive illness and anxiety disorders has also provided some insights. Life events are known to precipitate depressive illness in individuals with certain genetic predispositions [34, 59, 60]. Moreover, brain regions such as the hippocampus, amygdala, and prefrontal cortex show altered patterns of activity in PET and fMRI and also demonstrate changes in volume of these structures with recurrent depression—decreased volume of the hippocampus and prefrontal cortices and the amygdala [61–64] (Fig. 79.3). Interestingly, amygdala volume has been reported to increase in the first episode of depression, whereas hippocampal volume is not decreased [65, 66]. It has been known

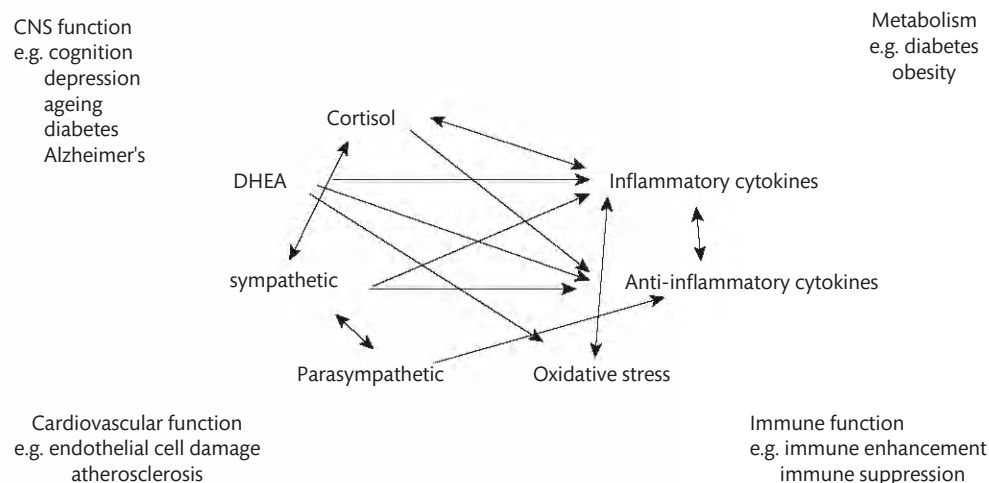

Fig. 79.3 Non-linear network of mediators of allostasis involved in the stress response. Arrows indicate that each system regulates the others in a reciprocal manner, creating a non-linear network. Moreover, there are multiple pathways for regulation; for example, inflammatory cytokine production is negatively regulated via anti-inflammatory cytokines, as well as via parasympathetic and glucocorticoid pathways, whereas sympathetic activity increases inflammatory cytokine production. Parasympathetic activity, in turn, contains sympathetic activity.

for some time that stress hormones, such as cortisol, are involved in psychopathology, reflecting emotional arousal and psychic disorganization, rather than the specific disorder per se [67]. We now know that adrenocortical hormones enter the brain and produce a wide range of effects upon it.

In Cushing's disease, there are depressive symptoms that can be relieved by surgical correction of hypercortisolaemia [68, 69]. Both major depression and Cushing's disease are associated with chronic elevation of cortisol that results in gradual loss of minerals from bone and abdominal obesity. In major depressive illness, as well as in Cushing's disease, the duration of the illness, and not the age of the subjects, predicts a progressive reduction in volume of the hippocampus, determined by structural MRI [61, 70]. Moreover, there are a variety of other anxiety-related disorders, such as PTSD [71, 72] and borderline personality disorder [73], in which atrophy of the hippocampus has been reported, suggesting that this is a common process reflecting chronic imbalance in the activity of adaptive systems, such as the HPA axis, but also including endogenous neurotransmitters such as glutamate.

Glucose regulation

Another important factor in hippocampal volume and function is glucose regulation. Poor glucose regulation is associated with smaller hippocampal volume and poorer memory function in individuals in their 60s and 70s who have 'mild cognitive impairment' (MCI) [74–76], and both MCI and type 2, as well as type 1, diabetes are recognized as risk factors for dementia [77–80]. Moreover, depression is often associated with insulin resistance (IR) and metabolic syndrome, and treatment with the peroxisome proliferator-activated receptor (PPAR) gamma agent pioglitazone showed improvement in depressive symptoms, but only in subjects with IR (81). Inflammation is also a factor related to many disorders of modern life, and elevation of IL-6 has been linked to reduced hippocampal volume [82], as well as to poor sleep (83). Regarding allostatic overload, a bifactorial model for calculating its impact on poor health

shows that mediators of inflammation, glucose level, and lipids are the most salient [84].

Insulin resistance

The original hypothesis that IR is a missing link between mood disorders and dementia [80, 85] has recently been supported by data on all components of the model, starting with the connection between depressive disorders and IR [86, 87] and also confirming a role of depressive disorders in accelerating the onset of dementia [88–90]. As IR is a modifiable metabolic pro-inflammatory state underlying type 2 diabetes mellitus, cumulative data indicate that, in middle-aged adults, IR is associated with disrupted memory and executive function and a corresponding metabolic decline in the medial prefrontal cortex, reductions in hippocampal volumes, and aberrant intrinsic connectivity between the hippocampus and the medial prefrontal cortex [91–93]. These findings are supported by recent work in animal models, in which antisense inactivation of the insulin receptor in the hippocampus leads to cognitive impairment without systemic consequences [94], whereas antisense inactivation of the hypothalamic insulin receptor creates systemic insulin resistance and dyslipidaemia and also insulin resistance in the hippocampus, along with depressive-like behaviour and cognitive impairment [95]. Remarkably, these changes are reversed by dietary restriction [96, 97], indicating that the brain can be resilient.

Progression towards dementia

Yet there is, at some point, a 'switch' that triggers irreversible changes that lead towards amyloid beta (Abeta) toxicity and dementia [89]. These authors point out that synaptic NMDA receptor activation normally has an antioxidant role by suppressing FOXO1 transcription factor in the hippocampus, but abnormal and excessive NMDA activation in the insulin-resistant state appears to enable FOXO1 translocation to the cell nucleus, leading to the generation of reactive oxygen species and possibly also activation of stress kinases, which further impairs insulin signalling. Moreover, Abeta production is

accelerated and Abeta oligomers enter into a vicious cycle, leading to further damage [89]. Mitochondrial function declines under these conditions and contributes to the positive feedback cycle of toxicity [98].

Epigenetics: two meanings that are both important for prevention and treatment

'Epigenetics' now refers to events 'above the genome' that regulate the expression of genetic information without altering the DNA sequence. Besides CpG methylation described earlier, other mechanisms include histone modifications that repress or activate chromatin unfolding [99] and the actions of non-coding RNAs [100], as well as transposons and retrotransposons [101] and RNA editing [102]. For prevention and treatment, in the spirit of integrative medicine, it is important to let the 'wisdom of the body' prevail and to focus upon strategies that centre around the use of targeted behavioural therapies, along with treatments, including pharmaceutical agents, that 'open up windows of plasticity' in the brain and facilitate the efficacy of the behavioural interventions [103]. This is because a major challenge throughout the life course is to find ways of *redirecting future behaviour and physiology in more positive and healthy directions* [104]. In keeping with the original definition of epigenetics [105] as the emergence of characteristics not previously evident or even predictable from an earlier developmental stage (for example, think about a fertilized frog or human egg which look similar and what happens as each develops!), *we do not mean 'reversibility' as in 'rolling back the developmental clock' but rather 'redirection' as well as 'resilience', which can be defined as 'achieving a successful outcome in the face of adversity'*.

Interventions that change the brain and improve health

Can the effects of stress and adverse early life experiences on the brain be treated and compensated, even though there are no 'magic bullets' like penicillin for stress-related disorders [104]? For psychiatric illnesses such as depression and anxiety disorders, including PTSD, it is necessary to complement, and even replace, existing drugs and adopt strategies that centre around the use of targeted behavioural therapies, along with treatments, including pharmaceutical agents, that open up 'windows of plasticity' in the brain and facilitate the efficacy of the behavioural interventions [103, 106, 107]. To that extent, meeting the demands imposed by stressful experiences via various coping resources can lead to growth, adaptation, and learning to promote resilience and improved mental health [108, 109]. BDNF is a mediator of plasticity and, while it can facilitate beneficial plasticity (for example, see [48]), it should be noted that BDNF also has the ability to promote pathophysiology, as in seizures [110–112].

How the brain gets 'stuck'

Depression and anxiety disorders are examples of a loss of resilience, in the sense that changes in brain circuitry and function, caused by stressors that precipitate the disorder, become 'locked' in

Box 79.3 Reactivating and redirecting brain plasticity

- *'Releasing the brakes'* that retard structural and functional plasticity [105]. Example amblyopia first done using fluoxetine [121] and caloric restriction [125], in which reducing inhibitory neuronal activity appears to play a key role. Replicated by putting cortisol in drinking water, instead of caloric restriction [125]. NOTE: ultradian fluctuations of cortisol according to a diurnal pattern modulate turnover of some spine synapses, in relation to motor learning and possibly other forms of learning [126, 127].
- *Opening windows of plasticity with physical activity*: regular physical activity, which has actions that improve prefrontal and parietal cortex blood flow and enhance executive function [128], increases hippocampal volume in previously sedentary elderly adults [46, 129] and complements work showing that fit individuals have larger hippocampal volumes than sedentary adults of the same age range [130]. Regular physical activity is an effective antidepressant and protects against cardiovascular disease, diabetes, and dementia [131, 132]. Moreover, intensive learning has also been shown to increase the volume of the human hippocampus, based on a study on medical students [133].
- *Successful cognitive behavioural therapies*, which are tailored to individual needs, can produce volumetric changes in both the prefrontal cortex in the case of chronic fatigue [134] and in the amygdala in the case of chronic anxiety [135], and in a brainstem area associated with well-being [136]. Mindfulness-based stress reduction (MBSR) practice has been shown to increase regional brain grey matter density in the hippocampus, cerebellum, and prefrontal cortex, the brain regions involved in learning and memory processes, emotion regulation, self-referential processing, and perspective-taking [137]. Enhancing self-regulation of mood and emotion appears to be an important outcome [138, 139].
- *Meditation* is reported to enlarge the volume of the hippocampus and to do so differently in men and women, suggesting to the authors that mindfulness practices operate differently in males and females [140].

a particular state and thus need external intervention. Indeed, prolonged depression is associated with shrinkage of the hippocampus [62, 113] and prefrontal cortex [63]. While there appears to be no neuronal loss, there is evidence for glial cell loss and smaller neuronal cell nuclei [114, 115], which is consistent with shrinking of the dendritic tree, described earlier, after chronic stress. Indeed, a few studies indicate that pharmacological treatment may reverse the decreased hippocampal volume in unipolar [116] and bipolar [117] depression, but the possible influence of concurrent cognitive behavioural therapy in these studies is unclear.

Even in adulthood, gene expression in the brain continually changes with experience [118] and there is loss of resilience of the neural architecture with ageing [119] that can be redirected by exercise [46] and by pharmacological intervention [120, 121]. Beyond ageing, there are new approaches to 'opening windows of plasticity' and redirecting the brain towards a more health-promoting state, and these are summarized in [Box 79.3](#).

Conclusions: what can one do about being 'stressed out'?

If being 'stressed out' has such pervasive effects on the brain, as well as the body, what are the ways in which individuals, as well as policymakers in government and business, can act to reduce the negative

effects and enhance the ability of the body and brain to deal with stress with minimal consequences? The answers are simple and obvious, but often difficult to achieve.

From the standpoint of the individual, a major goal should be to try to improve sleep quality and quantity, have good social support and a positive outlook on life, maintain a healthy diet, avoid smoking, and have regular moderate physical activity. Concerning physical activity, it is not necessary to become an extreme athlete, and moderate physical activity helps, as noted earlier, in relation to enlarging hippocampal volume.

From the standpoint of policy, the goal should be to create incentives at home and in work situations and to build community services and opportunities that encourage the development of the beneficial individual lifestyle practices.

As simple as the solutions seem to be, changing behaviour and solving problems that cause stress at work and at home are often difficult and may require professional help on a personal level, or even a change of job or profession. Yet these are important goals because the prevention of later disease is very important to increase 'healthspan' and promote full enjoyment of life and also to reduce the financial burden of disease and disability on the individual and on society.

Genetics of stress-related disorders

Michael G. Gottschalk and Katharina Domschke

Introduction

This chapter will highlight the genetic architecture of trauma- and stress-related disorders, exemplified by post-traumatic stress disorder (PTSD), which itself overlaps in symptom dimensions with acute stress disorder and adjustment disorder. Within DSM-5, this nosological group shares, as part of their diagnosis, the specific call for an environmental component in the form of direct or indirect exposure to a causative traumatic incident [1]. This unique position among psychiatric disorders is particularly relevant for studying the interaction of an organism's internal biological component with external stimuli in the pathogenesis of a mental disorder.

Here, we will review the genetics of stress-related disorders, focusing on clinical genetic approaches such as family and twin studies and molecular genetic studies, that is candidate gene and hypothesis-generating genome-wide association studies (GWAS), as well as gene–environment and epigenetic approaches. Due to the close phenomenological relationship between the categories of trauma- and stress-related disorders and anxiety disorders, the genetics of cross-disorder phenotypes and cross-cutting symptom measurements will build an additional focus.

Genetics of stress-related disorders

Family studies and twin studies

The requirement for trauma exposure as a key factor in the diagnosis of PTSD poses a challenge to estimates of familial aggregation, since the exact degree of trauma exposure is likely to vary between otherwise comparable relatives. The task to distinguish the heritable components of PTSD is difficult. Indeed, biological factors could affect an individual's liability to PTSD in several ways, including, but not limited to an increased susceptibility to trauma exposure (gene–environment correlation), an increased susceptibility to PTSD independent of the trauma, an influence on risk factors potentially linked to PTSD (for example, the personality trait of increased risk-seeking behaviour), and/or mediation of a pleiotropic effect on several of these. For example, in one family study, PTSD lifetime symptoms of mothers were significantly associated with PTSD symptoms in

children in a dose-dependent fashion, while similarly predicting increased trauma exposure in children, which accounted for 74% of the increased PTSD incidence rate [2].

Quantitative genetic analysis of Vietnam-era veteran monozygotic and dizygotic male twin pairs overcame some of the problems of unequal trauma exposure. It revealed a substantial genetic influence on the susceptibility to all assessed PTSD symptoms; a bivariate genetic model, adjusted for combat exposure, estimated the heritability of re-experiencing symptoms to range between 0.13 and 0.30 [3]. The heritability of avoidance and arousal symptoms varied between 0.30–0.34 and 0.28–0.32, respectively, with no evidence for a shared environmental component [3]. In a study of genetic and environmental effects on exposure to assaultive and non-assaultive trauma and occurrence of PTSD symptoms in male and female twin pairs of non-veteran volunteers with trauma exposure, the variance of reported symptoms was best explained by genetic factors for assaultive trauma (overall heritability of 0.53), with genetic factors particularly contributing to symptoms of re-experiencing (0.36) and numbing (0.36), whereas no genetic component was found in non-assaultive trauma (mainly explained by non-shared environmental factors) [4] (Table 80.1).

While both genetic and non-shared environmental influences affected PTSD symptoms, and the severity of PTSD symptoms has been linked to the number of assaultive traumatic events suffered, the influence of genetic factors has been suggested to decline with increase in total trauma number [5]. In other words, there appears to be a threshold beyond which the quantitative summation of environmental factors supervenes [5]. Another population-based twin sample estimated the magnitude of additive genetic influences, based on trauma quality, and reported a greater genetic contribution in high-risk trauma (0.60; trauma reported as most disturbing), as compared to low-risk trauma (0.47), with a genetic correlation between high-risk trauma and PTSD of 0.89, whereas for low-risk trauma and additive genetic and non-shared environmental influences, a lower correlation of 0.57 was observed [6].

Structural and rare variant studies

No systematic research efforts have been published linking PTSD to recognized neurodevelopmental disorders, structural genetic variations, or rare single-nucleotide polymorphisms (SNPs).

Table 80.1 Trauma- and symptom-focused perspectives on the heritability of stress-related disorders

	Additive genetic factors		Shared environment		Unique environment	
	a ²	95% CI	c ²	95% CI	e ²	95% CI
Trauma exposure						
Assaultive trauma ^a	0.53	0.40–0.67	–	–	0.42	0.33–0.60
Non-assaultive trauma ^a	–	–	0.32	0.21–0.45	0.68	0.55–0.80
Low-risk trauma ^b	0.47	0.35–0.57	–	–	0.53	0.43–0.65

Assaultive trauma comprised captivity and physical/sexual assault. Non-assaultive trauma comprised natural disasters, motor vehicle accidents, and the occurrence of a sudden death in the family. Low-risk trauma comprised combat exposure and accidents. High-risk trauma comprised rape, sexual molestation, and childhood neglect/abuse. Heritability estimates not adding up to 1.0 are derived from rounding up/down effects.

PTSD, post-traumatic stress disorder; CI, confidence interval; a², additive genetic factors; c², shared environmental factors; e², unique environmental factors.

GWAS, candidate genes, gene–environment interaction, and ‘therapy genetics’ studies

The first GWAS of PTSD was performed in a small trauma-exposed cohort of African-American veterans and their intimate partners (295 cases, 196 controls) and yielded several SNPs with suggestive associations, with one polymorphism in the RAR (retinoic acid receptor)-related orphan receptor alpha gene (*RORA*) reaching genome-wide significance (rs8042149, C allele) [7]. The rs8042149 finding failed to replicate in two independent replication samples, but interestingly, other *RORA* SNPs were implicated as PTSD risk variants [7]. Notably, a subsample analysis of the initial GWAS cohort, screening 606 SNPs spanning the *RORA* gene, significantly associated rs8042149 with the fear sub-factor of PTSD comorbidities (outcome of a 3-factor confirmatory factor analysis, next to an internalizing and an externalizing sub-factor) [8].

A GWAS conducted in a cohort of European-Americans (300 cases, 1278 controls) yielded rs406001 on chromosome 7p12 as a genome-wide significant hit, the nearest gene being the protein cord-bleu (*COBL*) and the second-best hit located in the first intron of the toll-like protein 1 (*TLL1*), barely missing genome-wide significance (rs6812849, $P = 2.99 \times 10^{-7}$) [9]. A SNP replication analysis of the top GWAS hits in another cohort and a subsequent combined cohort analysis resulted in a more favourable overall genome-wide statistical outcome for *TLL1* rs6812849 [9]. An analysis of the main effects of *COBL* SNPs in an African-American civilian population did not replicate, but a significant genotype–environment interaction with childhood trauma was found for *COBL* rs406001 [10]. The T allele mediated higher PTSD symptom intensity and was associated with significantly decreased fractional anisotropy in left hemisphere structures (inferior fronto-occipital fasciculus, uncinate fasciculus, orbitofrontal white matter tracts, and inferior longitudinal fasciculus) [10].

Screening for genome-wide significant association in a sample of trauma-exposed African-American women (94 cases, 319 controls) identified the minor G allele of rs10170218, a SNP within the long intergenic non-coding RNA sequence *AC068718.1* gene located at 2q32.1 [11]. This was replicated in a second independent cohort of European-American women [11]. A functional enrichment analysis of the nominally significant GWAS findings highlighted pathways related to the maintenance of telomere length [11].

Another GWAS (3167 cases, 4607 trauma-exposed controls) found a genome-wide significant hit in the ankyrin repeat domain-containing protein 55 gene (*ANKRD55*, rs159572) in subjects of African-American ancestry and one close to the zinc finger protein 626 gene (*ZNF626*, rs11085374) in the European-American subsamples [12].

A study analysing 3742 SNPs of over 300 genes previously reported as PTSD candidate risk genes in trauma-exposed European-American women (845 cases, 1693 controls) in a categorical and dimensional fashion found the most significant association between the intronic synaptic vesicular amine transporter (*SLC18A2*, involved in the ATP-dependent neurotransmitter storage) rs363276 A allele and a PTSD diagnosis [13]. In a similar experimental design examining the association of 3755 candidate genes and PTSD in a gene–environment interaction approach with childhood trauma in a cohort of male soldiers of European ancestry (810 samples), an association was identified between the beta-2 adrenergic receptor (*ADRB2*) rs2400707 G allele and increased childhood adversity load, resulting in heightened PTSD symptom intensity, which was subsequently replicated in an independent sample of predominantly female African-American civilians (2083 samples) [14].

A GWAS in trauma-exposed United States marines of mixed ancestry (940 cases, 2554 controls) resulted in a significant association for the phosphoribosyltransferase domain-containing protein 1

(*PRTFDC1*); the rs6482463 minor A allele was under-represented in PTSD. A replication attempt in an independent military cohort failed, and although a candidate gene screen, including *RORA*, *TLL1*, and *AC068718.1* SNPs, yielded nominally significant associations, no finding survived correction for the number of polymorphisms tested per gene [15]. In general, results of hypothesis-generating studies in such small samples must be viewed with caution, since it is difficult to exclude chance findings.

Finally, the largest GWAS of PTSD to date (5182 cases; 15,548 controls, 13,638 of which were trauma-exposed) suggested a genome-wide significant finding in the kelch-like protein 1 gene (*KLHL1*, rs139558732) detected in its African-American subsample (2520 cases, 7171 controls) [16]. However, recent GWAS investigations in

a cohort of mixed-ancestry Iraq–Afghanistan-era veterans [17] and of the DSM-5 dissociative subtype of PTSD in a cohort of European-American United States military veterans [18] did not report any genome-wide significant results.

In addition to GWAS, the impact of specific genetic variation in PTSD has focused on genes related to monoaminergic neurotransmission (Fig. 80.1) analogous to candidate studies performed in anxiety disorders (see Chapter 89) and neuroendocrine functioning, in particular the hypothalamic–pituitary–adrenal (HPA) axis. A recent meta-analysis of trauma-exposed samples found only a trend towards significance between PTSD and the short (s) allele of the serotonin transporter (*SLC6A4*, chromosome 17q11.2) 5-HTTLPR (5-hydroxytryptamine transporter-linked polymorphic region;

Fig. 80.1 Multi-level evidence linking the serotonergic system to trauma- and stress-related disorders, cross-disorder phenotypes, and anxiety disorders. The short allele/low transcriptional activity variants of the 5-HTTLPR were chosen as seed node. Arrows represent domain interrelations of systems analysis mediating interactions between genetic and environmental factors, potentially leading to observable meta-phenomena crossing classic nosological boundaries and connecting different spectra of psychopathology. Note that some authors include the rs25531 polymorphism in their analyses, with the minor G allele rendering transporter expression levels of the long 5-HTTLPR allele more closely to the short allele. Refer to the text for detailed supporting literature. ACC, anterior cingulate cortex; AMY, amygdala; CBT, cognitive behavioural therapy; HIP, hippocampus; IN, insula; MPFC, medial prefrontal cortex; PCC, posterior cingulate cortex; PD, panic disorder; PTSD, post-traumatic stress disorder; SAD, social anxiety disorder; SSRI, selective serotonin reuptake inhibitor; TH, thalamus.

the s allele is linked to decreased expression/transporter activity, compared to the long [l] variant) [19]. However, the s/s genotype and high trauma exposure were associated with PTSD, arguing for a further exploration of gene–environment interaction to clarify the polymorphism's role in trauma-related psychopathology [19]. Soldiers with one or two copies of the low-functioning 5-*HTTLPR*/rs25531 alleles (the minor rs25531 G allele reduces transporter expression levels like the s variant) reported increased symptoms of PTSD and anxiety in response to heightened exposure to war zone stressors, as compared to carriers of high-functioning alleles [20]. Accordingly, the genotype with low transcriptional efficiency was associated with PTSD diagnoses and PTSD symptom severity in veterans [21]. Interestingly, the low-functioning 5-*HTTLPR*/rs25531 alleles mediated an interaction effect of increased PTSD symptoms during battle deployment only in individuals with greater attentional avoidance of threats, rather than in individuals with vigilant threat appraisal [22]. Similarly, following a university campus shooting, the low-functioning 5-*HTTLPR*/rs25531 genotypes predicted increased acute stress symptom intensity 2–4 weeks after the event, even when correcting for shooting exposure; symptoms of avoidance and hyperarousal, but not of re-experiencing, were the most implicated [23].

Remarkably, a pharmacogenetic study examining the 4- and 12-week PTSD treatment response to sertraline linked l allele homozygosity to reduced dropout rates due to adverse effects and increased efficacy; most strikingly, there was a 48% response rate (defined as a minimum symptom reduction of 30%) by week 12, as compared to a 0% response rate in s allele carriers [24]. Correspondingly, low-expression 5-*HTTLPR*/rs25531 genotype carriers displayed a significantly worse 6-month treatment outcome following an 8-week exposure-based cognitive behavioural therapy (CBT) programme, controlling for pre-CBT symptom severity and the number of treatment sessions [25].

The catechol-*O*-methyltransferase *COMT* (chromosome 22q11.21) rs4680 A/A genotype has been associated with PTSD, particularly in patients who had experienced childhood adversities and possessed high neuroticism scores [26]. The minor A allele results in an exchange of amino acid 158 valine (major G allele) to methionine and significantly increased degradation of catecholamine neurotransmitters—often referred to as the val158met polymorphism. Surprisingly, it has been indicated further that, while *COMT* rs4680 G (val) allele carriers showed a classic dose–response relationship of lifetime trauma abundance and PTSD incidence rate, met/met genotype carriers exhibited an increased risk of PTSD, independent of trauma load [27].

The peptidyl-prolyl *cis-trans* isomerase FKBP5, commonly referred to as the FK506 binding protein 5 (*FKBP5*, chromosome 6p21.31), is probably one of the most extensively characterized candidate genes associated with PTSD. FKBP5 is an immunophilin family member with isomerase and chaperone functions; it interacts with unligated steroid receptor heterocomplexes through heat shock protein 90 (HSP90), influencing intracellular trafficking behaviour, receptor affinity, and nuclear translocation. Since *FKBP5* transcription is activated by glucocorticoid receptors via steroid response elements, a direct negative feedback loop is created [28]. Several SNPs within the *FKBP5* gene (rs1360780 T allele, rs3800373 C allele, rs9296158 A allele, and rs9470080 T allele) do not directly predict PTSD symptom outcome or interact with non-childhood trauma

[29]. Instead, they appear to interact with the severity of child abuse to predict increased levels of adult PTSD symptom levels and a greater suppression of cortisol release during a pharmacological challenge with dexamethasone [29]. A study evaluating *FKBP5* SNPs in a trauma-exposed African-American cohort (1963 samples) reported a significant association between the rs1360780 A allele (located in a functional enhancer region in intron 2 488 bp away from a glucocorticoid response element) and childhood trauma on PTSD symptoms [30]. The *FKBP5* rs1360780 T allele has been independently reported to predict an increased risk of long-term PTSD symptom relapse following narrative exposure therapy [31]. In the same African-American cohort, the rs9470080 T allele increased the risk to be diagnosed with PTSD in an interaction with childhood maltreatment; yet surprisingly, T/T genotype carriers without childhood trauma had the lowest risk of PTSD [32]. In studies with diffusion tensor imaging and resting state functional magnetic resonance imaging (fMRI), rs1360780 T allele carriers with PTSD displayed a decreased structural, as well as functional, connectivity between the anterior cingulate cortex and the hippocampus, which has been suggested as a source of the pathologically increased neuronal salience observed in PTSD [33]. Moreover, in an attempt to evaluate different biologically distinct subtypes of PTSD, it has been found that rs9296158 A allele carriers display increased plasma cortisol levels [34]. These, in turn, correlated with symptom intensity and significantly influenced peripheral mRNA levels of genes carrying steroid hormone transcription factor binding sites in whole blood [34].

Other work has focused on different elements of neurohormonal stress response regulation such as the gene coding for the pituitary adenylyl cyclase-activating polypeptide type I receptor (*ADCYAP1R1*, chromosome 7p14.3), a G protein-coupled receptor implicated in the modulation of adrenocorticotrophic hormone (ACTH) secretion. The C allele of *ADCYAP1R1* rs2267735, located in a putative oestrogen response element, has been linked to PTSD symptom intensity and PTSD diagnosis in females and reduced discrimination of danger and safety cues in a fear conditioning paradigm [35]. Subsequent gene–environment studies found significant interactions of the *ADCYAP1R1* rs2267735 C allele and the total amount of suffered traumata [36], or the degree of experienced childhood maltreatment [37], in predicting increased female PTSD symptom intensity. Imaging has revealed decreased hippocampal activity during contextual, but not during cued, fear conditioning in female *ADCYAP1R1* rs2267735 C allele carriers [38] and an increased reactivity of the amygdala and hippocampus to threat stimuli, as well as decreased functional connectivity between the amygdala and the hippocampus during passive viewing of threatening stimuli [39]. Moreover, with regard to HPA axis regulation, two SNPs (rs8192496 and rs2190242) in the corticotropin-releasing hormone receptor 2 (*CRHR2*, chromosome 7p14.3) gene have been linked to a decreased risk of suffering from PTSD in female trauma-exposed veterans, a proposed effect of an attenuated neurohormonal stress response [40]. Finally, in a prospective emergency department setting, a composite additive risk score derived off genes related to stress response and arousal, including, among others, *FKBP5*, *ADCYAP1R1*, the CRH receptor 1 gene (*CRHR1*, chromosome 17q21.31), and *COMT*, predicted increased PTSD symptoms in subjects without early post-trauma intervention classified as ‘risk’ carriers, as compared to ‘low-risk’ and ‘resilience’ genotypes [41]. Additionally, PTSD symptom intensity 12 weeks after trauma only correlated with the genetic risk

load in the group without intervention, but not in patients with imaginal exposure therapy to trauma memory, with the overall number of risk alleles significantly associated with an increased PTSD incidence rate [41].

Epigenetic studies

The potential relevance of maladaptive changes in chromatin structure and DNA methylation as mediators of the influence of traumatic experiences cannot be underestimated. An impact can be expected from the single cell level up to cognitive patterns and behaviour in the organism's allostatic biological load in general, and in manifestations of PTSD in particular.

A large microarray approach evaluating DNA methylation of more than 14,000 genes in 23 PTSD-affected and 77 PTSD-unaffected individuals suggested traumatic events to induce downstream alterations in immune system functions by reducing methylation levels of genes related to cytokine production and innate immunity [42].

At the candidate gene level, overall *SLC6A4* promoter region methylation influenced the risk of PTSD, independently of the 5-*HTTLPR* genotype, with low methylation levels correlating with an increased PTSD incidence rate in people who experienced multiple traumata [43]. Similarly significant associations were discerned between *SLC6A4* hypomethylation and increased PTSD symptom intensity and symptom quantity [43].

A study in a trauma-exposed African-American cohort found that *FKBP5* rs1360780 influenced chromatin conformation with respect to the transcription start site—A allele carriers exposed to childhood trauma displayed decreased methylation levels close to, and within, glucocorticoid response elements in intron 7, independent of recent lifetime trauma exposure [30]. It was hypothesized that this hypomethylation in risk allele carriers would imply an increased induction of *FKBP5* by glucocorticoid receptor activation and enhancement of the ultra-short negative HPA feedback loop, leading to increased glucocorticoid receptor resistance [30]. Additionally, structural imaging data revealed a significant negative correlation between peripheral *FKBP5* intron 7 methylation and hippocampal volume [30]. Thus, epigenetic changes in these genes not only alter the sensitivity of peripheral glucocorticoid receptors, but are also associated with morphological changes in limbic areas already believed to be indicative of a higher stress hormone system reactivity [30].

Transgenerational effects of trauma exposure have been explored in a study of Holocaust survivors and their offspring; survivors showed significantly increased *FKBP5* methylation, yet decreased levels in their offspring [44]. At the same time, significant interactions of the *FKBP5* rs1360780 T allele and CpG-specific methylation levels with either parental trauma intensity or the severity of self-experienced childhood trauma were reported, providing insights into the psychophysiological epigenetic integration of trauma across age groups [44].

Finally, in a cohort of children undergoing CBT for anxiety disorders, there was a significant correlation between the change in *FKBP5* methylation and therapy response, with responders demonstrating the greatest decrease in methylation, an effect which was specific to *FKBP5* rs1360780 T allele carriers [45].

Additional epigenetic evidence links other HPA regulators to PTSD. Remarkably, while increased *ADCYAP1R1* methylation was

associated with a PTSD diagnosis, rs2267735 C allele carriers displayed reduced cerebral mRNA expression levels [35]. Furthermore, decreased glucocorticoid receptor (*NR3C1*, chromosome 5q31.3) promoter region methylation in peripheral blood mononuclear cells was detected in veterans with PTSD [46]. It was further associated with increased cortisol levels following the dexamethasone suppression test, reports of psychiatric distress, peritraumatic dissociation, and poor sleep quality [46]. In Holocaust survivors' offspring with both parents suffering from PTSD, lower *NR3C1* methylation was observed, compared to offspring with only paternal PTSD, and lower methylation levels correlated with increased post-dexamethasone cortisol suppression [47].

Interestingly, the methylation state of DNA methyltransferases themselves has been investigated following trauma exposure, with probands developing PTSD later on showing increased methylation of DNA (cytosine-5)-methyltransferase 1 (*DNMT1*), whereas low pre-trauma methylation of DNA (cytosine-5)-methyltransferase 3B (*DNMT3B*) predicted increased levels of PTSD symptom severity [48].

Genetics of cross-disorder phenotypes of post-traumatic stress and anxiety

Heritability estimate studies suggest a shared genetic signature underlying PTSD and anxiety spectrum conditions, namely specific phobia (SP), social anxiety disorder (SAD), agoraphobia (AP), panic disorder (PD), and generalized anxiety disorder (GAD) [49]. A common diathesis of PTSD is further suggested with intermediate phenotypes, such as fear generalization, avoidance behaviour, anxiety sensitivity, state/trait anxiety, harm avoidance, and physiological hyper-responsiveness to certain stimuli, supported by their genetic correlation and joint cross-disorder familial risk [50, 51].

Unsurprisingly, in addition to an overlap in the genetic architecture of trauma- and stress-related disorders and anxiety disorders, both diagnostic categories are based upon a selection of highly connected, psychometrically assessable constructs, outlining, for example, the gradual development of normative stimulus-specific fears into functionally impairing generalized anxiety. Primarily, the study of these cross-disorder post-traumatic stress and anxiety phenotypes has focused on continuous traits, which are hypothesized to represent different forms of neuropsychiatric vulnerability for the diagnosis of the corresponding disorders during development. As outlined in later sections, various intermediate phenotype concepts have been suggested to affect the onset, therapy, or disease course of trauma-inflicted psychological stress. (Also see Chapter 89 for additional remarks on potentially relevant cross-disorder phenotypes.)

Serotonergic system

Fig. 80.1 depicts the multi-level, cross-disorder genetic vulnerability mediated by several intermediate phenotypes and environmental factors for *SLC6A4/5-HTT* gene variation. A meta-analysis of cortisol reactivity (1686 cases) to acute psychosocial stress reported a moderating effect of the 5-*HTTLPR* polymorphism, with homozygous s allele carriers demonstrating increased cortisol reactivity [52]. Increased vigilance towards negatively valenced

stimuli in carriers of low-active 5-HTTLPR alleles was further confirmed via a meta-analysis (807 cases) of studies focusing on attentional biases [53]. However, the low-expression forms of 5-HTTLPR could rather represent a plasticity factor capable of developing stronger biases for both negative and positive affective stimuli [54]. Thus, it has been suggested that the increased amygdala response to aversive stimuli in carriers of the short 5-HTTLPR allele is not mediated by 5-HTT availability in adults, but rather by amygdala size, with smaller amygdala volumes correlating with increased neural activation, suggesting a neurodevelopmental influence of the serotonergic polymorphism [55]. Another meta-analysis (9361 cases) of gene–environment studies in children and adolescents revealed that Caucasian carriers of the 5-HTTLPR s allele are not only significantly more vulnerable to negative environmental influences, but also more receptive to positive input than l/l carriers [56]. In a cohort of healthy subjects, the 5-HTTLPR l/l genotype resulted in higher anxiety sensitivity scores in an interaction with childhood trauma exposure, in particular with regard to somatic sub-dimensions of anxiety sensitivity [57]. Nevertheless, despite most studies focusing on risk factors, few have also included protective, resilience-increasing factors such as self-efficacy. When childhood trauma and self-efficacy were assessed in relation to trait anxiety, social anxiety, and agoraphobic anxiety in healthy adults genotyped for the 5-HTTLPR/rs25531, s allele carriers showed a positive correlation of trauma and anxiety, independent of self-efficacy [58]. Conversely, l_A/l_A homozygotes with low self-efficacy scored significantly higher in all available anxiety assessments when they had experienced childhood trauma but were resilient when they possessed high self-efficacy [58].

Hormone system

In relation to the HPA axis, carriers of the *CRHR1* rs110402 A allele, which has been implicated in elevated cortisol reactivity to acute stressors, displayed blunted basolateral amygdala habituation in a fear extinction paradigm, and an increased risk to be diagnosed with any anxiety disorder [59]. The *CRHR1* rs878886 minor G variant has been associated with reduced fear-conditioned responses to a threat cue and a tendency towards anxious generalization and increased contextual anxiety in an interaction with the low-activity alleles of the 5-HTTLPR [60]. A replication study confirmed the acquisition deficit and increased contextual anxiety in rs878886 G allele carriers and suggested a tri-allelic interaction with low-expression 5-HTTLPR/rs25531 variants on cued fear acquisition [61]. In imaging genetic approaches, several SNPs in both HPA-relevant genes, *CRHR1* and *NR3C1*, have been linked to increased amygdala activation during the acquisition phase of a fear conditioning paradigm and decreased prefrontal activity during the extinction phase, respectively [62]. Interestingly, to note from an epigenetic viewpoint, currently healthy subjects with a lifetime anxiety disorder diagnosis have lower levels of *NR3C1* promoter region methylation, while the number of experienced childhood adversities negatively correlated with promoter region methylation only in subjects without a lifetime diagnosis [63]. A micro-satellite marker [64] and several SNPs [65] within the *CRH* gene itself have also been linked to behavioural inhibition in children with a familial loading of PD. Moreover, carriers of the *FKBP5* rs1360780 T allele have been shown to display heightened levels of harm avoidance [66] and an attention bias towards threat cues and

increased hippocampal activation during threat evaluation [67], while amygdala activation was increased in risk allele carriers exposed to emotional neglect in childhood [68].

Catecholaminergic system

Evaluation of the *COMT* val158met polymorphism in association with childhood maltreatment demonstrated that *val/val* allele carriers displayed a significantly increased startle response to aversive pictures, while *met/met* carriers showed blunted responses to unpleasant stimuli [69]. The effect in *val* carriers was discerned to be potentiated by increased amounts of maltreatment, which had no interaction effect in *met* allele carriers [69]. In a double-blind, placebo-controlled design, it has also been shown that *val* allele carriers displayed an increased startle potentiation towards aversive stimuli, independently of an acute injection of levodopa (L-dopa), whereas in *met* allele carriers, the startle response to unpleasant pictures was only enhanced under L-dopa administration, but not by placebo [70]. This would support the influence of catecholaminergic neurotransmission on the emotion-potentiated startle reflex either by increased phasic dopamine abundance, as conferred by the high-activity *val* allele, or by pharmacologically enhanced dopamine availability, eventually leading to a maladaptive predisposition of the emotional valence system.

Clinical challenges and future perspectives

The gene–environment interactions reported in relation to PTSD highlight not only very appealing candidates, such as the serotonergic or HPA system, but also underline the importance of *individual vulnerability windows* in personal development, for example reflected by ‘plasticity polymorphisms’ influencing gene expression or protein activity, which interact with childhood experiences, yet are not influenced by recent life events. Due to the special position of PTSD in psychiatric nosology, genetic association and gene–environment studies pose the challenge that *causative and non-causative trauma* exposures are correlated and difficult to disentangle [71]. While trauma exposure is a diagnostic criterion of PTSD, one must distinguish that category which is sufficient to cause PTSD and that which increases the risk of a future PTSD diagnosis (but, by itself, is not enough to warrant a diagnosis) [72]. Another aspect, not to be underestimated, is the influence genetic polymorphisms may have on the exposure to trauma per se, mediated by a *gene-by-environment correlation*. Thus, a polymorphism might not only increase the susceptibility to trauma (and thereby to develop subsequent PTSD), but also rather influence the risk of a PTSD diagnosis via an increased trauma incidence rate (either of causative or risk-increasing trauma). With the ever growing feasibility and accessibility of large sample numbers in psychiatric genetics, the identification of rare variants with high penetrance could further substantiate efforts at multilocus predictions, by simultaneously integrating an array of molecular variations, next to other biological, developmental, environmental, epidemiological, or temperamental risk factors. Large-scale *machine-learning algorithms* have, for example, already been applied to identify the most significant predictors of PTSD, including demographic factors (females, married), traumatic experience (almost exclusively violence-related, including organized violence, interpersonal violence, and relationship/sexual violence),

and psychiatric lifetime diagnoses (attention-deficit/hyperactivity disorder, separation anxiety disorder, SP, GAD, and prior unrelated PTSD) [73]. Moreover, genetic findings in stress-related intermediate phenotypes point towards a *bottom-up, multi-dimensional, cross-disorder taxonomy*, for example, by suggesting a considerable degree of genetic correlation between trauma-related and anxiety disorders, spanning categorical classifications, subsyndromal dimensional constructs of symptoms, temperament and environmental risk, and behavioural, neurophysiological, and neuronal circuit readouts (Fig. 80.1). This could result in specified functional domains of behaviour built upon aggregated cross-discipline evidence and grouped into higher-level processes of emotional and cognitive functioning. These may then inform major constructs, like, for example, the negative valence system within the Research Domain Criteria (RDoC) initiative [74]. Finally, future studies will have to systematically explore the potential of genetic/epigenetic tools for treatment response prediction, aiming at establishing a biomarker-driven personalized, individually tailored ‘*precision medicine*’ approach in stress-related disorders [75].

Conclusions

Stress-related disorders display moderate heritability, as outlined by family and twin studies. Molecular genetic studies have begun to elucidate to what extent genetic and epigenetic variations shape the onset, clinical presentation, and therapy of stress-related disorders. So far, these have notably highlighted the relevance of the serotonergic and catecholaminergic systems, as well as HPA axis regulation in stress-related disorders (Table 80.2). GWAS and subsequent cross-sample meta-analyses in large cohort sizes complement the findings on candidate gene and gene–environment approaches. The potentially artificial boundaries created by a categorical diagnostic system are challenged by interdisciplinary studies gathering multi-level evidence for a common, cross-disorder genetic trunk. In light of the apparent intricacy of the implicated principal components and the heterogeneity of interaction effects and genetic pleiotropy, tools offered by systems biology could promote the synthesis of candidate genes into functional molecular processes linking environmental and psychological readouts. A central equivalent of

Table 80.2 Overview of genetic variants implicated in PTSD and cross-disorder post-traumatic stress and anxiety phenotypes. The overall degree of confidence was ranked from ‘+’ = ‘low’ to ‘++++’ = ‘high’, based on the reviewed evidence (refer to the individual sections in this chapter for detailed supporting literature)

Gene	Top risk variant	Evidence from structural, rare variant, GWAS, candidate gene, gene–environment, and epigenetic studies	Overall degree of confidence
SLC6A4	Serotonin transporter polymorphic region (5-HTTLPR) short allele	Meta-analytical evidence for increased PTSD risk [19] Meta-analytical evidence for interaction with high trauma exposure in PTSD risk [19] Increased PTSD symptoms in response to increased trauma exposure [20] Increased PTSD incidence rate and symptom severity [21] Interaction with attentional avoidance of threats, leading to increased PTSD symptoms [22] Increased acute stress symptom intensity [23] Decreased response to sertraline treatment [24] Decreased response to exposure-based CBT [27] Decreased promoter methylation associated with increased PTSD incidence rate and symptom intensity [43] Meta-analytical evidence for increased cortisol response to psychosocial stress [52] Meta-analytical evidence for attentional bias to negatively valenced stimuli [53] Meta-analytical evidence for increased vulnerability to negative environmental influences, but also increased receptiveness to positive influences [56]	++++
FKBP5	rs1360780 T allele	Increased PTSD symptoms in interaction with childhood trauma [29] Increased PTSD symptom relapse following narrative exposure therapy [31] Decreased functional and structural connectivity between the anterior cingulate cortex and the hippocampus [33] Interaction between CpG-specific methylation levels and parental or childhood trauma [44] Decreased methylation associated with increased CBT therapy response for anxiety disorders [45] Increased harm avoidance [67] Increased attentional bias towards threat cues and increased hippocampal activation during threat evaluation [68] Increased amygdala activation in interaction with emotional neglect during childhood [69]	++++
ADCYAP1R1	rs2267735 C allele	Increased PTSD symptom intensity and PTSD incidence rate in females and reduced discriminative fear conditioning [35] Increased female PTSD symptom intensity in interaction with trauma intensity [36] Increased female PTSD symptom intensity in interaction with childhood maltreatment [37] Increased amygdala and hippocampus activity during threat processing [39] Increased methylation associated with increased PTSD incidence rate [35]	+++
KLHL1	rs139558732 C allele	Nominal genome-wide significance in the African-American subgroup of the largest PTSD GWAS to date [16]	++
ADRB2	rs2400707 G allele	Top hit in a multi-candidate gene association study in interaction with childhood trauma exposure and replication in an independent cohort [14]	++
COMT	rs4680 G allele (val158met, val variant)	Increased PTSD incidence in interaction with lifetime trauma abundance [27] Increased startle response to aversive pictures, especially in interaction with childhood maltreatment [70]	+

PTSD, post-traumatic stress disorder; GWAS, genome-wide association study; CBT, cognitive behavioural therapy.

this integration between organism–internal molecular layout and organism–external environmental impact is emerging with psychiatric epigenetics. The potential of a dynamic gene-specific structural change in covalent DNA modifications or histone assembly could finally bridge the gap between genetics and environment. Besides its relevance for innovative and personalized treatments, the clinical potential of psychiatric genetics/epigenetics with regard to stress-related disorders lies in the prospective characterization of disease risk allowing for targeted prevention strategies, designed to counteract genetically determined at-risk states with resilience-increasing interventions and thus lower the incidence of stress-related disorders.

Imaging of stress-related disorders

Navneet Kaur, Cecilia A. Hinojosa, Julia Russell, Michael B. VanElzakker, and Lisa M. Shin

Introduction

Over the past two decades, researchers have used structural and functional neuroimaging techniques and neuroscience-based paradigms to study the mediating neurocircuitry of stress-related psychiatric disorders, with a focus on post-traumatic stress disorder (PTSD). The ultimate goals of such investigations are to identify neurocircuitry abnormalities, to determine whether those abnormalities are useful in diagnosis or in predicting treatment response, and to elucidate treatments that could address the abnormalities and ameliorate symptoms. In the text that follows, we will review the imaging methods, paradigms, and findings of neuroimaging studies of PTSD and acute stress disorder (ASD). We will present the results in the context of a neurocircuitry model of PTSD that emerged from basic neuroscience studies of fear conditioning and extinction. Finally, we will identify current gaps in our knowledge regarding brain structure and function in PTSD and discuss how future studies might address those gaps.

Imaging methods

The structure and function of the human brain have been assessed using neuroimaging techniques, including magnetic resonance imaging (MRI), functional MRI (fMRI), and positron emission tomography (PET) (for a review, see Chapter 12).

MRI generates three-dimensional images of the brain structure [1]. MRI data can be gathered and analysed in different ways, including traditional morphometry, voxel-based morphometry (VBM), and diffusion tensor imaging (DTI). In traditional morphometry, the borders of specific brain regions of interest are traced, and the volumes of these regions are calculated and compared between patients and comparison groups [2]. In VBM, grey matter density is measured at each voxel (that is, three-dimensional pixel) in the entire brain, averaged across participants, and compared between patient and control groups [3]. By measuring the linear diffusion of water molecule protons along axons, DTI can indicate the location, thickness, health, and orientation of white matter tracts [4].

fMRI measures blood oxygen level-dependent (BOLD) signal, which is the difference in magnetic susceptibility in oxygenated vs deoxygenated blood and an indicator of brain activity [1]. During emotional or cognitive tasks, brain structures become metabolically active and consume oxygen. The flow of oxygenated blood to that specific brain region is increased, creating a measurable magnetic resonance (MR) signal [5]. fMRI has good spatial and fair temporal resolution and does not use ionizing radiation, thus making it a highly desirable psychiatric neuroimaging technique.

PET is a functional neuroimaging technique that allows researchers to assess regional cerebral metabolic rate for glucose (rCMRglu), regional cerebral blood flow (rCBF), or receptor occupancy [6]. Due to its poor spatial and temporal resolution and because PET requires the injection of radioactive isotopes, it is not the preferred method for measuring the brain's responses to stimuli or tasks. However, PET is the preferred method for measuring rCMRglu and receptor occupancy.

Paradigms

Functional neuroimaging studies of stress-related disorders commonly use behavioural or cognitive paradigms such as fear conditioning and extinction, symptom provocation, cognitive activation, and resting state methods. For example, fear conditioning and extinction paradigms elucidate the neurobiological basis of failure to extinguish fear responses to stimuli that formerly predicted threat but no longer do—a model for some PTSD symptoms. Fear conditioning involves repeated predictive pairings of a previously neutral conditioned stimulus (CS) (for example, a coloured light) with an aversive unconditioned stimulus (US) (for example, a shock), to create an association resulting in the CS alone eliciting a conditioned response (CR) (for example, increased skin conductance) [7]. Later, during extinction, the CS is repeatedly presented without the US, typically resulting in a diminished CR. Then 24 hours later, the memory of extinction training can be assessed by presenting the CS without the US. In symptom provocation paradigms, researchers present participants with audiotaped descriptions of traumatic events (known as 'scripts') or trauma-related pictures, odours, or

sounds during functional neuroimaging in order to elucidate the brain regions and networks that mediate the symptomatic state [8]. In cognitive activation paradigms, researchers implement cognitive tasks that are known to activate specific brain regions or networks in order to test their function in PTSD vs comparison groups. Finally, resting state paradigms measure fMRI BOLD signal or rCMRglu in the absence of a task [9]. Resting state fMRI permits the examination of functional connectivity, that is, associations between different brain regions.

Neurocircuitry model

Early psychophysiological and neuroimaging studies began gathering evidence for a fear conditioning model of PTSD, which posits that the principles of Pavlovian fear conditioning and extinction underlie the acquisition and maintenance of anxiety and stress-related disorders (reviewed in [7, 10]). Through the lens of the fear conditioning model, sustained symptoms of PTSD and related conditions can be conceptualized as an overexpression of fear to cues that once predicted a threat but should now be considered safe (for example, a veteran who was once injured in a loud combat explosion and who now experiences fear upon hearing loud fireworks). Neuroimaging studies of PTSD have demonstrated structural and functional abnormalities in the brain circuits that underlie fear conditioning and extinction, as well as emotion regulation and memory (Fig. 81.1).

Consistent with its role in the acquisition and expression of conditioned fear and related defensive behaviours, the amygdala is

generally hyper-responsive in PTSD, and in many studies, its activation is positively correlated with symptom severity. The structures comprising the ventromedial prefrontal cortex (vmPFC) generally hold inhibitory influence over the amygdala and are key to the learning and subsequent recall of fear extinction. These vmPFC structures, such as the rostral anterior cingulate cortex (rACC), subgenual anterior cingulate cortex (sgACC), and medial frontal gyrus (MFG), are hypo-responsive in PTSD, indicating functional deficits in learning and remembering safety information and inhibiting fear responses. Conversely, the dorsal anterior cingulate cortex (dACC) is implicated in the expression of learned fear and is hyper-responsive in PTSD, and its activation often positively correlates with amygdala activation. Likewise, the insular cortex tends to be hyper-responsive in PTSD. Given its role in monitoring bodily states, insula activation in PTSD may be related to subjective experiences like anxiety and pain. Findings regarding the hippocampus in PTSD are mixed, with some studies showing hyper-responsiveness and some showing hypo-responsiveness. In PTSD, difficulty identifying safe contexts and updating contextual cues to include safety information, as well as more general deficits in declarative and episodic memory, may reflect hippocampal dysfunction.

While the fear conditioning-based neurocircuitry model of PTSD has been quite fruitful (for example, [7, 10]), it cannot directly account for several important aspects of PTSD symptomatology, including endocrine abnormalities, deficits in executive cognitive function, and ongoing anxiety, in the absence of a conditioned stimulus or context (for example, [11, 12]). However, one of the most striking aspects of the functional neurocircuitry abnormalities seen in PTSD is that they are expressed not only in studies that directly assess fear conditioning and extinction, but also in symptom provocation, cognitive activation, and resting state studies [13]. The following sections will review some of these studies.

Amygdala

Function

Exaggerated amygdala activation in PTSD is now a well-replicated finding that can be observed during fear conditioning paradigms, for example in response to an electric shock US [14] and to the CS during acquisition of conditioned fear (for example, [15, 16]). Furthermore, in PTSD, the amygdala continues to be hyper-responsive to the CS, even during or after extinction (for example, [16, 17]). These findings are evidence that, relative to controls, the amygdala in those with PTSD is hyper-responsive to threat and to cues that predict threat and continues to be hyper-responsive to such cues after they no longer predict threat. The amygdala also shows exaggerated responses to trauma recollection (for example, [18, 19]) and trauma-related sensory stimuli (for example, [20–22]). Interestingly, amygdala hyper-responsivity can occur in response to trauma-unrelated emotional stimuli such as emotional facial expressions (Fig. 81.2) (for example, [23–27]) and aversive images (for example, [28, 29]). Individuals with PTSD even show exaggerated amygdala activity at rest [30] or in response to tasks using neutral stimuli [31]. However, not all studies have found increased amygdala activation in PTSD (for example, [32–34]).

Fig. 81.1 Structural magnetic resonance images showing brain regions of interest in PTSD. (a) A sagittal section showing the dorsal anterior cingulate cortex (dACC), as well as structures that comprise the ventromedial prefrontal cortex (vmPFC) such as the rostral anterior cingulate cortex (rACC), medial frontal gyrus, and subgenual anterior cingulate cortex (sgACC). (b) A horizontal section showing the bilateral insular cortex. (c) A sagittal section showing the hippocampus and amygdala. In PTSD, the amygdala, dACC, and insula tend to be hyper-responsive, and the vmPFC tends to be hypo-responsive. Findings regarding the hippocampus have been more mixed, as they may depend on the specific experimental paradigm.

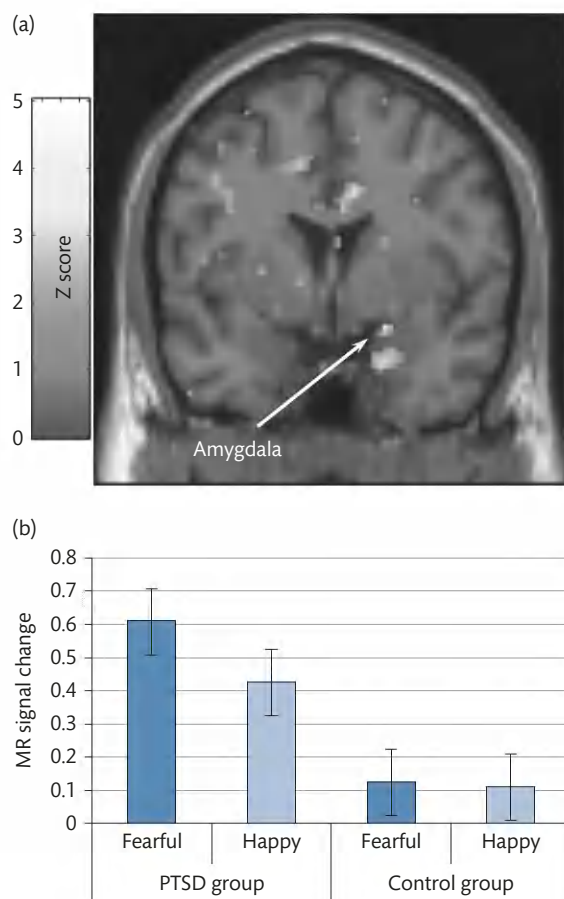

Fig. 81.2 (see Colour Plate section) Example of functional magnetic resonance imaging (fMRI) data. (a) Amygdala activation to fearful vs happy facial expressions was greater in the PTSD group vs control group. (b) MR signal change in the amygdala in each condition for each group. Error bars represent the standard error of the mean.

Adapted from *Arch Gen Psychiatry*, 62(3), Shin LM, Wright CI, Cannistraro PA, *et al.*, A functional magnetic resonance imaging study of amygdala and medial prefrontal cortex responses to overtly presented fearful faces in posttraumatic stress disorder, pp. 273–81, Copyright (2005), with permission from American Medical Association.

Within PTSD groups, amygdala activation is positively correlated with PTSD symptom severity (for example, [18, 23, 26, 35–37]), and symptomatic improvement is associated with a decrease in amygdala activation (for example, [38–40]). Although these findings might suggest that exaggerated amygdala activation is a state-like, acquired characteristic of PTSD, other findings suggest that it may reflect a trait-like vulnerability factor—pre-trauma amygdala responses predict greater PTSD symptoms following trauma (for example, [41, 42]). Finally, pretreatment amygdala activation appears to predict a less favourable response to treatment (for example, [43, 44]).

Far less research has been conducted on amygdala function in ASD. In a small longitudinal study, Reynaud and colleagues (2015) found that firefighters who developed ASD showed a greater increase in amygdala activation post-trauma, relative to pre-trauma baseline, despite not showing differences in amygdala activation before trauma [45]. However, given the small sample in the ASD group ($n = 2$), this study requires replication.

Structure

Findings regarding amygdala structure in PTSD are somewhat mixed. Several studies have found smaller amygdala volumes or reduced grey matter density in PTSD [46–50], with some studies reporting a negative correlation between amygdala volume and symptom severity (for example, [46, 51, 52]). However, some studies have found greater amygdala volumes in PTSD (for example, [53–55]) or no group differences (for example, [56–60]). These discrepancies could be attributed, in part, to variability in imaging methods and/or in participant samples across studies. Indeed, one meta-analysis suggested that diminished amygdala volumes are significant when PTSD groups are compared to trauma-unexposed control groups, but not trauma-exposed control groups [61]. In general, the latter is a more appropriate comparison group as it controls for exposure to trauma. Furthermore, because attempts to relate structural and functional abnormalities in the amygdala in PTSD have been lacking, it is difficult to determine whether structural abnormalities in the amygdala in PTSD are the origin of corresponding functional abnormalities. More studies examining amygdala structure and function within the same cohort are needed.

In the only study to examine amygdala structure in ASD, no abnormalities were found [62].

Ventromedial prefrontal cortex

Function

Individuals with PTSD show relatively diminished vmPFC activation during extinction learning and recall (for example, [15, 17, 63]), during the recollection of traumatic events (for example, [18, 33, 64–71], but see [72]), in response to other trauma-related stimuli (for example, [21, 67, 73–75]), in response to trauma-unrelated emotional stimuli such as fearful facial expressions or unpleasant scenes (for example, [22, 24, 27, 76–78]), and even in response to neutral stimuli or at rest (for example, [31, 79–85]). Finally, successful treatment with cognitive behavioural therapy (CBT), eye movement desensitization and reprocessing (EMDR), or a serotonin reuptake inhibitor (SSRI) appears to be related to increased prefrontal cortex activation (for example, [39, 40, 43, 86]).

However, not all studies have reported diminished vmPFC activation in PTSD; some have reported no group differences or greater activation in PTSD (for example, [87, 88]). The direction of the functional abnormality in the vmPFC may depend on the state of the participants and the nature of the task completed in the scanner. For example, greater vmPFC activation can be observed when PTSD groups experience a dissociative state (for example, [87, 89]) or view stimuli below the threshold of conscious awareness [90].

Structure

Structural MRI studies of PTSD have reported abnormalities in the vmPFC in the form of reduced volumes (for example, [50, 53, 57, 91–96]), reduced white matter tract integrity (for example, [97, 98]), and reduced grey matter density (for example, [99–108]). In addition,

relatively smaller pretreatment grey matter density in the pregenual ACC predicted a less favourable response to CBT [43]. Kasai and colleagues used monozygotic twin pairs discordant for combat exposure to determine whether grey matter density reductions observed in PTSD are familial vulnerability factors for developing PTSD or an acquired characteristic of PTSD. Results showed that grey matter volume density reductions in the pregenual ACC were an acquired characteristic of PTSD [102].

The only study of vmPFC structure in ASD did not find abnormalities [62].

Dorsal anterior cingulate cortex

Function

Neuroimaging studies have shown dACC hyperactivation in PTSD, relative to trauma-exposed control groups, during conditioning, early extinction learning, and extinction recall (for example, [17, 63, 109]). Furthermore, dACC activation is negatively correlated with extinction recall in PTSD and trauma-exposed non-PTSD controls [17], and dACC resting metabolism in PTSD is positively correlated with both activation during extinction recall and symptom severity in PTSD [109].

dACC hyper-responsivity in PTSD has also been found in studies presenting trauma scripts [18] and words [110], emotional facial expressions [81], neutral stimuli (for example, [31, 82, 111]), and in resting state studies [112]. In one study, greater dACC activation in response to negative vs neutral photographs predicted a poorer outcome following treatment [44].

The findings of two twin studies have suggested that dACC hyperactivity and hyper-responsivity are familial vulnerability factors for developing PTSD following trauma exposure. In the first, Shin and colleagues assessed rCMRglu in combat-exposed veterans with PTSD and their identical co-twins unexposed to combat, as well as combat-exposed veterans without PTSD and their identical co-twins unexposed to combat. Veterans with PTSD and their co-twins had significantly greater resting rCMRglu in the dACC/mid cingulate cortex (MCC), compared with veterans without PTSD and their co-twins (Fig. 81.3) [112]. Similarly, using fMRI and the Multi-Source Interference Task, Shin and colleagues found greater dACC activation in combat-exposed veterans with PTSD and their unexposed co-twins, as compared to combat-exposed veterans without PTSD and their co-twins [111].

Whether the dACC is hyperactivated in ASD is not clear. In one symptom provocation study, Cwik and colleagues found greater dorsal medial frontal cortex activation in participants with ASD, compared to healthy trauma-unexposed control participants [113]. However, this increased activation occurred not in dACC proper, but in a region just dorsal to that.

Structure

Reduced grey matter volume in the dACC has been observed in trauma survivors with PTSD, compared to those without PTSD (for example, [103, 114]).

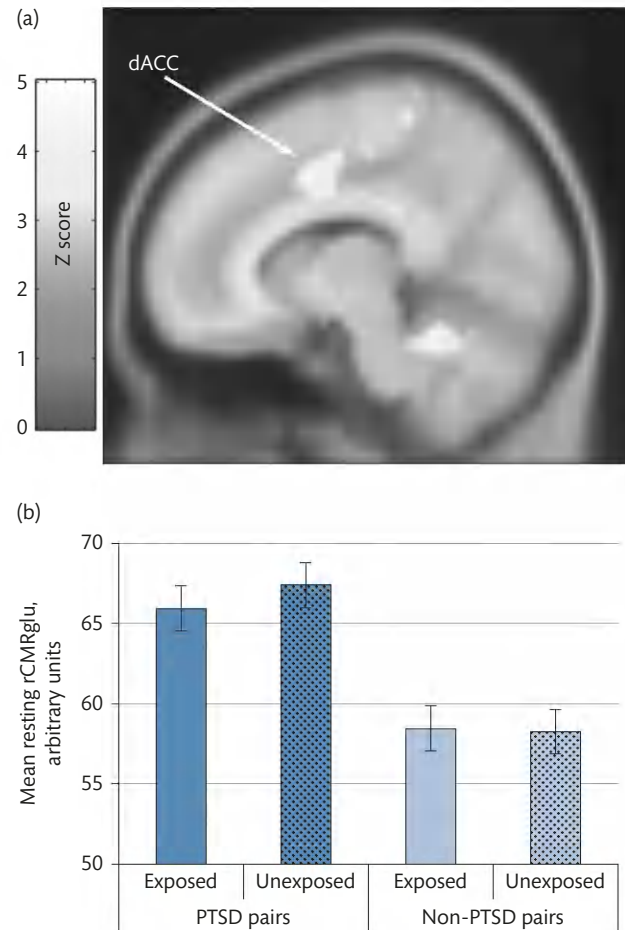

Fig. 81.3 (see Colour Plate section) Example of positron emission tomography (PET) data. (a) Greater resting regional cerebral metabolic rate for glucose (rCMRglu) in the dorsal anterior cingulate cortex (dACC)/mid cingulate cortex (arrow) in combat-exposed twins with PTSD and their identical co-twins, compared with combat-exposed twins without PTSD and their identical co-twins. (b) Group rCMRglu means. Error bars represent the standard error of the mean.

Insula

Function

The insula is hyper-responsive in PTSD during the recollection of traumatic events (for example, [64, 115, 116]), the presentation of other trauma-related stimuli (for example, [21, 110, 117, 118]), the presentation of emotional, but trauma-unrelated, stimuli such as negative words, fearful facial expressions, and aversive photographs (for example, [76, 87, 119, 120]), and at rest [85]. In addition, greater insula activation in response to negative vs neutral photographs predicted a poorer outcome following treatment [44]. However, not all studies have reported insula hyper-responsivity in PTSD (for example, [22, 29, 68]).

Structure

Insula volume [57] and grey matter density (for example, [100, 102, 104, 121]) are reduced in PTSD, relative to comparison groups. Furthermore, a twin study has shown that diminished grey matter volume in the insula appears to be an acquired characteristic of PTSD and is negatively correlated with re-experiencing symptoms. Thus, this abnormality appears to be state-like and hence could potentially be used in diagnosis or as a biological indicator of symptomatic improvement [102].

Hippocampus**Function**

Functional neuroimaging studies of the hippocampus in PTSD have been mixed. Some studies found that the hippocampus is hypo-responsive in PTSD, for example during extinction recall [17], script-driven imagery (for example, [40, 69]), trauma-unrelated and neutral stimuli (for example, [73, 122–124]), and at rest (for example, [125, 126]). However, other studies show that the hippocampus is hyper-responsive in PTSD during tasks with trauma-related stimuli such as words [127] and emotional and neutral stimuli (for example, [28, 79, 90, 123, 128]). These mixed findings may be accounted for by differences in task demands upon the hippocampus or imaging modality [129].

Structure

Many studies have reported reduced overall hippocampal volume or grey matter volume in PTSD, compared to control groups (for example, [48, 57, 80, 93, 108, 130–141]). In addition, one study found that relatively smaller hippocampal volume predicted a less favourable response to treatment with prolonged exposure [142]. However, a few studies have reported larger hippocampal volume in PTSD (for example, [53, 143]) or no differences in hippocampal volume (for example, [50, 144–148]).

The results of at least one study suggest that diminished hippocampal volume is a familial vulnerability factor rather than an acquired characteristic of PTSD. In a twin design similar to those described previously (for example, [111, 113]), Gilbertson and colleagues found smaller hippocampal volumes in combat veterans with PTSD and their identical co-twins, relative to combat veterans without PTSD and their identical co-twins. Furthermore, severity of PTSD in the combat veterans was negatively correlated with hippocampal volume of their identical co-twins, consistent with a vulnerability factor [149].

Future directions

Over the past 20 years, an enormous amount of progress has been made in our understanding of the neurocircuitry of PTSD. Despite this, many questions remain either unanswered or entirely unaddressed. For example, we do not yet know whether neurocircuitry abnormalities differ by trauma type, duration of trauma, and age of trauma onset. Part of the problem lies in the fact that single studies tend to focus on just one trauma type, duration, and age of onset. In the future, different imaging data sets, all using the same paradigm

(for example, fear conditioning/extinction), might be combined to permit a proper examination of these variables.

Most studies that we reviewed have included participants with chronic PTSD, and whether the findings extend to acute PTSD is undetermined. On a related note, as shown in our literature review, very little is currently known about the neurocircuitry of ASD. Practically speaking, ASD is difficult to study because an ASD diagnosis must be made within the first month after a traumatic event. This requirement makes it challenging to find and enrol such participants for imaging studies.

Another question that is not yet fully answered relates to the origin of neurocircuitry abnormalities in PTSD. Most current studies are cross-sectional and hence cannot determine whether these abnormalities reflect pre-existing familial vulnerability factors or acquired characteristics of the disorder. If an abnormality, such as dACC hyper-responsivity, is a familial vulnerability factor and can increase the risk for developing PTSD, it could potentially be used to screen individuals who are likely to experience trauma and develop PTSD such as police officers and firefighters. In contrast, if an abnormality is an acquired characteristic of PTSD, it could potentially be used as a biological marker in diagnosis or in the assessment of treatment response. In the future, studies implementing longitudinal designs (that include a baseline assessment of participants prior to trauma exposure and follow participants over time after trauma) or twin designs will help clarify the origin of neurocircuitry abnormalities in PTSD.

In the United States, the National Institute of Mental Health (NIMH) is now requiring that all psychiatry research it funds be conducted in a new framework that focuses on symptom dimensions, rather than on categorical diagnoses. This means that future studies of PTSD will be based on correlational analyses associating symptom severity with other measures like brain activation, psychophysiology, behavioural performance, and self-report. One difficulty with this change in approach is that the results of new studies may be difficult to fully reconcile with those of existing studies that took a more categorical approach.

One of the goals of neuroimaging studies is to elucidate the brain regions or networks that function abnormally in PTSD. Such information could lead to new treatments that are focused on ‘normalizing’ that brain function. In the future, researchers will undoubtedly use non-invasive neuromodulation tools and techniques such as transcranial direct current stimulation (tDCS) and transcranial magnetic stimulation (TMS) to determine whether modulating brain function can ameliorate symptoms.

Another important potential clinical application of neuroimaging data in psychiatry is the prediction of response to treatment. For example, although CBT is arguably the most effective in the treatment of PTSD, not all patients respond well, and finding a good treatment fit can take months to years. Thus, patients and clinicians would benefit from having objective pretreatment measures that can be used to predict treatment response. Neuroimaging could be such a measure. Furthermore, researchers are beginning to use sophisticated machine-learning algorithms (which include multiple measures such as imaging, genetic, psychophysiological, behavioural, clinical, and demographic) to best distinguish between treatment responders and non-responders and hence improve the prediction of treatment response.

Conclusions

Neuroimaging studies of stress disorders (predominantly PTSD) have revealed functional abnormalities consistent with a fear conditioning model. The results reviewed herein suggest that the amygdala and dACC are hyper-responsive in PTSD, consistent with their involvement in fear learning and expression. In contrast, the vmPFC is hyporesponsive, as might be predicted, given its role in inhibiting the amygdala during the successful extinction of fear. The insula is hyper-responsive in PTSD, likely reflecting the processing of interoceptive cues such as anxiety. Finally, functional abnormalities in the hippocampus have been more mixed in PTSD, and further research ought to clarify its role in memory and identifying safe contexts in this disorder.

Overall, although much progress has been made in our understanding of the neurocircuitry of PTSD, many questions remain unanswered. Future research will be needed to clarify the trauma-related factors that affect neurocircuitry abnormalities, the origin of such abnormalities, and the role of neuroimaging in assessing and predicting treatment response.

Primary prevention and epidemiology of trauma- and stress-related disorders

Maria Bragesjö, Emily A. Holmes, Filip K. Arnberg, and Erik M. Andersson

Introduction

In this chapter, we will focus on prevention of disorders that largely arise after single traumatic events. Such events can strike many people at once, such as disasters or terrorist attacks, or only single or few individuals such as severe motor vehicle crashes or a sexual assault. We focus on strategies to help prevent post-traumatic stress disorder (PTSD) and acute stress disorder (ASD). These are the two most well-researched disorders within the new *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) ‘Trauma- and stressor related disorders’ chapter [1]. Further, a unique aspect of both these disorders within DSM-5 is the presence of an *index traumatic event* or events. Therefore, once we know that such an event has occurred, PTSD and ASD are mental disorders for which we could, and should, seek strategies to prevent the emergence of the full-blown disorder. We first discuss what prevention means in this context. Next, we consider diagnostic features of PTSD and ASD to understand what it is that could be prevented after trauma. Then, we consider the associated epidemiology and risk indicators of developing these disorders, that is, the scale of the prevention challenge and who we might target. Given the limited prevention strategies to date, considerable further research is needed to advance the field.

Trauma- and stressor-related disorders

In DSM-5, a new chapter ‘Trauma- and stressor-related disorders’ was formed that includes seven diagnoses (**Box 82.1**) [1]. The focus in this chapter is on PTSD and ASD as the two most well-researched disorders within this new DSM-5 chapter [1]—and the ones for which there is a clear clinical demand for prevention. Critically, a unique aspect of both these disorders within DSM-5 is the occurrence of an *index traumatic event* or events. A traumatic event here is defined as exposure to actual or threatened death, actual or threatened serious injury, or actual or threatened sexual violence [1]. Therefore, once we know that such an event

Box 82.1 Trauma- and stress-related disorders according to DSM-5

- Acute stress disorder
- Post-traumatic stress disorder
- Reactive attachment disorder
- Disinhibited social engagement disorder
- Adjustment disorders
- Other specified trauma- and stressor-related disorder
- Trauma- and stress-related disorder not otherwise specified

Source: data from *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, DSM-5, Copyright (2013), American Psychiatric Association.

has occurred, PTSD and ASD are mental disorders for which we could, and should, seek strategies to prevent the emergence of the full-blown disorder.

Regarding the other diagnoses in the ‘Trauma- and stressor-related’ section of this book (see Chapters 78–85), reactive attachment disorder and disinhibited social engagement disorder are viewed as general consequences of inadequate child care or maltreatment. The diagnosis of adjustment disorder reflects the case when someone is in a serious crisis and experiences very distressing reactions to, and cannot cope with, any of a great variation of stressors, often related to life events such as unemployment or divorce. The crisis is expected to resolve within a few months. The diagnoses of ‘other specified’ or ‘not otherwise specified’ trauma- and stressor-related disorder are clinically relevant when someone presents with, for example, a debilitating reaction to a sudden death in the family that is beyond a crisis or when the presenting problems do not match any other trauma-related disorder. All of the last three disorders in **Box 82.1** are of clinical utility but have not been researched to any greater extent—because of their great variation in what they encompass, they are difficult targets for *prevention*. The childhood-onset disorders require preventive strategies targeted towards parents and are not described further in this text.

Prevention strategies adapted to trauma- and stressor-related disorders

Prevention is, broadly speaking, defined as stopping ‘something’ from happening or arising [2]. Preventive interventions can be implemented in many different ways. A long-used medical model of prevention is the ‘three-level concept of prevention’ developed by Leavell and Clark [3, 4] in the late fifties. This model makes a distinction between primary, secondary, and tertiary prevention interventions from a physical health perspective. The primary prevention level refers to health promotion and protection from a disease or disorder, for example immunization from a disease through vaccination. The secondary prevention level refers both to early detection and treatment of a disease in order to avoid chronicity (for example, prostate-specific antigen screening to detect prostate cancer). Tertiary preventions are interventions that aim to reduce as much damage as possible from a disease and can be considered equivalent to physical rehabilitation.

Prevention for mental disorders also has as its aim the reduction of symptoms, and ultimately the disorder [4]; the term primary prevention can encompass a wider range of definitions, compared with this medical model [3, 5]. Primary prevention for mental disorders has been described as including interventions which are ‘universal’ (targeting the whole population), ‘selective’ (targeting population subgroups or individuals who are at higher risk than the average population), and ‘indicated’ (targeting high-risk people who are identified as *‘having minimal detectable signs or symptoms foreshadowing mental disorder or biological markers indicating a predisposition but who do not meet diagnostic criteria for the disorder at that time’* [3, 5]. Of note here is that, according to this latter aspect, primary prevention in a trauma context could include targeting those with early symptoms (such as intrusive memories of the traumatic event) which may precede the diagnosis of a full-blown disorder such as ASD and PTSD. In a mental health context, secondary prevention has been described as seeking to lower the prevalence through early detection and treatment of a diagnosable disease. Tertiary prevention interventions include those to reduce disability and prevent relapse. The World Health Organization [3, 5] uses similar terms regarding mental health and notes that given that while the traditional medical model *‘works well for medical disorders with a known etiology. Mental disorders, on the other hand, often occur due to the interaction of environmental and genetic factors at specific periods of life. It becomes difficult even to agree on the exact time of onset of a mental disorder’*. However, as discussed, PTSD and ASD are unique in DSM-5 in that their aetiology is clear and forms part of the diagnosis—the presence of an index traumatic event.

In relation to aetiology, another question of importance in prevention research is *when* a preventive intervention should be administered. The definition of primary prevention requires further thought when applied to psychological trauma. Several terms are in use synonymously. Some argue that primary prevention for trauma- and stress-related disorders should only encompass interventions *before* trauma exposure, while any intervention after trauma exposure, but before the development of PTSD (for example, before 1 month of symptoms), is to be considered secondary prevention [6]. However, as described, a form of prevention focusing on early symptoms prior to a diagnosis may have utility; traumatic events

are often unpredictable, which restricts knowledge of who to target in advance in the reality of limited health care resources. Therefore, there would be benefits for the mental health field in developing ‘selective’ intervention strategies and tools to offer soon *after* a traumatic event where the applicability is restricted to a group with higher known risk of the disease emerging (see Epidemiology of ASD and PTSD, p. 862). Thus, another related view is that, in the mental health field, it may also be possible, by analogy, to provide a form of ‘therapeutic vaccination’ after an index traumatic event has occurred (that is, a *post-event* preventive intervention). For example, in physical medicine, *after* a patient is bitten by a dog, a ‘therapeutic vaccine’ [7] is given to protect against rabies. After a traumatic event, an equivalent ‘primary’ prevention approach would be the metaphor of a ‘cognitive therapeutic vaccine’ that could be administered soon *after* the event—whether psychological or pharmacological. We are not at the stage where there is a strong evidence base for this approach, but the analogy of preventing the worsening of symptoms soon after an index stressor is a useful one, both clinically and to guide research.

While the remainder of this chapter will focus on pragmatic and research approaches to prevention from a mental health perspective, it should be noted that many other fields have a role to play in achieving a wider prevention agenda related to trauma. For example, public health and efforts in society in general should seek to prevent potentially traumatic events such as road traffic accidents, assault with weapons, rape, and so forth. Reducing the incidence of potentially traumatic events would clearly have a major role to play in reducing the incidence of disorders such as ASD and PTSD. Examples of such intervention include implementation of blood alcohol limits for drivers, addition of separation barriers to freeways, strengthening of community-based support services, and laws limiting access to firearms.

About post-traumatic stress disorder

We first consider the background, the definition of traumatic events, and the diagnostic features of PTSD to understand the nature of symptoms from this particular disorder that could be prevented after trauma. PTSD is defined by a set of criteria that include the event characteristics, four groups of symptoms, a duration criterion, and a distress/disability criterion [1]. The disorder is seen as the cardinal psychopathological consequence of traumatic events, although such events may also contribute to several other forms of psychopathology [8]. PTSD is often associated with high levels of distress, a high degree of chronicity, and high levels of disability [9–11].

The traumatic event that precipitates PTSD is defined as the ‘index event’ and means that the individual is exposed to actual or threatened death, actual or threatened serious injury, or actual or threatened sexual violence [1]. Thus, everyday stressors, like losing a job or going through a divorce, do not meet the criterion for a potentially traumatic event in DSM-5. The exposure to the event could have occurred directly or indirectly (learning that a close relative/friend has been through a trauma or being exposed to aversive material through work). It is not possible to receive a diagnosis of PTSD after being exposed indirectly through electronic media, television, or

movies (that is, by watching a frightful film clip on the Internet), unless it occurred in the line of work (such as by police reviewing traumatic crime footage). It is important to note that no set of objectively discerned individual characteristics of any kind of event have been found to consistently lead to PTSD [12–14]. The subjective experience of the threatening nature of the event appears to be key factor in the ‘toxicity’ of an event [15]. That is, people who experience high levels of threat peritraumatically have higher risk for later PTSD [15–17].

The four symptom clusters of PTSD in DSM-5 include intrusion symptoms, avoidance, cognitive and mood changes, and arousal. The intrusion symptoms include intrusive memories of the trauma, flashbacks, nightmares, and distress in response to reminders of the trauma.

The core clinical feature of PTSD is arguably the recurrent, involuntary, and intrusive distressing memories of the traumatic event [18]. Such memories are intrusive in that they spring to mind unwanted and unbidden. They typically take the form of discrete episodes from within a trauma—so called ‘hotspots’ in the memory [19]. They are recurrent in that it is often the same selection of hotspot scenes that appear repeatedly (rather than, say, the whole trauma from beginning to end). Such memories are ‘seen in the mind’s eye’ and ‘heard in the mind’s ear’—that is, they comprise typically visual, but multisensory, mental images [20].

The next symptom cluster of PTSD involves avoidance. PTSD patients often try to avoid stimuli that are associated with the traumatic event. They therefore often avoid thoughts and feelings or situations/persons/places that are reminders of the experienced trauma (for example, car crash survivors often avoid driving or using public transportation). Consequently, many trauma survivors live restricted lives, constantly avoiding reminders of the trauma.

The third symptom cluster involves marked changes in cognitions and mood after trauma. Some trauma survivors with PTSD report a persistent negative emotional state (e.g. shame), or that they feel numb and cannot get in touch with their emotions as they did before (e.g. happiness). They can experience persistent cognitive symptoms, with negative beliefs about themselves (for example, ‘I’m a bad person’), others, and the world (for example, ‘The world is unsafe’), and distorted perceptions about why the trauma occurred are also common (for example, ‘It was my fault that the trauma occurred’).

The fourth symptom cluster of PTSD involves arousal symptoms. PTSD patients often describe themselves as in a chronic state of alert, constantly scanning the environment for potential threats. This group of symptoms also includes insomnia, irritability, and concentration—these symptoms can follow from the hypervigilance and disrupted stress responses.

The symptoms must have been present for at least 1 month since the index event. This is called the ‘duration criterion’, and was originally introduced to reduce the risk of overdiagnosis of common acute responses to distressing events. The symptoms should cause clinically significant distress or impairment in social, occupational, or other important areas of functioning, and they should not be better explained by another psychiatric or somatic disorder. Hence, it is important to note that the symptoms must not be attributable to the effects of a substance (for example, medication, alcohol) or another psychiatric or medical condition, stating the importance of a good differential diagnosis.

About acute stress disorder

ASD was introduced in DSM-IV as a way to describe a distressing response *within* the first month after the event that could identify patients at high risk for developing PTSD [21]. The diagnostic criteria of ASD are similar to those of PTSD, except that the presenting problems do not have to be as many as for PTSD and they should be present during the first month.

ASD was originally thought to be an antecedent to PTSD, and although it has some bearing on how to identify trauma survivors who are at high risk for developing PTSD, it has become evident that many patients with ASD never develop PTSD. In fact, of those diagnosed with ASD, less than half will meet criteria for PTSD after 12 months [22].

Assessing PTSD and ASD

The assessment of ASD and PTSD is slightly different from the assessment of other mental disorders in that the clinician must assess not only the presence and severity of the symptoms, but also whether or not the individual’s experience satisfies the traumatic event criterion and if the presenting symptoms started or worsened after the event. It should be evident to the reader that in order to make a diagnosis of ASD or PTSD, it requires both trained assessors and time for the assessments. The clinician should be trained and preferably use well-described methods such as the Acute Stress Disorder Interview [23] or the Clinician-Administered PTSD Scale [24]. Next, we consider the scale of occurrence of traumatic events and stress-related disorders.

Epidemiology of ASD and PTSD

Prevalence rates

Traumatic events are common in the population. In the large World Mental Health (WMH) surveys, where more than 70,000 respondents were interviewed between 2001 and 2012, the lifetime exposure to potentially traumatic events was estimated to be 70% across 24 countries [25].

How prevalent is PTSD? One influential study was the National Comorbidity Survey, conducted in the United States in 1995, in which the lifetime prevalence rate of PTSD in the United States was estimated to be 8% [10]. Within the UK, the best estimate of the whole population PTSD point prevalence is 3%, which is derived from the 2007 Adult Psychiatric Morbidity Study [26]. In the WMH surveys, the lifetime prevalence of PTSD was estimated to be 3.9%, with two-thirds having an adult age of onset [25]. Interestingly, in populations with a high risk of exposure, the prevalence rates vary and are not necessarily higher than the general population estimates. For example, United States military veterans seem to be at higher risk of combat-related PTSD than UK veterans [27]. Among UK veterans, the prevalence was 3–6%, which is close to the estimates of PTSD in the general population. A review of resettled refugees concluded that resettled refugees in western countries could be approximately ten times more likely to have PTSD than the general population in those countries [28], which is perhaps unsurprising, given the dose-wise effect of trauma exposure and the multiple exposure of different events, for

example, war, torture, and rape, in this group. Additional studies of rescue and recovery workers suggest that the risk of PTSD decreases, the more training and familiarity the personnel in high-risk occupations have with the task [29].

Some research studies have pointed to evidence that certain types of traumatic events make it more likely to develop PTSD. Notably, high rates of occurrence are seen after rape and torture. For example, the risk of developing PTSD is approximately ten times higher in populations exposed to assault, compared to populations that survive a motor vehicle crash [30]. It should be noted that there are challenges with comparing the conditional prevalence across event types; for example, people at risk of an assault can be more likely than others to have a history of potentially traumatic events. Prevention strategies aimed towards victims of high-risk events such as interpersonal violence would therefore benefit from taking into account the influences of past stressors [31].

The time course of trauma symptoms

As previously mentioned, it is common to experience some adverse reactions such as intrusive memories, avoidance, and hyperarousal in the immediate aftermath of trauma. For many these symptoms disappear without professional help [32]. This is thought to be the case in most trauma populations, including motor vehicle accidents [33], rape victims [34], New York City residents following the terrorist attacks of 11 September 2001 [35, 36], and for individuals who experienced the 2004 South East Asia tsunami [37].

The high proportion of exposed individuals who either are resilient or experience a natural recovery after trauma means that the timing of preventive interventions is important to consider. High natural recovery rates mean that many people that are encompassed by unselective prevention strategies shortly after an event could recover anyway, raising issues of cost and efficiency. Interventions that target high-risk groups among survivors need to consider the time frame. For example, an initial screening to select people for preventive interventions may be based on current distress levels, though more research on screening would be needed to inform evidence-based practice.

The risk of negative consequences of intervening in people who otherwise would recover anyway is also important to consider. Adverse effects of psychological interventions have only recently received greater attention, driven particularly by the discovery of adverse consequences from some early interventions for trauma survivors and bereaved individuals [38, 39]. Several reviews have shown that critical stress incident debriefing, a widely disseminated intervention after trauma, may *increase*, rather than decrease, the risk of developing PTSD [40]. In summary, to establish successful prevention strategies of trauma-related disorders in populations exposed to highly distressing events, there is a need to consider not only what the strategies should be, but also to pay careful attention to the target population and the time course of action.

Trauma and risk indicators

There has been extensive research in the last decades on risk factors in the trauma population and identifying individuals most vulnerable following exposure to a traumatic event. A common classification of different types of indicators of risk are pre-trauma, peritraumatic, and post-trauma indicators.

Pre-trauma risk indicators

Gender is perhaps the most well-known pre-trauma risk factor. A consistent finding has been that women have more or less twice the risk of PTSD, as compared to men overall [41–44]. For example, one large study found a lifetime prevalence of PTSD of 20.4% in female trauma survivors and 8.2% of male trauma survivors [10]. However, studies are also needed which control for exposure to the same type of event. Low socio-economic status, previous exposure to highly distressing events, previous psychiatric symptoms, and high levels of neuroticism also increase the risk of later developing PTSD [16, 45]. New research suggests that there may be genes that make certain people susceptible to PTSD. Genetic research has expanded greatly the last decade, and twin studies estimate the heritability of PTSD to up to 35%, but this varies when individual PTSD symptoms are examined [46].

Peritraumatic risk indicators

What happens during the event plays an important role in the development of PTSD. People who thought that they would be killed or severely injured during the event have a higher risk of developing PTSD [16, 17], and very high levels of distress emotions or dissociative symptoms during, and immediately after, the trauma are strong indicators of PTSD [16, 47, 48]. In contrast, the degree of physical injuries of the trauma, sometimes thought of as an objective measure of exposure severity, does not seem to affect the probability of developing PTSD [16, 49, 50].

Post-trauma risk indicators

Low socio-economic status plays a role post trauma as well as pre trauma in the development of PTSD [16, 51, 52]. Perceptions of a lack of social support is one of the strongest indicators of PTSD [16]. Catastrophic appraisal of the traumatic event in the long-term aftermath of trauma is also considered a risk factor [32].

Some studies have elucidated a relationship between biomarkers and the development of PTSD [53]. One recent meta-analysis showed that higher heart rate after trauma exposure predicted long-term PTSD symptoms. Neither cortisol nor blood pressure was associated with any elevations in PTSD symptoms [54]. Heart rate, cortisol, and systolic blood pressure played a significant role in developing PTSD in younger patients, but not in the older population [54]. Inflammatory responses in the aftermath of trauma has also been investigated in several studies, showing heightened concentrations of inflammatory signals, including cytokines and C-reactive protein [55].

Although there has been considerable research on the determinants of trauma and PTSD, science has not yet found decision algorithms that can reliably distinguish patients who require intervention from those who will recover on their own.

Primary prevention of PTSD

Primary prevention strategies for PTSD have traditionally used two types of approaches—they have either targeted all individuals exposed to a trauma (for example, a disaster) or targeted those individuals who are displaying symptoms of ASD. The most effective approach remains unclear. Although several risk indicators for

PTSD have been identified, their clinical application is underdeveloped for targeting preventive interventions, and more evidence is needed.

Screening in the aftermath of trauma

The diagnostic accuracy of screening instruments in the immediate aftermath of traumatic events is unclear at this point. Although there have been several studies investigating the usefulness of PTSD/ASD questionnaires in the immediate aftermath of trauma, results have shown overall low positive predictive values [56, 57], meaning that if we would screen all individuals who were afflicted by an event by using a cut-off value on a self-report screening measure, the number of false positives could far outnumber the true cases that would be detected. Consequently, the development of European guidelines for psychosocial services following a disaster [58] reached a consensus against screening everyone affected because of the absence of evidence for the effectiveness of screening and scarce resources could be better allocated elsewhere.

Pharmacological prevention

Several pharmacological treatments have been proposed as possible preventive strategies of PTSD. The first trials testing pharmacological agents in a preventive context for PTSD have used benzodiazepines. However, these trials showed negative results. If anything, there were tendencies on harmful effects, that is, benzodiazepines could potentially increase the risk of developing PTSD [59, 60].

Another pharmacological preventive approach that has been tested is the β -adrenergic blocker propranolol. Propranolol is thought to block and disrupt the consolidation of newly acquired trauma memory via post-synaptic β -adrenergic receptors in the basolateral nucleus of the amygdala [61]. One double-blinded trial conducted in 2002 with 41 participants found positive results in preventing PTSD with propranolol in an emergency room setting [62]. However, a subsequent trial comparing propranolol with gabapentin and placebo ($N = 38$) administered propranolol within 48 hours of trauma exposure and found no difference in PTSD rates in physically ill patients [63]. One study randomized 29 children to propranolol or placebo; results showed a tendency to negative effects in girls and no significant difference in PTSD rates overall, compared to placebo [64]. One double-blinded trial with 41 participants attempted to prevent PTSD by administering propranolol within 6 hours after exposure to trauma in an emergency room context. Results were overall negative, but patients randomized to propranolol showed less psychological reactivity, compared to the placebo group, when confronted with a trauma reminder 3 months later [65].

The administration of glucocorticoids is thought to result in the impairment of retrieval of declarative memory and to decrease the hyperactive fear response that is associated with the newly acquired trauma memory [66]. Schelling *et al.* performed two RCTs examining the effects of stress doses of hydrocortisone in preventing PTSD symptoms, following septic shock and cardiac surgery, in intensive care units. They found a significant reduction of PTSD symptoms in long-term survivors, as well as improvements in quality of life outcomes [67, 68]. Another RCT in an emergency room context on high-dose hydrocortisone treatment administered in the first hours after trauma exposure was associated with a lower risk of

developing PTSD [69]. Administration of low-dose hydrocortisone in another RCT was found to prevent the onset of PTSD, compared to placebo, particularly in acutely injured trauma victims without a history of significant psychopathology [70].

There have also been attempts to test other pharmacological agents such as morphine [71], SSRIs [72], and ketamine [73], but high-quality randomized trials are currently lacking. Two naturalistic studies of morphine administration following trauma exposure in civilian and combat-related injury have suggested that morphine may prevent later PTSD [71, 74]. One RCT on the effect on early administration of imipramine and fluoxetine in thermally injured children showed no effect in preventing PTSD [72]. Intranasal oxytocin has also been evaluated as a prevention strategy for PTSD, showing effect in patients with a high acute clinician-rated PTSD symptom severity [75]. Ketamine administration in naturalistic studies on moderately injured accident victims has been shown to decrease the incidence of PTSD [76, 77].

To summarize, although some important steps have been taken, more research on pharmacological agents to prevent the development of PTSD is still needed. Some studies have shown promising effects, but it is too soon to provide any definite recommendation in clinical practice yet. Importantly, one systematic review concluded that the small number of studies and their limited methodological quality cast uncertainty about the effects [78].

Psychological prevention

A range of different early psychological interventions have been developed in order to prevent negative psychological reactions after trauma. However, as in the pharmacofield, high-quality clinical trials have been lagging considerably behind. Descriptions of the most well-researched interventions are given in the following sections.

Critical incident stress debriefing

Critical incident stress debriefing (also commonly known as 'debriefing') takes place in the first hours following a traumatic event and typically consists of one individual or group session (1–3 hours), in which the participants describe what they experienced, their thoughts and feelings during the event, and how they think of how this event will influence them in their future [79]. Interestingly, there are several reviews of this intervention that have found that it may actually *increase*, rather than decrease, the risk of developing PTSD, that is, interfering with the natural psychological recovery after trauma [80, 81]. This is of some concern, as this is a commonly used intervention worldwide by, for example, first responders, government organizations on victims of mass disasters, and responders to traumatic incidents in the work setting. A summary of the Cochrane review even stated that 'compulsory debriefing of victims of trauma should cease' [40].

Cognitive behavioural interventions

Trauma-focused cognitive behavioural therapy (CBT) has been tested as a secondary preventive strategy (that is, treating patients with ASD with the aim to lower the incidence of PTSD) in several trials, showing a decreased incidence of PTSD, in comparison to supportive counselling [82, 83, 84]. In this treatment, the patient usually receives 4–5 sessions covering standard CBT techniques

(psychoeducation, anxiety management, exposure, and cognitive restructuring) a couple of weeks after the traumatic event.

In the case of mental health primary prevention (that is, treating individuals immediately after trauma exposure), the evidence base is more limited. Resnick *et al.* [85] developed a psychological intervention for rape victims that consists of a 17-minute video presentation consisting of general psychoeducation and coping strategies for anxiety. This intervention was shown to decrease both PTSD symptoms and marijuana abuse compared with standard care in a randomized trial with 140 participants with sustained long-term effects [86].

Another primary prevention strategy tested is ‘prolonged exposure’ (PE) which is a form of CBT. In PE treatment, PTSD symptoms are seen as signs of an incompletely processed trauma memory, making the memory associated with high levels of fear and stress. The high level of distress drives avoidance behaviours that prevent the person from facing their memories and situations that, since the trauma, are perceived as dangerous, although objectively safe, and from overcoming their problems. Thus, in this model, the patient is asked to reactivate the trauma memory repeatedly in a safe and non-stressful context (that is, visualizing the event in their mind’s eye several times—the so-called imaginal exposure). The aim of this is to allow the fearful responses associated with the memory to gradually decline and afterwards to verbally process the revisiting of the traumatic memory. The patient is also asked to confront objectively safe but feared situations (the so-called exposure *in vivo*).

There is, to date, one randomized trial that has tested prolonged exposure as an early intervention after trauma [87]. In this study, 137 emergency trauma care patients received three sessions with a clinical psychologist, starting the intervention 12–24 hours after trauma exposure in the emergency department. Results showed that, compared to a control group consisting of assessment only, the modified PE intervention decreased PTSD symptoms at 12 weeks later [87]. Trials that aim to replicate and extend these promising findings are needed.

Cognitive science-driven interventions

A new line of enquiry from experimental psychopathology studies has sought to create psychological prevention techniques ‘*de novo*’ from cognitive science—that is, suggesting that by translating emerging neuroscientific insights and experimental research, we begin to develop new low-intensity psychiatric intervention that could prevent intrusive memories following trauma [88]. It differs from the application of PE or CBT techniques in several ways. First, this line of research focuses on targeting a core clinical feature of post-traumatic distress, rather than a whole disorder—here the recurrent intrusive visual memories of a traumatic event which are distressing and disruptive. Second, the preventive behavioural intervention is derived from various combined aspects of cognitive neuroscience (rather than being an adaptation of an existing talking therapy). The hypothesis is that engaging in a visuo-spatial task during memory consolidation competes for working memory resources with visual imagery and interferes with the formation of intrusive memories. Dual-task experiments also indicate that when similar cognitive tasks compete for shared resources, they interfere with each other and thereby impede memory processing; for example, a visuo-spatial pattern-tapping task interfered with holding a visual mental image in mind (making it become less vivid and emotional) [89]. An example of such a visuo-spatial task is the computer

game Tetris [90, 91]. Critically, a competing task needs to be done within the time period of memory consolidation—within an estimated 6 hours following an event [92], during which time memory for events is still labile and vulnerable to disruption. Several laboratory experiments were done using healthy volunteers before bringing this approach to ‘the real world’.

As a first proof-of-concept step towards clinical translation, Iyadurai *et al.* [88] compared a Tetris-based intervention (trauma memory reminder cue plus about 20 minutes of Tetris game play) vs attention-placebo control (written activity log for the same duration), both delivered in an emergency department within 6 hours of a traumatic motor vehicle accident. The primary outcome of the RCT was the number of intrusive trauma memories (core clinical feature post-trauma) measured daily in the subsequent week. Results supported the efficacy of the Tetris-based intervention, compared with the control condition; there were fewer intrusive memories overall, while time-series analyses showed that intrusion incidence declined more quickly. Convergent findings were found on a measure of clinical post-trauma intrusion symptoms at 1 week, but not on other symptom clusters or at 1 month [88]. This proof-of-concept study opens the way for a larger trial, powered to detect differences at 1 month.

A similar pattern of results has been found in a conceptual replication by Horsch *et al.* [93] who tested the Tetris intervention on women in hospital who had a traumatic childbirth in the previous few hours [93]. The treatment group received usual care plus the Tetris-based intervention (20 minutes of Tetris game play, but no reminder cue as mothers were in the same hospital context as where the index trauma occurred, so a reminder was not deemed necessary) vs a control group of usual care. The reduction in the number of intrusive memories was almost two-thirds in the following week in mothers who played Tetris, compared with the control group. At 1 month, there was an indication of a lower rate of PTSD in the treatment condition.

Advantages of this type of cognitive science-driven approach include the fact that it is brief (approximately one half-hour session), it does not require a highly skilled therapist or talking about the trauma—and it could be readily scalable, which is required for preventive approaches post-trauma.

Other psychosocial interventions

Psychoeducation delivered via a self-help booklet has also been investigated in two trials but has not demonstrated any effect in preventing PTSD [94, 95]. An RCT using an early eye movement desensitization and reprocessing (EMDR) protocol delivered either 48 or 72 hours after exposure to trauma showed a decreased incidence of PTSD symptoms 3 months later in patients exposed to workplace violence [96]. However, the control group in this study consisted of debriefing, and as debriefing can potentially be harmful (see Critical incident stress debriefing, p. 864), the results should be interpreted with caution.

Psychological first aid (PFA) is a set of practices that were compiled in their current form by the National Child Traumatic Stress Network and the National Center for PTSD to reduce PTSD in adolescents, adults, and their families. The model is based on a set of principles: sense of safety, calming, sense of self, and community efficacy, connectedness, and hope [97]. Importantly, despite the widespread acclamation of PFA as an ‘evidence-informed’ intervention

[98], comprehensive literature reviews have not yet found evidence of its efficacy in the prevention of PTSD.

To summarize, as in the case of pharmacological agents, there are to date as yet no psychological interventions that have shown consistent, reliable results in preventing the development of PTSD, with the exception of a form of trauma-focused CBT with patients who already have ASD for which there is some evidence. Importantly, there are too few published high-quality large-scale trials to give any consistent recommendation of what psychological treatment to use for trauma survivors in the early aftermath of trauma.

Conclusions

A considerable amount of research has looked at risk factors for PTSD, but no stable and reliable decision algorithm has been developed that can distinguish patients who require intervention from those who will recover on their own. Some early trials on primary intervention have shown promising effects, but it appears it is too soon to provide strong recommendations for clinical practice. After high-profile events such as a disaster, immediate post-trauma support can be demanded—it is as important to know the evidence on what interventions *not* to give (for example, debriefing is counterindicated). Meanwhile, active research efforts are needed to develop a range of interventions that could be used soon after trauma. Given the presence of an index traumatic event—a known aetiology—prevention efforts based on science and clinical practice should be within our reach.

Management and treatment of stress-related disorders

Leigh van den Heuvel and Soraya Seedat

Introduction

Mental disorders where trauma or stress plays a central role are grouped together in ‘Trauma- and stressor-related disorders’ in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) [1] and in ‘Disorders specifically associated with stress’ in the beta version of the *International Classification of Diseases*, eleventh revision (ICD-11) [2]. This group of disorders can only be diagnosed following exposure to a stressful or traumatic event. In DSM-5 and the beta version of ICD-11, these include reactive attachment disorder, disinhibited social engagement disorder, post-traumatic stress disorder (PTSD), and adjustment disorders (ADs). DSM-5 also includes acute stress disorder (ASD), whereas the beta version of ICD-11 distinguishes between PTSD and complex PTSD and includes prolonged grief disorder. The beta version of ICD-11 specifies an acute stress reaction, but this is dissimilar from ASD as it is viewed as a normal response to trauma that subsides within a few days. Here we will focus on the management of PTSD, ASD, and ADs in adults. The management of ASD is discussed in the context of prevention of PTSD.

Post-traumatic stress disorder

Prevention

Both ASD and PTSD develop following exposure to a traumatic event involving actual or threatened death, serious injury, or sexual violence; ASD occurs 3 days to 1 month following the trauma, and PTSD is diagnosed when the symptoms have lasted at least 1 month [1]. Their clear relation to an instigating event(s) provides an opportunity to institute strategies to prevent the development of ASD and PTSD. Preventing the development of PTSD is of major societal significance, as the disorder is often chronic and disabling once it sets in. Although several individuals who have ASD go on to develop PTSD, there are also many who develop PTSD without a prior diagnosis of ASD [3]. In the context of PTSD, primary prevention refers to preventing exposure to traumatic events or strategies aimed at

enhancing resilience (for more information on primary prevention, see Chapter 82) [4]. Secondary prevention entails interventions instituted after trauma exposure, with the intention of preventing the development of PTSD. Once PTSD symptoms are present, the aim of tertiary prevention is to treat symptoms early and try to avert the development of chronic PTSD. Prevention strategies can be universal, aimed at all individuals exposed to a traumatic event, or can be targeted towards individuals at higher risk of developing PTSD, such as individuals with ASD.

Psychological interventions

Various psychological interventions have been investigated in the prevention of PTSD, as well as in the treatment of ASD. These include single-session interventions, such as debriefing, and multiple-session interventions such as counselling, multiple-session debriefing, cognitive behavioural therapy (CBT), memory restructuring, and psychoeducation. Debriefing is a psychological intervention usually provided in a group format, as a single session, within a few days after exposure to a traumatic event. Debriefing sessions usually involve a discussion of the traumatic event and encourage participants to recollect their experience and to express their emotional reactions to the event. The intention of debriefing is to reduce acute distress and prevent the development of psychiatric disorders—PTSD, in particular. Systematic reviews and meta-analyses have consistently found that debriefing does not reduce the incidence of PTSD nor does it lead to improvements in PTSD symptoms, depression, anxiety, or functioning [5, 6]. There is even some evidence that debriefing may worsen PTSD outcomes [6]. Similarly, a Cochrane review found that early multiple-session psychological interventions were not superior to control conditions for any PTSD-related outcomes when administered to all trauma survivors [7]. There is, however, evidence from meta-analyses that trauma-focused CBT (TF-CBT) is superior to waitlist/treatment as usual (TAU), as well as supportive counselling in the treatment of ASD (TF-CBT is described in *Psychotherapy*, p. 870) [5, 8]. Although various other psychosocial interventions have been investigated, there is insufficient evidence at this stage to support any of them in the prevention of PTSD.

Pharmacotherapy

Medications that have been investigated in the prevention of PTSD include steroids (hydrocortisone), beta-blockers (propranolol), drugs for depression (fluoxetine, escitalopram, sertraline, and imipramine), benzodiazepines (BZDs) (temazepam, alprazolam, and clonazepam), anticonvulsants (gabapentin), opioids (morphine), beta-adrenergic agonists (albuterol), NMDA receptor antagonists (ketamine), and omega-3 fatty acids. The only drug that has demonstrated efficacy in preventing PTSD in meta-analyses is hydrocortisone. In two meta-analyses ($n = 5$ studies; $n = 164$), hydrocortisone was superior to placebo in reducing the incidence of PTSD [number needed to treat (NNT) = 7–13], as well as in improving PTSD symptom severity [9, 10]. In the studies, hydrocortisone was usually administered within 6–12 hours of trauma exposure at doses of between 20 mg and 140 mg. Glucocorticoids are hypothesized to work by facilitating extinction learning and impairing memory consolidation of the traumatic event. The known adverse effects of hydrocortisone, such as affective changes, increased susceptibility to infection, and detrimental cardiovascular outcomes, remain a concern. Another drug investigated in PTSD prevention—propranolol—showed promise in early trials but has not demonstrated efficacy in meta-analyses [9, 10]. Beta-blockers are thought to disrupt memory consolidation and to dampen sympathetic tone and, in so doing, to reduce hyperarousal and intrusive symptoms. The few studies that have evaluated drugs for depression, BZDs, anticonvulsants, and omega-3 fatty acids have largely been negative [9, 10]. Morphine administered following trauma exposure, in cohort studies, may reduce the risk of PTSD presumably by impairing amygdala fear conditioning [4, 9]. Similarly, there is limited evidence from cohort studies that ketamine and albuterol administration following trauma may moderate the incidence of PTSD [4, 9]. At this stage, there is insufficient evidence to recommend the routine clinical use of any pharmacologic intervention.

Other interventions

Another approach examined in the prevention of PTSD involves collaborative stepped care where trauma-exposed individuals are assigned case managers and referred for evidence-based treatments (CBT and/or pharmacologic treatments), according to individual requirements. Although studies are limited, collaborative care appears to lead to improved outcomes, compared to usual care [4, 5].

Conclusions

Overall, there is a lack of evidence to draw clear conclusions for most interventions [5]. The only intervention that can be firmly recommended is TF-CBT, but only once symptoms of ASD are present. No universal interventions aimed at all trauma-exposed individuals can currently be supported. A collaborative care approach could possibly assist in identifying individuals with PTSD symptoms earlier and increasing access to evidence-based interventions. Without clear evidence to guide interventions, clinicians should employ a pragmatic approach. This entails not interfering with spontaneous recovery, but rather providing practical assistance and support and monitoring for the emergence of symptoms of ASD or PTSD and timely referral for appropriate treatment if symptoms persist or are distressing. Providing information

regarding responses to trauma and when to seek help to trauma-exposed individuals and encouraging them to engage with their available sources of social support may also be helpful. Further research is required to improve detection of individuals at increased risk of PTSD to allow for targeted interventions. Well-designed trials are required to determine the efficacy of interventions and to determine individual factors influencing treatment outcomes. Timing of preventive interventions may be of particular importance, especially if the aim is to disrupt memory consolidation of the traumatic event.

Treatment

Psychotherapy

Trauma-focused cognitive behavioural therapies

TF-CBT is the most frequently studied form of psychotherapy in PTSD. TF-CBT is a broad category of therapies where the principles of CBT have been adapted to focus on behaviours and cognitions central to the disorder. Some TF-CBTs are primarily behavioural, while others are predominantly cognitive, and others have a combined behavioural and cognitive approach. TF-CBT is usually provided in weekly sessions lasting 60–90 minutes for around 8–12 weeks and can be delivered individually or in groups. All TF-CBTs incorporate psychoeducation regarding PTSD, particularly during initial sessions, and frequently also impart anxiety management techniques. The broad aim of TF-CBT is to alter maladaptive thinking and behaviours that develop in relation to the traumatic event and thereby alleviate symptoms and improve functioning. Cognitive-based therapies focus on altering trauma-derived cognitive distortions and negative beliefs. Specific manualized variants of cognitive therapy have been developed, such as cognitive restructuring and cognitive processing therapy (CPT), which allow for a standardized approach. The behavioural-based interventions usually involve exposure therapies, which are founded on the principles of extinction learning, whereby repeated exposure to trauma-related cues in a safe environment leads to extinction of the fear response. The most frequently studied form of exposure therapy in PTSD is prolonged exposure (PE), a manualized intervention. Exposure therapy involves either imaginal or *in vivo* exposure to trauma-related stimuli, while anxiety and distress are managed with a relaxation technique such as controlled breathing. In imaginal exposure, the person recalls memories of the event, while *in vivo* exposure involves exposure to situations that the person avoids because they trigger reminders of the trauma. Recent meta-analyses have demonstrated the efficacy of individual TF-CBT in changing PTSD diagnostic status (NNT 2–4), improving PTSD symptoms, depression, anxiety, and functioning, as compared to waitlist/TAU [11–14]. The results remain similar, whether the focus is on cognitive therapy, exposure therapy, or mixed TF-CBT approaches, and effects appear to persist up to 12 months following completion. Group TF-CBT has also demonstrated efficacy for PTSD-related outcomes, although the number of studies are limited [11]. Gender appears to influence outcomes, as effects are larger in women-only studies [11]. Meta-analyses have reported higher dropout rates for TF-CBT than for waitlist/TAU, which raises concerns regarding the acceptability of TF-CBT [11].

Non-trauma-focused cognitive behavioural therapies

Other CBT-based therapies that do not focus on the specific trauma have also been investigated in PTSD. The most frequently studied non-TF-CBT is stress inoculation training (SIT), which focuses on increasing an individual's ability to manage stress and to prevent future episodes of anxiety. It incorporates coping skills training and relaxation techniques, as well as broad CBT-based approaches. The frequency and duration of sessions are similar to those used in TF-CBT. Although fewer studies have investigated non-TF-CBT, results indicate efficacy in improving PTSD symptoms, depression, and anxiety directly following treatment [11, 14]. Other meta-analyses, however, cite insufficient evidence for the efficacy of SIT [12].

Eye movement desensitization and reprocessing

Eye movement desensitization and reprocessing (EMDR) has features in common with other TF-CBTs and is one of the most commonly studied forms of psychotherapy in PTSD. During EMDR sessions, individuals bring to mind the traumatic experiences and negative cognitions associated with the trauma, while performing saccadic eye movements as they follow the therapist's finger from left to right for a few seconds. The process is repeated until the person becomes desensitized to the distressing content, after which the individual practises holding positive self-efficacious statements in mind, while imagining the trauma. The saccadic eye movements are thought to interfere with working memory and to reduce distress related to the trauma and thus reduce avoidance [15]. Treatment with EMDR also usually involves 8- to 12-week sessions, lasting around 60–90 minutes each. Meta-analyses have reported that EMDR is superior to waitlist/TAU in changing PTSD diagnostic status (NNT = 2), improving PTSD symptoms, depression, and anxiety up to 3 months following treatment [11–14].

Other psychotherapies

Psychodynamic psychotherapy, which is usually a longer-term intervention, employs traditional psychodynamic principles of bringing unconscious content into conscious awareness where it can be processed and conflict surrounding the trauma can be resolved. Brief eclectic therapy (BET) is a manualized therapy provided over 16 sessions that combine CBT and psychodynamic approaches. Interpersonal therapy (IPT) is usually provided in 10–20 sessions and concentrates on improving interpersonal relationships to enhance the management of interpersonal distress. Narrative exposure therapy (NET) combines features of exposure therapy, as well as narrative therapy, to allow desensitization and reframing of the traumatic experience within the person's life story. Person-centred therapy and supportive counselling are non-directive and allow the person to talk about their problems and feelings, with support from an accepting therapist. Supportive therapy is often used as an active comparator in clinical trials. A Cochrane review that combined 'other therapies' reported superiority to waitlist/TAU in PTSD symptoms, depression, and anxiety directly following treatment; however, dropout rates were higher than waitlist/TAU [11]. There is some evidence of efficacy, based on a limited number of studies, for NET and BET in improving PTSD-related outcomes above waitlist/TAU [12, 13]. IPT was not superior to waitlist/TAU in one meta-analysis [14], but group IPT demonstrated efficacy in a single trial [13]. Psychodynamic psychotherapy, resilience therapy, and hypnotherapy have demonstrated efficacy only in single small trials [13].

A meta-analysis of six hypnotherapy trials found large effects in improvements of PTSD symptoms post-treatment but did not report outcomes, as compared to control conditions [16].

Comparative effectiveness of psychotherapies

In terms of efficacy, the largest body of evidence, supported by the largest effect sizes [13], is for TF-CBT, followed by EMDR. Although there is some evidence for non-TF-CBT and other psychotherapies, these results are less clear. Effect sizes for all psychotherapeutic interventions are larger when compared against waitlist/TAU than against active comparators [13]. Fewer head-to-head comparisons for psychotherapies exist. One meta-analysis found no difference between PE and cognitive-based TF-CBTs, SIT, or EMDR [17]. Exposure therapy has demonstrated superiority to relaxation in reducing PTSD symptoms [12]. There is some evidence that TF-CBT and EMDR are superior to non-TF-CBT and 'other therapies' for certain PTSD-related outcomes [11]. One meta-analysis found that EMDR was superior to TF-CBT only in improving anxiety symptoms directly following treatment [17]. Only one study observed non-TF-CBT was superior to 'other therapies' [11].

Pharmacotherapy

The most commonly studied medications are drugs for depression, SSRIs in particular, followed by drugs for psychosis.

Drugs for depression (antidepressants)

Meta-analyses have demonstrated small, but significant, effects favouring these drugs overall [13], and SSRIs as a class [13, 18], above placebo. Although guidelines often combine SSRIs as a drug class in treatment recommendations, the evidence reveals that this may not be appropriate in the management of PTSD. Currently, paroxetine and sertraline are the only two SSRIs that are FDA-approved for PTSD. Of the individual SSRIs, paroxetine and fluoxetine have consistently been found superior to placebo in meta-analyses [13, 14, 18]. There are some inconsistencies in meta-analyses regarding the efficacy of sertraline, with some reporting superiority to placebo [13, 14] and others not [18]. These inconsistencies can be explained by varying inclusion criteria in clinical trials (that is, some more stringent than others) and by whether or not unpublished results were included. Citalopram and escitalopram have failed to demonstrate efficacy in a few studies [13, 14, 18]. The serotonin and noradrenaline reuptake inhibitor (SNRI) venlafaxine has demonstrated superiority over placebo in meta-analyses including two RCTs [13, 14, 18]. Meta-analyses have not shown efficacy for the monoamine oxidase inhibitor (MAOI) brofaromine, the tricyclic antidepressants (TCAs) desipramine and imipramine, and the noradrenaline/dopamine reuptake inhibitor (NDRI) bupropion [13, 14, 18]. The results for the MAOI phenelzine, the TCA amitriptyline, the noradrenergic and specific serotonergic antidepressant (NaSSA) mirtazapine, and the discontinued serotonin antagonist and reuptake inhibitor (SARI) nefazodone have been inconsistent in meta-analyses [13, 14, 18]. Even in those reporting superiority over placebo, the results were based on single trials.

Drugs for psychosis (antipsychotics)

In two meta-analyses, dopamine antagonists were superior to placebo overall, but with a small effect [13, 14]. In two meta-analyses, olanzapine failed to demonstrate efficacy [13, 18], but in another, it

was superior to placebo as monotherapy, but not when used as augmentation of an antidepressant [14]. Risperidone was superior to placebo, both as monotherapy and when used in augmentation in two meta-analyses [13, 14], but failed to demonstrate any efficacy in another [18]. Based on a single trial, aripiprazole was not superior to placebo [14]. Despite these small positive effects, their use is limited by their significant adverse effects.

Anticonvulsants

Anticonvulsants as a class have not demonstrated efficacy [13, 14]. One meta-analysis found that topiramate was superior to placebo as monotherapy in two trials and as augmentation in a single trial [13], whereas others did not observe evidence of its efficacy [13, 18]. The other anticonvulsants valproate semisodium, tiagabine, and lamotrigine have failed to demonstrate efficacy in limited trials [13, 14, 18].

Benzodiazepines

Systematic reviews and meta-analyses have consistently found that BZDs are ineffective in preventing or treating PTSD symptoms [13, 14, 18, 19]. Furthermore, BZDs increased the likelihood of developing PTSD and were associated with other negative sequelae such as worsened PTSD severity, psychotherapy outcomes, depression, anxiety, aggression, and substance use [19].

Adrenergic drugs

Although there have been some negative findings [13], the alpha-1 adrenergic receptor antagonist prazosin has been found to be superior to placebo in meta-analyses in improving PTSD symptoms and sleep quality and in reducing nightmares [14, 20]. Prazosin presumably works by dampening noradrenergic activity, and thereby decreasing hyperarousal, as well as by disrupting reconsolidation of fear memories [19]. Prazosin is usually initiated at 1 mg and titrated up every 2–3 days up to mean daily doses of between 3 mg and 15 mg. It is usually well tolerated, although dizziness is the most commonly reported adverse effect. The alpha-2 agonist guanfacine has not demonstrated efficacy in PTSD thus far [13, 14].

Other emerging drugs

Efficacy has been demonstrated for GR205171 (a neurokinin-1 antagonist) [18] and the herbal drug ginkgo biloba [13] in single RCTs. Due to its positive effects in depression, ketamine has received increased interest in the treatment of PTSD. Ketamine, commonly used as an anaesthetic for surgical procedures, was associated in a case series with both worsened and improved PTSD symptoms. A pilot RCT (ketamine vs midazolam) and a case study reported improvements in PTSD symptom severity [21]. A meta-analysis of 19 intranasal oxytocin trials in various mental disorders, including two PTSD trials, reported a small effect favouring oxytocin; however, of the individual disorders, significant improvements were only found for autism spectrum disorders. The two trials evaluating oxytocin in PTSD were, however, very small ($n = 18–30$), one of which showed promising results [22]. Both oxytocin and ketamine warrant further investigation in PTSD.

Combined psychotherapy and pharmacotherapy

A Cochrane review evaluated whether combined pharmacotherapy and psychotherapy was superior to either treatment modality alone [23]. Only four trials were eligible for the review, and all of the trials utilized SSRIs and TF-CBT. Two trials compared combined treatment to pharmacotherapy alone and found no evidence that combined treatment was superior. Two trials, one in adults ($n = 25$) and one in children ($n = 24$), compared combined treatment to psychotherapy alone and found no difference between the groups. A more recent RCT ($n = 228$) similarly found that the combination of PE and paroxetine was not superior to either alone in achieving remission; PE, however, was superior to paroxetine alone in adults with PTSD secondary to a motor vehicle accident (MVA) [24]. In contrast, another RCT ($n = 37$) found combined paroxetine and PE to be superior to PE alone in improving PTSD symptom severity and in achieving remission [25]. No clear conclusions on the benefits of combination therapy can be drawn until larger well-designed RCTs are executed to address this question (Table 83.1).

Table 83.1 Evidence-based treatments for stress-related disorders

	First line	Second line	Third line (reserved for specialist practice and treatment resistance)	Interventions demonstrating potential
PTSD				
Prevention	No evidence for any universal preventative interventions TF-CBT for symptomatic individuals or those diagnosed with ASD			Collaborative care approaches Hydrocortisone
Treatment	TF-CBT EMDR	Other psychotherapies (group TF-CBT, non-TF-CBT, NET, BET) Drugs for depression (paroxetine, fluoxetine, venlafaxine, sertraline) Combined pharmacotherapy and psychotherapy	Other medications [prazosin, risperidone (monotherapy and augmentation), olanzapine (monotherapy), topiramate]	Distance-delivered TF-CBT VRET Mindfulness-based therapies Drug-assisted psychotherapies TMS Exercise
	Problem-solving therapy	Other brief psychotherapies	Targeted pharmacotherapy	Resiliency training programmes Mindfulness-based therapies Exercise

ASD, acute stress disorder; BET, brief eclectic therapy; EMDR, eye movement desensitization and reprocessing; NET, narrative exposure therapy; PTSD, post-traumatic stress disorder; TF-CBT, trauma-focused cognitive behavioural therapy; TMS, transcranial magnetic stimulation; VRET, virtual reality exposure therapy.

Treatment selection

Effects sizes for TF-CBT and EMDR, whether compared to waitlist/TAU or comparator conditions, are significantly larger than those found in pharmacotherapy trials, which are generally small [14]. Psychotherapy benefits also persisted after therapy completion, whereas medication had to be continued to maintain efficacy [14]. The effect sizes for drugs, however, are equivalent to those observed in depression trials [18]. Based on the available evidence, TF-CBT and EMDR are first-line interventions and other psychotherapies and psychopharmacological interventions can be considered as second-line interventions. Drugs with the best evidence for efficacy are fluoxetine, paroxetine, and venlafaxine. Even though the findings of meta-analyses have been inconsistent, sertraline was equivalent to venlafaxine in one RCT [14] and can thus be considered as well. In individuals with prominent sleep difficulties, prazosin may be an option, and atypical antipsychotics, as monotherapy or augmentation, should rather be reserved for treatment-resistant cases.

Generally, dropout rates for pharmacotherapy trials have not been significantly different from placebo, suggesting that overall psychopharmacological treatment was well tolerated. Acceptability of psychotherapies is of concern, as dropout rates in studies are often high, particularly in TF-CBT, which may be related to avoidance of trauma-related reminders. A systematic review evaluating patient preferences regarding treatments for PTSD largely found that individuals preferred psychotherapy above medication; they, however, preferred medication to receiving no treatment [26]. Medication was generally preferred when there was comorbidity (depression, insomnia) and when there were practical concerns such as perceived faster effect with pharmacotherapy. Predictors of psychotherapy preference were PTSD as a primary diagnosis, perceived threat to life, previous psychiatric history, traumatic injuries, sexual assault, and female gender.

There is a lack of evidence to guide treatment selection based on trauma type or individual-level characteristics. For both psychotherapy and pharmacotherapy, studies with women only had larger effect sizes and studies with veterans smaller effect sizes [13]. Concerns regarding methodological quality and publication bias have been raised for both psychotherapeutic and pharmacologic interventions [13, 14]. Of note, individuals in psychotherapy trials are often on concomitant medications and tend to have had more prior treatments than those in pharmacotherapy trials [14]. Another factor that influences treatment choice is the availability of various treatment options. Access to psychotherapy is limited in many settings. Perceived barriers to treatment that have been identified include stigma, shame, and fear of negative social consequences, low mental health literacy, doubts regarding treatments, limited resources and time, and apprehension regarding re-experiencing the trauma [27], whereas perceived facilitators of treatment include social support and acceptance, severity of the disorder, and recognizing a need to change, positive experiences with health professionals, and avoiding negative social interactions [27]. Individual preference, along with current best evidence, should guide treatment selection.

Special populations

Children and adolescents

Meta-analyses have demonstrated evidence favouring psychological therapies overall in the treatment of PTSD in children and

adolescents (C&A) [28, 29]. Psychological interventions studied included TF-CBT (including PE), EMDR, narrative therapy, supportive counselling, psychodynamic psychotherapy, child-centred therapy, multi-disciplinary treatment, meditation, and classroom-based interventions. Effect sizes overall were larger when compared to waitlist/TAU than to active controls. Psychological therapies were superior to control conditions in changing PTSD diagnostic status and improving PTSD symptom severity up to 1-year follow-up, as well as depression and anxiety in the short term. The only individual therapy type that was superior to both TAU/waitlist and supportive counselling was TF-CBT. A Cochrane review of psychological therapies for preventing PTSD in trauma-exposed C&A also showed a benefit for psychological treatments as a whole in preventing PTSD and in reducing PTSD symptoms, when compared to waitlist/TAU/no treatment (NNT = 6.3), for up to a month follow-up [30]. There was a small effect demonstrating superiority of TF-CBT over EMDR, play therapy, and supportive therapy in improving PTSD symptoms.

There have been very few trials evaluating pharmacotherapy in the management of PTSD in C&A. A recent systematic review of RCTs in C&A identified only two pharmacotherapy trials, both evaluating sertraline; they could not perform a meta-analysis due to the limited number of studies [28]. Another systematic review that evaluated psychopharmacology in the management of PTSD in C&A reported that in three RCTs of SSRIs (two sertraline, one fluoxetine), there was no benefit to SSRI treatment, and in one brief RCT of imipramine, the latter was superior to chloral hydrate in improving ASD symptoms in child burn victims [31]. They also found small open-label studies that demonstrated improvements in PTSD symptoms when using citalopram, quetiapine, carbamazepine, high- vs low-dose valproate semisodium, and the alpha-2 agonists clonidine and guanfacine (clonidine improved re-enactment symptoms, and guanfacine improved nightmares). However, beta-blockers did not prevent PTSD or reduce symptoms severity in an open study. In C&A with PTSD, pharmacotherapy is not routinely indicated and should be reserved for the management of treatment resistance in specialist practice.

Psychiatric comorbidity

There is very little evidence to inform the management of PTSD with psychiatric comorbidity, although PTSD is highly comorbid with depressive, anxiety, and substance use disorders (SUDs). Many of the psychotherapies investigated in PTSD improve associated depression and anxiety symptoms as well. The same drugs with evidence in PTSD can also be utilized in the management of depressive and anxiety disorders because of their broad spectrum of action. A Cochrane review of psychological therapies for comorbid SUD and PTSD found that TF-CBT was superior to TAU in improving symptoms of PTSD and SUDs, but not when compared to active comparators [32]. Treatment completion rates were lower in TF-CBT groups. Non-TF-CBT-based therapies were not superior to TAU, whether delivered in a group/individual format. A meta-analysis evaluating integrated treatment for SUD and PTSD, which involves simultaneous treatment for both disorders by the same treatment team, found that integrated programmes improved PTSD and SUD symptoms, but integrated programmes were not superior to non-integrated programmes [33]. Thus far, there is no clear evidence of specific pharmacotherapy interventions that improve symptoms of both PTSD and SUDs in individuals with comorbidity [34].

Emerging interventions

Alternative psychotherapy delivery modes

Due to problems with access to evidence-based psychotherapies, efforts have been under way to examine alternative methods of delivering psychotherapies. Existing therapies have been adapted into remotely delivered interventions (Internet, telephone, email, and videoconferencing). Meta-analyses have found that Internet-delivered CBT was superior to waitlist/TAU in improving PTSD symptom severity and depressive and anxiety symptoms, but not when compared to active controls [35–37]. Virtual reality exposure therapy (VRET) follows the same principles as traditional exposure therapies, but the person is exposed to cues related to the trauma in a computer-generated virtual reality (VR). In VR, the person can interact with the environment, allowing for an immersive experience. A systematic review of VRET in PTSD identified ten studies, seven of which demonstrated that VRET was superior to waitlist, although no difference was found between VRET and traditional exposure therapies [38]. Although preliminary, these results suggest the potential utility of VRET, particularly as VR headsets have become increasingly available and affordable.

Mindfulness-based therapies

Over the last three decades, there has been a proliferation of research into mindfulness-based interventions. Mindfulness has its origin in Buddhist contemplative teachings, and current therapies have been adapted in accordance with medical and scientific practice. The practice of mindfulness involves a non-judgemental moment-to-moment observation of internal and external experiences, with the aim of enhancing awareness. Through sustained practice, mindfulness aims to decrease distress by developing greater acceptance of things as they are and enhance self-regulation and positive qualities such as compassion and equanimity [39]. Mindfulness has been incorporated into various therapeutic approaches such as mindfulness-based stress reduction (MBSR), mindfulness-based cognitive therapy (MBCT), acceptance and commitment therapy (ACT), and dialectical behaviour therapy (DBT) [39, 40]. MBSR and MBCT are manualized programmes delivered in eight weekly group sessions, lasting around 2 hours, with one full-day session. Both MBSR and MBCT incorporate mindfulness meditation and yoga practices. MBCT also has a cognitive component where participants are instructed to change their relationship to their thoughts, rather than to challenge the content, as is commonly done in CBT. A recent systematic review of mindfulness-based interventions, mostly MBSR, in trauma-exposed adults reported that overall studies demonstrated positive effects and improvements in PTSD symptoms, particularly avoidance subscales [40]. However, the results were based on small studies with variable methodological rigour, and further studies of higher methodological quality are required before any clear conclusions can be drawn. Another meta-analysis reported that meditation-based interventions (MBSR, yoga, and mantra repetition programmes) were superior to waitlist/TAU in improving PTSD and depressive symptoms [41]. A benefit of mindfulness-based interventions is that they are often delivered in groups and thus increase accessibility.

Drug-assisted psychotherapies

There is an increased interest in the therapeutic potential of methylenedioxymethamphetamine (MDMA), commonly known

by its recreational use name ‘ecstasy’, in the treatment of PTSD [42]. The psychoactive properties of MDMA were first investigated in the late 1970s, and prior to it being classified as an illegal Schedule 1 drug in the mid-1980s, it was utilized by clinicians as an adjuvant to psychotherapy. For more than 20 years, research into MDMA was limited to investigations of the risks and potential neurotoxicity of MDMA, particularly with regard to its recreational use. Despite extensive research, the debate on whether MDMA is neurotoxic persists. There are, however, known potential dangers associated with recreational ‘ecstasy’ use such as dehydration and brain oedema [42]. MDMA-assisted psychotherapy (MDMA-AP) typically involves 1–3 drug-assisted psychotherapy sessions, lasting 8 hours each, with non-drug psychotherapy sessions provided prior to, and following, the MDMA-AP sessions. MDMA putatively assists in the treatment of PTSD by decreasing anxiety and increasing the individual’s ability to trust, and thus strengthening the therapeutic alliance, by providing a sense of increased insight, and by enabling memory retrieval and reconsolidation [42]. This is partly due to its known physiological effects such as increased serotonin, dopamine, noradrenaline, oxytocin, and vasopressin release. In a preliminary meta-analysis of two RCTs ($n = 35$), the authors demonstrated large effect sizes for PTSD symptoms, favouring MDMA-AP [43]. They also compared the effect sizes and dropout rates against those reported in a meta-analysis of PE17 and found that the effect sizes were slightly larger for MDMA-AP, and that dropout rates were lower in MDMA-AP (12.7%) than in PE (27.0%).

Most of the studies evaluating cognitive enhancers of CBT have used d-cycloserine (DCS). DCS is thought to enhance extinction learning due to its partial agonism of the *N*-methyl-*D*-aspartate (NMDA) receptor complex. A recent Cochrane review evaluated the efficacy of DCS augmentation of CBT in anxiety disorders, including PTSD and included 21 RCTs, five of which were on PTSD [44]. Overall, DCS-augmented CBT was not superior to placebo-augmented CBT in both adults and C&A. The studies were heterogeneous, and the quality of evidence overall was low. The subgroup analysis revealed that DCS-augmented CBT was superior to placebo in achieving remission of PTSD at 1–6 months’ follow-up and in improving comorbid anxiety symptoms. In C&A, however, placebo-augmented CBT was superior to DCS-augmented CBT in improving anxiety and depressive symptoms in one study ($n = 57$).

Transcranial magnetic stimulation

Transcranial magnetic stimulation (TMS) is a non-invasive neuromodulation modality. Electromagnetic pulses are delivered by a TMS stimulator via a coil placed over the scalp. TMS presumably works by inducing changes in the electrical field in the focal brain region being stimulated and through altering function downstream via connected neural circuits. Repetitive TMS (rTMS) is a type of TMS usually utilized in treatment protocols and can vary according to the stimulation site and the intensity, frequency, duration, and sequence of pulses. Low-frequency (LF) rTMS (≤ 1 Hz) is generally considered to have inhibitory effects, and high-frequency (HF) rTMS (≥ 5 Hz) to be excitatory. rTMS is generally considered safe when administered according to accepted safety guidelines [45]. The most frequently reported adverse effects include headaches and facial pain, and the most severe adverse effect is the induction of seizures, though the risk is very low. Since the late 1990s,

rTMS has been investigated as a potential treatment for PTSD in different patient populations, utilizing varying protocols [46]. Due to its role in complex cognitive and behavioural functions, the dorsolateral prefrontal cortex (DLPFC) has been researched as a treatment target in PTSD and several other neuropsychiatric disorders. A meta-analysis and systematic review evaluating the efficacy of rTMS to the DLPFC in PTSD identified three RCTs ($n = 64$) of HF and LF rTMS to the right DLPFC, and one RCT evaluating HF rTMS to the left DLPFC [47]. All rTMS protocols were administered over ten sessions, with a mean total number of 6250 pulses. Their meta-analysis demonstrated statistically significant improvements in PTSD symptoms, anxiety, and depression, favouring active rTMS to the right DLPFC. Dropout rates did not differ between active and sham rTMS, although individuals in the active rTMS group had more severe PTSD symptoms at baseline. The RCT investigating the left DLPFC had similar results. A more recent meta-analysis pooled the results of five RCTs ($n = 108$) for HF rTMS and LF rTMS to the right and left DLPFCs, as well as HF deep TMS to the bilateral medial prefrontal cortices (mPFC) [48]. They also demonstrated an overall benefit favouring active rTMS, and a meta-regression identified no specific variables that influenced outcomes. Although preliminary, the results suggest that rTMS holds promise as a treatment option for PTSD. Further studies with larger sample sizes are required to prove efficacy for routine clinical practice, and ideal treatment protocol parameters still need to be defined.

Exercise

Akin to many other psychiatric disorders, cardiovascular disease (CVD) risk is higher in individuals with PTSD. One meta-analysis revealed that individuals with PTSD had almost double the risk of metabolic syndrome than matched general population controls [49]. A recent systematic review and meta-analysis evaluated the efficacy of physical activity as a treatment for PTSD [50]. They included four RCTs ($n = 200$); two trials evaluated active yoga, one evaluated an aerobic intervention (stationary cycling) and one evaluated a combined resistance and aerobic intervention. The duration of the interventions varied between 6 and 12 weeks, with 1–2 supervised sessions per week. The meta-analysis found that the exercise interventions were superior to the comparator interventions in improving PTSD and depressive symptoms, with no significant adverse effects. There were insufficient data to evaluate the effect on anthropometric measurements. Although preliminary, the results suggest that exercise interventions hold potential as an adjunct in the treatment of PTSD.

Other interventions

Biofeedback involves a process whereby an individual can gain voluntary control of a physiological process by receiving electronic monitoring feedback. When the feedback incorporates brain function, such as electroencephalography (EEG), it is called neurofeedback. A recent systematic review including three studies (one RCT) reported improvements in PTSD symptoms and associated neurobiological changes [51]. A meta-analysis of hyperbaric oxygen therapy (HOT) (100% oxygen being delivered at an increased atmospheric pressure) in traumatic brain injury (TBI) found that although HOT led to improved Glasgow coma scale (GCS) scores, there was no effect on PTSD severity [52]. Stellate ganglion block, an anaesthetic procedure where a local anaesthetic is injected next to the cervical

sympathetic ganglion, has shown promise as a treatment for PTSD in case studies and case series [53].

Deep brain stimulation (DBS) of brain regions involved in PTSD pathophysiology could be a potential treatment option for refractory PTSD. Preclinical studies have demonstrated promising results with stimulation of the basolateral amygdala (BLA), ventral striatum, hippocampus, and PFC, and one case study reported an improvement in PTSD symptoms in a veteran treated with BLA DBS [54].

Of six studies identified in a systematic review of art therapy in traumatized adults, two studies reported significant improvements in PTSD-related symptoms and two in anxiety, compared to waitlist/TAU or an art control condition [55]. A recent systematic review evaluated animal-assisted therapy in the treatment of trauma-exposed individuals; three studies were in adults, and seven in C&A. The animals most frequently utilized were dogs, followed by horses. Although very preliminary, results overall were promising, demonstrating improvements in PTSD symptoms, depression, and anxiety [56].

Adjustment disorders

An AD involves a maladaptive response, either emotionally or behaviourally, or both, to an identifiable stressful situation or multiple stressors. ADs usually have their onset within 1 [2] to 3 [1] months after the onset of a stressful event and usually resolve within 6 months after the stressor has terminated. The types of stressful events that can lead to an AD are broad and can include severe traumas or more common events such as financial difficulties, interpersonal conflict, illness, or work-related stressors. ADs cannot be diagnosed if the person meets criteria for another mental disorder, such as major depressive disorder (MDD) or PTSD, and is distinguished from a normal response to a stressful situation by significant functional impairments or severe distress, out of proportion to what would be accepted culturally. Although ADs are frequently encountered and can be a useful clinical diagnostic classification, research specifically evaluating ADs is scant. Here we expand the discussion by including interventions in non-clinical populations or in subclinical depression and anxiety. ADs are associated with heightened suicide risk, and thus suicide risk assessment should form part of the routine management of ADs [57, 58].

Psychological therapies

Due to the time-limited nature of ADs, brief therapies are usually preferred, unless the stressor is more chronic in nature. Interventions can be aimed at reducing or removing the stressor, facilitating adaptation, or reducing distress and functional impairment [57]. Problem-solving-based approaches can assist in directly dealing with the stressor. Adaptation to the stressor can be facilitated by approaches that reframe the stressor and with practical interventions. The specific symptoms of ADs can be addressed by similar psychological interventions used to treat depression, anxiety, and stress-related disorders such as CBT, relaxation therapies, IPT, and supportive and psychodynamic therapies [57]. Resilience-enhancing approaches can assist both with reducing the risk of developing ADs as well as with the treatment thereof. A Cochrane review evaluated CBT and problem-solving therapy (PST) to assist individuals with ADs to return to work [59]. PST involves identifying problems and then

generating, implementing, and evaluating solutions to the problems. There was evidence that PST, but not CBT, had significant effects on AD-related symptoms and on the time to return to partial, but not full, work.

A meta-analysis evaluating group CBT in subclinical depression reported that group CBT was superior to waitlist, but not to comparator interventions, and did not reduce the risk of incident depression [60]. Meta-analyses of the efficacy of resiliency training programmes in diverse clinical and non-clinical populations found these programmes had a moderate effect on improving resilience overall, and trauma-focused resilience training programmes, specifically, had a moderate effect in reducing stress and depression [61, 62]. Meta-analyses of mindfulness-based interventions in diverse psychiatrically or medically ill and non-clinical populations have demonstrated improvements in anxiety, depression, stress, and quality of life [63, 64]. Meditation-based programmes were, however, not superior to active comparators. Self-help-based mindfulness interventions, such as Internet-based therapies and books, have also been demonstrated superior to control groups in improving stress, depression, anxiety, and mindfulness in meta-analyses involving non-clinical populations [65, 66]. Relaxation training, such as progressive relaxation, autogenic training, and meditation, has also demonstrated efficacy in a meta-analysis of mixed clinical and non-clinical samples [67].

Pharmacotherapy

There are very few trials evaluating pharmacotherapy for ADs. Intervention that have been studied include BZDs, drugs for depression, and other anxiolytics. Single studies have found that etifoxine, a non-BZD anxiolytic, was superior to lorazepam, while others demonstrated no differences between drugs for depression (mianserin, tianeptine, viloxazine, trazodone) and BZDs (alprazolam, clorazepate, lormetazepam) and s-adenosyl methionine in improving anxiety [57]. Herbal medicines, such as kava-kava, valerian, ginkgo biloba, and plant extracts, have also demonstrated superiority in improving anxiety, compared to placebo, in one or two studies [57, 58, 68]. In practice, drugs for depression are frequently prescribed for ADs, despite the available evidence [68]. A meta-analysis of their efficacy in subthreshold depression demonstrated a small, but significant, effect favouring the SSRIs, fluoxetine, and citalopram, but not paroxetine, above placebo [69]. A Cochrane review also reported that kava was significantly superior to placebo in improving anxiety symptoms; however, concerns regarding liver toxicity limit the use of kava [70].

Exercise

A recent meta-analysis found that physical activity improved depression and anxiety in non-clinical adults [71]. Exercise is postulated to have beneficial effects on anxiety and depressive symptoms due to neurophysiological effects such as HPA axis regulation, increased monoamine levels, and increased neurogenesis in limbic structures [72]. Yoga has also been demonstrated to improve ADs in a single study [68].

Overall, the quality of evidence for treatments in ADs is poor, and it is difficult to draw clear conclusions. In general, practical problem-focused approaches are supported by the evidence and make clinical sense (Box 83.1).

Box 83.1 Practical approach to the management of PTSD

General guidelines

- Routinely screen for a history of trauma exposure and for symptoms of PTSD.
- Assess for ongoing trauma and ensure individual safety.
- A sensitive and empathic approach is required in dealing with trauma-exposed individuals.
- Respect autonomy, and involve the individual in treatment choices and in their management plan.
- Be aware of existing treatment options for PTSD in your community of practice, and build a referral database, including organizations that provide support to trauma-exposed individuals.
- Follow available treatment guidelines and evidence-based practices.
- Avoid potentially harmful interventions such as debriefing or prescribing benzodiazepines.

Following trauma exposure

- Do not interfere with spontaneous recovery.
- Provide practical support and assistance.
- Provide information regarding responses to trauma and when to seek help.
- Encourage utilization of social support structures.
- Monitor for symptom emergence.
- If ASD is diagnosed, refer for TF-CBT.

Management of PTSD

- Assess for suicidality and other risk behaviours.
- Confirm that PTSD is present, and exclude other differential diagnoses.
- Assess for comorbidity (medical/psychiatric/substance use), and manage comorbidity appropriately.
- Refer on to the appropriate level of care, depending on severity and complexity.
- Address potential barriers to treatment.
- Consider risks and benefits of treatment, alongside individual factors, when formulating a management plan.
- Institute first-line treatments, unless specific reasons exist for an alternative treatment option that is not first line (for example, availability, individual preference, comorbidity).
- Monitor adherence, response to treatment, and tolerability, and adjust the management plan accordingly.
- If first-line treatment has failed, confirm that the diagnosis is correct and assess for any complicating factors before instituting second-line interventions.
- Treatment-resistant individuals should ideally be managed in specialist practice.

ASD, acute stress disorder; EMDR, eye movement desensitization and reprocessing; PTSD, post-traumatic stress disorder; TF-CBT, trauma-focused cognitive behavioural therapy.

Bereavement

Beverley Raphael[†], Sally Wooding, and Julie Dunsmore

Introduction

Bereavement is the complex set of reactions that occur with the death of a loved one: the emotions of grief with yearning, angry protest, and sadness; the cognitive processes of understanding and making meaning of the finality and nature of death; and the social, cultural, spiritual, and religious contexts of adaptation. Grief may also result from other losses such as health, home, country, and safe worlds. There have been investigations into potential neurobiological substrates, without, as yet, a consensus about the explanatory model. In *Mourning and Melancholia*, Freud [1] described the psychological processes of mourning which involved the gradual relinquishment of bonds with the deceased, and how mourning differed from melancholia. Lindemann [2] described the symptomatology and management of acute grief in his classic paper on his experiences assessing and treating the survivors of a nightclub fire. Engel [3] asked, 'Is grief a disease?' and concluded in the negative. Bowlby's work on attachment, separation, and loss [4–6] has been the most influential in informing research and clinical practice, with many studies of both adults and children utilizing such concepts. Early research focused chiefly on bereavement following the death of a spouse, describing normal, high-risk, and pathological patterns of grief [7–9]. There is also a number of excellent reviews of theory and research, including those of Stroebe's group [10, 11].

Phenomenology of 'normal grief'

Common phenomena of the grief experience of adults, identified through many research studies [12–14], relate to similar domains influenced by developmental trajectories through childhood and adolescence. Adult studies indicate consistent patterns: numbness and disbelief; yearning, angry protest, and 'searching' behaviours representing separation distress; sadness with reviewing of memories of the lost relationship, with a range of associated emotions; and progressive acceptance of the death and changed circumstances, sometimes referred to as resolution. Bonanno *et al.* [14] has shown that resilient trajectories, defined by low overall distress, are common. Other transient phenomena described by clinicians working with bereaved people [15] include: identificatory symptoms, reflecting the deceased's illness; and a sense of the deceased's

ongoing presence, at times as though seeing the face, hearing the voice, or feeling the touch of the dead person. 'Yearning' is considered to be the most pathognomonic of these grief phenomena, which usually settle over the first year but may continue, triggered by anniversaries or specific memories. Older people who have had a long relationship with a spouse may continue this relationship in their minds for the comfort of 'talking' with the person and a need for the ongoing closeness [16]. Recent research [17] has modelled sequential peaks of the reactive phenomena: disbelief, yearning, anger, and depression, which bereaved people more usually describe as sadness. Grief may be a precipitant of depression in those with pre-existing or bereavement-related vulnerabilities, and the differentiation of normal and more pathological forms of grief from depression is important clinically [15, 18]. Intense grief and the peaks of distress identified in this chapter do not usually continue beyond the first 4–6 months [12, 13]. Continuing 'acute' grief beyond this time suggests the possibility of a pathological response, as do other risk indicators, although some phenomena may continue intermittently for many years. Comparative studies have demonstrated that the intensity of adult grief is likely to be greatest for the death of a child, then spouse or partner, then parent [12, 19].

Neurobiology of bereavement

Recent research has examined the neurobiology of grief through studies using functional magnetic resonance imaging of grief [20] and brain activity in women grieving the break-up of a romantic relationship [21]. Workers have attempted to develop a theoretical model, based on a wide range of relevant data, encompassing a 'neurobiopsychosocial' framework for sadness and loss [22]. Stress hormones [23] and psychoimmune function is a further area of research. A comprehensive model integrating the relevant research findings is yet to be established.

Risk and protective factors influencing course and outcome

Pre-existing vulnerabilities that may influence the course and outcome have been reviewed, alongside other risk factors [24].

[†] It is with regret that we report that Beverley Raphael died on 21 September 2018.

These include personality vulnerabilities related to relationship styles such as avoidant and insecure attachments. Genetic factors do not appear to have been directly studied, but it is likely that the short allele of the serotonin gene promoter polymorphism of *5HTTLPR*, which influences response to adversity, may contribute through gene–environment interactions [25]. Prior loss and adverse experiences may add vulnerability, for instance multiple losses faced by indigenous peoples, with loss of culture, land, and loved ones, with multiple premature deaths and separations [26]. Separation anxiety in childhood, as well as pre-existing psychiatric disorder, family psychiatric disorder, and substance abuse, may add to vulnerability. Successful negotiation of earlier losses, mature defence styles, and optimism may be protective. The nature of the lost relationship has been identified in a number of studies as being a significant factor [15, 27]. The special relationship between parent and child is associated with greater vulnerabilities, including an increased risk of psychiatric hospitalization and even death by suicide. Patterns of distress differ by gender with stillbirth, neonatal deaths, and sudden infant death syndromes, perhaps suggesting different attachment patterns [28]. The death of an adolescent child is not infrequently by accident, suicide, or risk-taking with illicit drugs, bringing the extra complexities of adaptation for the grieving parents. A great deal of research has explored the grief associated with the death of a partner or spouse, both young and old. High levels of dependence and ambivalence have been shown to complicate grief and to be associated with more difficult bereavement [15, 27], and prolonged or complicated grief may be more likely. Family members may have different relationships with the deceased, and thus varying patterns and trajectories of grief, which may cloud the recognition of children's and others' needs. Adults' loss of an older parent appears to be the least distressing, although there is still sadness plus the recognition of one's own mortality. Here, as at any age, intense fantasies of reunion with the deceased may indicate a risk of suicide, especially for older widowed men. Circumstances of the death may influence outcome. When dying is prolonged, as in the later stages of a terminal illness, the dying person may experience grief over his or her own life and the loved ones who will be lost to him, alongside the anticipatory grieving of family members. While palliative care systems may provide bereavement programmes, families have complex dynamics and may require family-focused interventions [29]. Sudden unexpected deaths bring an extra level of emotional shock [30], especially if also untimely, as with children's death. When violent death occurs, as with homicide or the mass violence of terrorism or war, those bereaved may experience a complex mixture of traumatic stress reactions and grief reactions, sometimes called traumatic grief [31]. The specific issues facing those bereaved by violent deaths of loved ones have been reported in a recent volume by Rynearson [32], which deals with homicide, terrorism, and other violent deaths. The prolonged and difficult grief in such circumstances is highlighted by findings from September 11, Oklahoma, and Bali bombings. When people are missing, believed dead, the uncertainty and other stressors, including complex legal and evidentiary processes (for example, Disaster Victim Identification requirements), may lead to alternating hope and dread. When there are no remains, it will be more difficult for those bereaved to accept the reality of the death. Seeing and 'saying goodbye' to the dead person have been

shown to help those bereaved in disasters. If remains are much disfigured, as with burns, it is important that those bereaved are supported in their choice about this. Social support, particularly the perceptions of the supportiveness of the family and social network, are likely to be protective and assist the bereaved psychologically [33], while perceptions of unhelpfulness may be associated with more negative outcomes [9]. Cultural requirements for social support may differ, as may the delineation of the period of mourning, the roles of the bereaved, and associated spiritual and religious needs [34]. Multiple other adversities may occur, either coincidentally or as a consequence of the circumstances and the loss of the person, for instance financial difficulties, loss of resources, changed status, loss of meaning and identity, or other profound stressors of illness, injury, or other bereavements. Such additional stressors may increase vulnerability [15]. In terms of prolonged grief disorder (previously known as complicated grief disorder, and initially traumatic grief), Prigerson *et al.* [35] have carried out extensive research to refine this syndrome. Bringing together the views of international researchers, they have developed consensus criteria for a distinct psychiatric disorder to be considered for inclusion in DSM-5. This definition requires that the reaction to loss encompasses one of three symptoms of separation distress (for example, yearning) and a minimum of five from a total of nine other symptoms, experienced at least daily, to a distressing or disruptive level. These include: shock; emotional numbing; avoidance of the reality of the loss; difficulty accepting the loss; feelings of meaninglessness; difficulty moving on with life; bitterness over the loss; mistrust; and a diminished sense of self. Such symptoms would need to last at least 6 months and be associated with significant levels of functional impairment. These findings fit well with earlier research identifying more chronic patterns of grief [12, 13].

Physical and mental health consequences of bereavement

A recent valuable review [36] outlined the evidence of increased mortality for bereaved spouses, particularly males, which is most pronounced in the first 6 months and includes a range of conditions such as heart disease, leading to death from a 'broken heart'. It is also more pronounced for those younger. Death of a child is associated with an even greater mortality risk, particularly for mothers. Suicide is one of the heightened risks, especially for mothers and older males. Physical health impairments are also found [36], with a variety of physical symptoms, as well as greater use of medical services and medications. Further research is needed to clarify the nature of any increased rate of specific diseases. Changed health behaviours, the impact of loss of a health-supporting partner, functional or social changes, or shared environments of risk may contribute. With regard to mental health, there may be an increased level of anxiety and depressive symptoms. There may be a heightened risk for some bereaved individuals for exacerbations of pre-existing conditions or the precipitation of new illnesses, including post-traumatic stress disorder when there is a violent death [32]. Other anxiety disorders, major depression, substance use disorder, and bipolar disorder may be precipitated by bereavement. Complicated or prolonged grief disorder may also represent a psychiatric consequence [35].

Assessment and management

Most bereaved people do not require counselling, so assessment must be a basis for intervention. Assessment should be simple and synchronous with need and do no harm, addressing the death and its circumstances, the relationship, and the bereaved's experience since, including social support [31]. A more structured format, potentially including grief measures [37], can clarify the presence of PTSD, depression, or prolonged grief, or other health needs, including physical health changes or problems, establishing the basis for intervention. Initial management of acutely bereaved persons requires empathic, compassionate support, and responding to any acute needs in ways that are protective of their mental health, recognizing the 'rollercoaster' of emotions that may occur, and facilitating natural resilience. Concepts of psychological first aid are also valuable in the immediate period after the death [38]. Dealing with concerns about the deceased's suffering and support to view the dead person's remains, should the bereaved choose to, are likely to be helpful. Most evidence-based interventions focus on psychotherapeutic methods, ranging from preventive counselling of those with demonstrated heightened risk [39] to self-help guided interventions [40], interpersonal psychotherapy modifications for traumatic grief [41], integrated cognitive behavioural therapy models [42], or psychodynamically informed models [43] and web-based treatments [44]. Counselling models [45] and psychoeducation have also focused on those bereaved through specific deaths such as those of infants [46]. Other models deal with grief work and tasks [47], as well as specific treatment for morbidity of complicated grief [48] and depressive or anxiety disorders, including the use of pharmacotherapy for such conditions when indicated [49]. Rynearson's [32] work with 'restorative retelling' following violent deaths emphasizes the narrative story which is central to much bereavement counselling and testimony. A practical approach to assessment and counselling may be initiated with some gentle queries such as: 'Can you tell me a little about your loss?', 'What happened with 'John's' death?', 'Can you tell me about 'John' and your relationship?', 'What's been happening since?'. If there is intense continuing distress, circumstances of death which are untimely or traumatic, a complex relationship with the deceased, disruption of family functioning which is impacting on the needs of children, inadequacies of social support, 'unresolved' earlier losses, and multiple additional stressors, the bereaved may be at heightened risk of adverse outcomes. Preventive counselling, which facilitates grieving, is attuned to the bereaved person's readiness, vulnerabilities, and strengths, and helps them to tell the story of their experiences and the person they have lost, is likely to improve outcomes [39]. If assessment indicates that psychiatric disorders have arisen, for instance depression, post-traumatic stress disorder, anxiety, or substance use disorders, these conditions should be managed appropriately, alongside counselling for the bereavement, should this be required. The use of antidepressants or other medication is not indicated for bereavement itself but may be appropriate for such complications [49]. Monitoring for suicide risk should accompany clinical management.

Prolonged or complicated grief may benefit from cognitive behavioural therapy interventions, as well as relevant rehabilitation. Those who are both traumatized and bereaved may need the traumatic stress issues to be dealt with first, and facilitation of grieving

following this [43]. There is a need for more comprehensive research and evaluation of prevention, early intervention and treatment modalities, and their appropriate provision to individuals, families, or groups [50]. Culturally appropriate models of support and intervention also need to be further developed. Many bereaved people present first within primary care settings and to their general practitioners who will need the skills and knowledge to deal with their distress, assess their needs, counsel them as appropriate, and refer when necessary. Much support also comes from community and non-government agencies, including bereavement focused groups for specific losses or for grief generally, and from specialized services in public or private mental health sectors. Telling the bereaved person how to grieve, that they should 'forget about the past', and that 'time heals all' is usually perceived as unhelpful. Treating grief as a disease, for example antidepressant medication for normal sadness, is seen by many bereaved people as interfering with their capacity to grieve for their loved one. Counselling bereaved people requires hopeful, compassionate psychotherapeutic intervention, which recognizes the human suffering involved, validates the person's strengths, and respects their spiritual needs. Loss is a central issue for all of us, both our fears of it and its reality. Counselling requires those involved to recognize their own sensitivities in this regard and to assist the 'journey' of those affected in dealing with their loss. Most people grieve, remember with love those whom they have lost, and continue to love and love anew.

Recovered memories and false memories

Deborah Davis and Elizabeth F. Loftus

Introduction

The concept of repressed memory has been around for at least a century. It is the notion that, as a defence mechanism, horribly traumatic experiences can be involuntarily banished into the unconscious, even for decades, yet at some later point return to awareness, unchanged, vivid, and accurate—protected from the ravages of time and immune to the normal laws of memory functioning and decay.

The idea of repression is everywhere. Characters in television shows, movies, and books repress memories of their dark pasts and recover them with the help from fictional therapists—using memory recovery tools such as hypnosis, guided imagery, or age regression. Or memories return in fragments until the full story bursts into memory in time to solve a crime, to prompt a long awaited reckoning, or to allow recovery from psychological problems. And national media discuss claims involving repressed memories of satanic abuse, witnessing murder, alien abduction, and other fantastical events, some disclosed by celebrities. Psychologists are exposed to the concept of repression in introductory psychology classes and throughout their careers. Moreover, the police use memory recovery techniques with witnesses and suspects. And innocent suspects confess to crimes they did not commit and did not remember when the police convinced them they ‘repressed’ the memory of committing the heinous act [1, 2].

Though the idea of repression and memory recovery had been part of cultural and professional zeitgeists for decades, controversy regarding the validity of so-called ‘recovered memories’ broke out in force during the late 1980s and early 1990s. Cases in which a memory allegedly ‘repressed’ for years, even decades, was ‘recovered’ fully intact and in detail formed the basis of widely publicized criminal charges ranging from sexual abuse to murder. Families were destroyed; personal careers, reputations, and liberty were lost, and millions were spent on litigation of the claims.

Controversy regarding the reality of these claims was fuelled by several forces. For decades after Freud repudiated his initial view that many psychological problems were caused by child sexual abuse (CSA) by family members and theorized instead that the many accounts he heard in therapy were fantasies, CSA was widely considered to be rare and lacking in severe consequences. Changes to these assumptions began during the 1960s and 1970s among professionals and feminist writers. At the same time, there were a number

of widely publicized cases of alleged sexual abuse involving multiple children in day care centres across the country. In this context, new data were emerging that suggested that CSA had been occurring more frequently than previously assumed. Together, these forces significantly increased scholarly research on the topic (for reviews of this history, see [3, 4]).

Feminists adopted the view that CSA was a violent crime of rape, not simply an inappropriate sexual act. This encouraged the trauma perspective on CSA, emphasizing the severity of short- and long-term effects of abuse that took hold during the late 1970s and 1980s. Dozens of books (many by victims), news articles, movies, and television documentaries increased public awareness of the frequency of CSA (and specifically incest) and dramatically portrayed the proposed traumatic nature of abuse and the severity of its consequences [4].

Among such reports was that of actress Roseanne Barr in 1991 [5]. She appeared on the cover of *People* magazine, claiming recent recovery of memories of abuse by her mother in infancy and later her father, who continued to abuse her until she was 17. Also in *People* magazine that year was the story of former Miss America Marilyn Van Derbur, who claimed to have recovered repressed memories of abuse by her father [6]. *Ms. Magazine*, perhaps the most prominent feminist publication of the time, published an issue with the cover ‘BELIEVE IT! Cult Ritual Abuse Exists (January/February, 1993). The author described her mother as a Satanist and alleged activities such as witnessing multiple murders, cannibalization of her baby sister, and others.

A number of self-help books focusing on the link between sexual abuse and repression were published during this time frame, claiming that sexual abuse was more common than recognized, that it is traumatic and therefore memories of abuse are often repressed, that these repressed memories are the source of many psychological problems (including multiple personality disorder), and that repressed memories can be brought back into consciousness, with the result that the psychological problems will resolve. Prominent among these were *The Courage to Heal* [7], *Secret Survivors* [8], and *Repressed Memories: A Journey to Recovery From Sexual Abuse* [9].

Collectively, these influences encouraged many to self-diagnose repressed memories and/or to seek the help of therapists in recovering them, and led some therapists to focus on the possibility that repressed memories of sexual abuse were responsible for their

patients' problems. Some even began to describe themselves as 'recovered memory' therapists. But the same reports and writings that, in some quarters, encouraged belief in repression and the role of sexual abuse in causing it fuelled disbelief and criticism in others. In part, disbelief stemmed from incompatibility of claims regarding trauma and repression with theoretical and empirical work on memory. And, in part, it stemmed from the very nature of many reported recovered memories. Both children's reports of day care abuse and adults' reports of their recovered memories were peppered with fantastical allegations, not all relating to sexual abuse. Children reported activities such as riding on flying cows, being forced to eat faeces, being flushed down toilets, or killing and burying large animals. Adults reported recovered memories of Satanic ritual abuse, forced impregnation by Satan, ritual human sacrifice, alien abduction, multiple past lives, or witnessing murder. Some claims were patently impossible (such as riding flying cows, being flushed down toilets). Many were regarded by most as impossible (such as alien abduction, forced sex and breeding with aliens, multiple past lives, impregnation by Satan, memory for events within the scope of infantile amnesia, and others) [10]. For critics, the question became one of how such clearly false memories had been created.

The ensuing widespread debate has left us with two clear practical problems without clear solutions. Firstly, how should therapists deal with the issue of sexual abuse and the potential existence of repressed memories underlying patients' problems? Secondly, how should claims of recovered memories be treated in legal contexts?

In sections to follow, we focus on a question informing both issues. How can false memories of such dramatic autobiographical events as sexual and/or satanic abuse be created? We explicate the repression hypothesis and point readers to excellent reviews of the positions of supporters and critics and the evidence offered in support of each position. We then turn to the false memory perspective, focusing on empirical literature demonstrating the processes and procedures through which false memories for autobiographical events are formed. We end with commentary on implications of this literature for therapeutic practices and for the legal system.

The repression hypothesis

The repression hypothesis offers the seemingly counterintuitive proposition that the more traumatic an event at the time it occurs, the more likely the memory of the event is to be repressed, banished from consciousness, and unresponsive to attempts to retrieve it until it is psychologically 'safe' to again become aware of it (for example, [11–14]). This view is rooted in Charcot, Janet, and Freud's theories of the role of sexual abuse in prompting repression (for a review of such theories, see [15]). Central to these theories is the idea that victims may be completely unaware of the traumatic event during repression, yet it will nevertheless cause psychological problems, acting 'like a foreign body which long after its entry must continue to be regarded as an agent that is still at work' [11, p. 6].

Though Freud eventually abandoned his initial theory implicating repressed memories of CSA as the foundation of psychological problems, modern repression theorists have adopted and expanded them (for example, [13, 16]). One variant of the repression perspective—the betrayal trauma theory [14]—entails predictions that are even more counterintuitive than the basic proposition that

trauma promotes repression. For example, it asserts that sexual abuse is more likely to be forgotten if it involves greater betrayal such as when committed by an adult on whom one depends (such as a father or other close family member). The betrayal trauma theory also asserts that memory for other (particularly emotional) types of events is facilitated by repetition. But traumatic amnesia or repression is assumed to be more, rather than less, likely with repetition of traumatic events such as abuse.

The original Freudian notion of repression and variants, such as the betrayal trauma theory, have directly promoted the recovered memory movement among therapists. The assumption was that if the repressed memories could be 'recovered', processed, and integrated into the patient's life narrative, the patient's problems would improve. This led therapists to adopt suggestive techniques to uncover memories of the offending events. Principal among these was the explicit suggestion to patients that their symptoms reflect sexual abuse and that failure to remember that abuse reflects repression of the memories. Secondary to this was the use of a variety of suggestive memory recovery techniques such as hypnosis, guided imagery, dream interpretation, participation in 'survivor' support groups, and others (for reviews, see [17, 18]).

The critics

Though the repression hypothesis has enjoyed widespread support in the therapeutic community, this has been much less true within the scientific community, particularly among memory scientists and many clinical scientists. Many criticisms address the incompatibility of the repression hypothesis with theory and research on memory. Inherent to the notion of repression is the idea that all stages of memory operate differently and through different mechanisms for traumatic material. While many on both sides of the controversy would agree that there are differences between the operation of memory for traumatic, highly emotional, and more neutral events, controversy centres on the nature of those differences.

For critics, the view is that more traumatic or emotional memories are more likely to be remembered, to be highly accessible, and to be remembered through normal processes of retrieval—though some argue for greater equivalence between traumatic and non-traumatic material. For repression theorists, the view is generally that traumatic material is more likely to be forgotten (repressed), to be inaccessible, and to be resistant to recall through normal mechanisms such as salient cues or reminders or efforts to recall (thereby necessitating the extraordinary efforts to retrieve the memories). Moreover, it is assumed that memory for traumatic material does not decay or become distorted in the normal manner, such that even when retrieved after decades of disuse, such memories will be accurate and detailed (for explication and reviews, see [19]).

Secondly, disagreement surrounds whether, and by what methods, each side's claims can be validly tested. Each has offered methodological criticisms of the efforts of the other. Though there have been some attempts to provide laboratory demonstrations of processes related to repression (such as memory suppression or blocking) (for reviews, see [20, 21]), repression theorists have largely attempted to demonstrate the reality of repression for traumatic events such as CSA or to test the conditions under which it is most likely to occur with real-life alleged victims. Critics have raised such concerns

as: (1) verification of alleged abuse (that is, of the same actions entailed in the recovered memories); (2) verification of a period of inability to remember the abuse (vs failure to think about the abuse or episodes of remembering that are themselves forgotten); (3) verification of repression as the mechanism of failure to remember (vs normal mechanisms of forgetting); or (4) verification that even if an episode seemed inaccessible to memory for some period, the episode was indeed traumatic in nature. The latter concern is important, in that studies showing some report that they had been abused, but had not remembered it for long periods of time, are not relevant if the unremembered event was not traumatic. Essentially, critics argue that these concerns indicate that the hypothesis has not been adequately tested and arguably may be untestable (for reviews of these concerns, see [4, 18, 22]).

On the other hand, proponents of the repression hypothesis have argued that laboratory demonstrations of techniques and processes promoting the development of false memories are not relevant to the kinds of traumatic events that might trigger repression. Ethical constraints on laboratory research prevent either exposure to traumatic events or efforts to implant memories of such events. Moreover, though many real-life patients who have claimed to have recovered false memories of abuse through therapy have later recanted and claimed the new memories were false, repression proponents claim that these recantings are themselves subject to doubt (for example, they might be the product of social influence to recant), and not evidence of false recovered memories (for a discussion of retractor experiences, see [23]).

These debates continue. Nevertheless, we believe that the reality of false memories of highly traumatic autobiographical events has been convincingly demonstrated, if nothing else by the fantastical nature of many purportedly recovered memories, such as those for sex, childbearing, and infanticide with Satan; alien abduction and impregnation; impossible memories from beyond the veil of infantile amnesia; past lives; and others. Moreover, these false memories were developed through normal processes of memory distortion. Next, we discuss how this occurs.

If this memory is not real, where did it come from?

Of issues relevant to the controversy, questions of whether and how false memories can be created are, in some respects, the easiest to answer. To understand this, it is important to begin with the concept of memory itself.

The nature of memory

Many laypersons think of memory as akin to an enhanced movie consisting of sensory images replaying the event in question. Memory science has revealed that instead memory consists of at least sensory images, beliefs (the story we tell ourselves about what happened), and information relevant to the plausibility of those beliefs. A memory judgement criterion is then applied to these narrative cognitions, assessing whether the ‘memory’ is or is not a real memory for a real event. Some, for example, may require of themselves clear detailed sensory images to decide something is a memory. At the other extreme, a person may be convinced that a bodily sensation is an embodied memory of sexual abuse (for a review, see [24]).

Given that a real event did occur, each memory component can change over time. But each can also be fully created independent of the occurrence of a real event. We review the evidence of whether and how this happens in the sections to follow. We present evidence that false autobiographical memories can be fabricated, even for relatively extreme events and even for events that would seem rather implausible.

Evidence that extreme false memories do occur

False autobiographical memories can develop for events ranging from the relatively mundane (for example, school performance) to the seemingly impossible (for example, having been abducted by aliens, having sex with the devil). Many find it implausible that a person could falsely remember ‘extreme’ experiences such as alien abduction, satanic ritual abuse, sexual abuse by one’s father, or having witnessed or committed a horrific crime.

Real-life examples

Nevertheless, real-life examples of each of the aforementioned extreme false memories have been documented in the scientific literature: witnessing murder [25, 26], alien abduction [27], enduring the painful surgical removal of one’s clitoris, sexual abuse (including satanic ritual abuse [18, 25]), witnessing dramatic fatal accidents [23, 28], and committing a crime that one did not actually commit [1, 2, 29].

Laboratory studies

Research demonstrating that false memories for events that never happened can be easily planted is commonplace in psychology. Many such demonstrations involve planting false memories for relatively trivial events such as hearing sounds or words, seeing various (actually unseen) objects, saying things one did not actually say, and many more [30]. False memories can be developed in people of normal cognitive function and lacking any mental illness or abnormality. Even those exceptional people who purportedly have near-perfect autobiographical memory (who can remember every day of their lives) have been led to develop false memories [31].

Though laboratory procedures for planting such false memories may seem inadequate to provoke the relatively extreme false memories of concern here, it is important to note that they involve similar processes. Countless demonstrations of schema-consistent memory intrusions illustrate the tendency to develop false memories based on what makes sense, given other relevant knowledge of similar situations, such as to falsely remember seeing books in a professor’s office that had none (for example, [32]).

Plausibility and inference are also implicated in the development of dramatic false autobiographical memories. But perhaps the most relevant research has been experiments demonstrating that procedures leading to relatively mundane false memories (such as establishing plausibility, active imagination, suggestive interviewing, etc.) can also lead to the development of rich (realistic sensory detail) false autobiographical memories in a subset of study participants.

One paradigm for planting false autobiographical memories is the ‘familial informant false narrative procedure’ or simply the ‘lost-in-the-mall’ technique [33, 34]. Researchers first solicit the cooperation of a ‘familial informant’ (such as a parent) to ensure that a target event did not actually happen to the participant. Participants

are told the family member had told researchers about several events that happened to the participant as a child. Some are true, but the target event is false. The participant may be interviewed several times about the target event, using suggestive procedures (sometimes including guided imagination). In a final session, participants report on, and describe, any memories they have developed of the target event.

Across many studies, an average of approximately 30% of subjects have developed partial or complete false memories (for reviews, see [33, 35]), varying from 0% (when an odd variation was used to attempt to plant a relatively implausible event memory) to more than 50% for more mundane events (a ride in a hot air balloon). More developed false memories either with imagination procedures included or with additional 'evidence' included (such as a doctored photo). Some develop false memories right away, whereas others begin with little memory but, after several suggestive interviews, begin to recall false events in great detail. While researchers have not attempted to plant memories of abuse, they have planted memories for highly unpleasant events such as hospitalizations, medical procedures, near drowning, or vicious animal attacks. They have also planted highly implausible memories for both mundane (for example, rubbing chalk on one's head or kissing a plastic frog) and strange or dramatic events (witnessing demonic possession as a child) (for reviews, see [17, 36]), and for personally committing specific aggressive acts [37] or crimes [38].

Notably, such false memories are consequential. Participants led to develop false beliefs or memories of being made sick by particular foods in the past avoided eating the food in follow-up assessments of a week to a month later (for example, [39, 40]).

The path to false memory

Memory is essentially a narrative story of the event, combined with sensory images. A memory judgement criteria is applied to assess the likelihood that the 'memory' is a true memory of a real event. In part, the question of whether the 'memory' is accurate is evaluated in light of other knowledge. In part, it is evaluated in light of other criteria one may use to decide the reality of the memory, such as the clarity of the sensory images or the way it was remembered (for example, in a dream or under hypnosis). Thus, to consider how false memories might be constructed, we must consider how the narrative or images may be constructed or altered and how one's other relevant knowledge might be altered in a way favouring the validity of a new narrative, as well as how memory judgement criteria can be altered.

Developing plausibility as the foundation for belief in the narrative

Memory is primarily semantic—the story we tell ourselves about what happened, accompanied by sensory images that become increasingly vague over time. This story is informed by other relevant knowledge suggesting that the story does or does not make sense. This knowledge can affect our interpretations of events at the time they happen and also cause them to change over time.

It is easy to see how our general knowledge and beliefs can affect the immediate interpretation of experiences. For example, shadows in one's bedroom at night might be interpreted as an alien visitation

by those who believe that aliens visit the earth and make such personal visits. For those who do not possess such beliefs, the shadows are more likely to be interpreted as created by wind in the trees outside one's window.

But in a related way, they direct the development of false memories. The formation of false memories entails the construction of a narrative that is plausible in light of one's other knowledge and beliefs, including beliefs about oneself, others involved, and the way the world works. Thus, it is important to understand how a narrative involving seemingly impossible or improbable events can become plausible. Without such an element of plausibility, the person is unlikely to believe the false narrative and thus will not consider it a memory.

Regarding sexual abuse, this can happen via multiple pathways. It can begin with psychological issues leading the person to search for explanations and solutions. In the course of this search, the person may be exposed to information that increases the plausibility of: (1) repression itself; (2) sexual abuse as a cause of repression; (3) sexual abuse as a cause of symptoms such as the person is experiencing; and (4) the possibility that one could have personally experienced abuse (or that a specific person could have committed it). This can happen via exposure to media accounts of repressed and recovered memories and through exposure to self-help literature, accounts of friends or family, among many other sources.

Cultural acceptance of the trauma narrative, the idea of repression, and the link between sexual abuse and many symptoms can lend plausibility to the ideas that one may have personally been sexually abused (even in the absence of any memory of it) and that this unremembered abuse is causing most psychological/behavioural symptoms for which the person is most likely to seek psychotherapy or self-help advice. If the person sees a therapist, the therapist may further magnify the plausibility of repression and abuse narratives by actively discussing trauma and repression and/or alleged links between specific symptoms and sexual abuse or by explaining why he or she believes the patient was abused. Once beliefs linking sexual abuse, trauma, and repression are adopted, this can facilitate the formation of false memories of abuse via several mechanisms.

Implications of fuzzy trace theory

'Fuzzy trace theory' (for example, [24]) explicates how general knowledge and beliefs can distort memories or create false memories. When one thinks about an event, both event-related images and beliefs *and* our general relevant knowledge and beliefs about such types of events and people are activated in memory. When clear verbatim sensory images (like an enhanced video) are not available to distinguish what actually happened from other information activated in memory, the person may misattribute the additional activated information from his or her general knowledge store as part of the event in question. Essentially, expectations based on our additional relevant knowledge and beliefs can result in false memories or false details, consistent with those expectations (for a review of schematic effects, see [32]).

Schemas for specific persons (oneself or others involved in the event in question) will include expectations of behaviour—how the person thinks he or she is likely to behave, as well as expectations for others' behaviour. 'Negative stereotyping' of a person suspected of CSA is commonly viewed as contributing to false memories of sexual abuse and refers to conveying information about the accused,

characterizing him as the ‘type of person’ likely to commit abuse specifically or other damaging or aggressive acts (for example, [41]). Beliefs that sexual abuse tends to cause specific physical or psychological effects will also tend to make the belief that a person experiencing those symptoms was indeed abused more plausible.

It is easier to create false beliefs and memories if the event itself is viewed as more plausible. False memories for actions have been more easily planted in experimental subjects if the person found it plausible that he or she *would have* committed such an act (such as when a person who often behaves aggressively finds it plausible that he or she *would have* committed another aggressive act (for example, [37])). It is also easier to plant memories for things others have done if those actions are seen as plausible for the other person. Whereas it may be more difficult to plant implausible memories in many circumstances, implausibility itself is malleable [42]). For example, Mazzoni *et al.* [43] first exposed some participants to material designed to enhance the plausibility of demon possession and later attempted to plant memories of having witnessed such an event. Those exposed to the plausibility-enhancing manipulation later reported greater likelihood of having witnessed demon possession.

Many things can happen to increase the plausibility of an event. Among these is exposure to information that the type of behaviour or event in question happens relatively frequently (vs rarely) (for example, [44]) or repeatedly imagining the event in question (for example, [45]). Regarding sexual abuse, many popular books claim a high prevalence of sexual abuse and offer lists of symptoms purportedly characteristic of abuse survivors (including failure to remember the abuse) that are so inclusive as to encourage almost anyone with problems to attribute them to abuse. E. Sue Blume, in *Secret Survivors* [8], lists the most common problems for which therapy is sought: depression, addiction, phobias, sexual issues, self-destructiveness, obsessions, and countless others. It includes many opposites such as too much or too little eating, sex, sleeping, etc. It even includes failure to remember abuse as a symptom of abuse, asserting that failure to remember abuse is not evidence that one has not been abused. Such claims and lists of abuse symptoms in the survivor literature at the least make plausible that virtually any problem can be caused by sexual abuse.

Perhaps reflecting the influence of widespread depictions of abuse and repression, Rubin and Boals [46] found a relationship between self-rated likelihood of entering therapy and beliefs that one had experienced (and could not now remember) childhood trauma and abuse. Notably, such patients may influence their therapists to focus upon abuse, creating a bi-directional cycle of suggestion [17].

At some point, the person may become fully convinced that sexual abuse did occur and even develop false memories of that abuse. Kihlstrom [47] described a condition in which a person’s identity, lifestyle, and interpersonal relationships are centred around an objectively false memory of traumatic experience that the person strongly believes is true. This ‘false memory syndrome’—or the definition of one’s identity as an abuse survivor—becomes a central aspect of relevant knowledge that serves as context for interpretation and evaluation of new information as plausible or not and as the schematic basis of memory intrusions [17].

Finally, related to the issue of plausibility, it is important to note that it is easier to convince a person that they must have done or experienced something that would otherwise seem implausible

(or to otherwise alter beliefs) if they doubt their own memories—a phenomenon Gudjonsson has dubbed ‘memory distrust’. This phenomenon has been implicated in many cases of internalized false confession (that is, a confession where the person comes to believe falsely that they did commit the crime) [1, 2]. Therapeutic clients may, for various reasons, doubt the reliability of their memories and therefore be more easily convinced of things they do not initially remember.

The role of belief: the transition from ‘it could have happened’ to ‘it did happen’

Many false memories develop through persuasion that an event happened or happened in a particular way (for example, [17, 48, 49]). In practice, there are many pathways through which beliefs regarding sexual abuse or other seemingly implausible events can be created or altered. These include conversations with other witnesses, police, therapists, and other interviewers, exposure to media accounts, and exposure to ‘evidence’ that the event occurred in a particular way or was committed by a particular person. Internal processes are also important, such as attempts to reason about what must have happened or attempts to understand the ‘evidence’ the person is aware of. Some may interpret dreams as reflecting reality. Essentially, any source of information or argument can convince the person that a particular event, or a version of that event, is true.

Loftus and Davis [17] describe influence processes in therapy that can convince a client he or she must have been abused. This may happen at first in the absence of ‘memory’ of abuse. The therapist may tell clients that their symptoms suggest abuse, offer information and arguments to support the assertion, refuse to accept denials, and persist in asserting they were abused until the clients agree. These assertions can be supplemented by a variety of therapeutic procedures that appear to offer ‘evidence’ that clients were abused.

Evidence of many kinds can lead people to falsely believe they experienced specific autobiographical events. In the ‘lost-in-the-mall’ procedure, family members’ assertions that an event did happen to participants as young children provided evidence crucial for the development of the many different false memories elicited through the procedure. False evidence against criminal suspects has been implicated as an important contributor to false confessions, particularly of the sort where suspects come to falsely believe (and sometimes falsely remember) that they committed the crime (for reviews, see [1, 2]). Dream interpretation suggesting that a specific type of event happened or exposure to doctored photographs depicting events that did not occur have led subjects to falsely believe and/or remember that they experienced events ranging from before the age of 3 to their recent past [36, 50].

Therapeutic techniques and persuasion can enhance belief in an event directly, by seeming to provide evidence that the event did happen. They can also do so indirectly, by making it more plausible that the event happened as believed, such as when information that a person is generally aggressive or has a criminal record can make it more plausible that he or she committed a specific aggressive act. Or information that sexual abuse is often committed by stepfathers can make it more plausible that one’s own stepfather would plausibly engage in abuse.

Beliefs regarding sexual abuse can come from many sources of suggestion. These can include others who have become concerned about the possibility of abuse, others who talk to the person about the general issue of abuse or their own (or about the abuser), information acquired in sex education classes, media, etc., forensic interviewers, popular 'survivor' literature, and others.

Even the simple process of thinking about an event can make it seem more likely to have happened in the past or to happen in the future. Studies of imagination inflation have demonstrated this with a very simple procedure. Participants first rate the likelihood that specific events happened to them in the past (or will in the future). Then they imagine that event happening. Finally, they rerate the likelihood of the event's occurrence. Imagination increases the perceived likelihood that the event did (or will) happen (for example, [51]). Analogous to the process of imagination inflation, Sharman, Manning, and Garry [52] illustrated 'explanation inflation' whereby the process of explaining how or why childhood events *could have* happened leads persons to become more confident that they *did* happen. Both imagination inflation and explanation inflation have been demonstrated for a variety of past and/or future events [52].

Another laboratory procedure is analogous to situations where a therapist provides feedback to clients that their symptoms suggest abuse. Participants first rate the likelihood that certain events occurred during particular periods of their life. They then answer a series of questions (sometimes by computer) and receive false feedback that their scores indicate they experienced a particular kind of event. Sometimes this is followed by imagination procedures to picture the event in question. Finally, participants again rate the likelihood that the event actually happened and, in some studies, indicate the extent to which they recall the event. Like the imagination or explanation inflation studies, some participants in the false feedback studies develop stronger beliefs that the target event did happen and some also develop memories of the event.

Generally, procedures targeting belief that an event did occur vary in suggestiveness, with imagination/explanation procedures falling at the lower end of suggestion, false feedback studies suggesting that the person did or probably did experience the event in the middle, and those providing 'evidence' that the event did occur at the high end (such as false claims by family or doctored photos). The more suggestive procedures tend to more strongly affect belief in, and/or memories of, the suggested event (for a review, see [35]). These processes can make the event more familiar, more accessible in memory, and more fluent (easy to picture or understand), all bases upon which people judge whether or not something is or is not a memory. Moreover, the procedures can cause the person to generate images of the event that can become misinterpreted as veridical memory.

The role of sensory images: developing what 'feels' like a memory

Most think of event memory in terms of the ability to replay sensory images of the event in one's mind. Some might not think of newly developed autobiographical beliefs as memories, until they can produce a sensory replay of the event. Sensory images are indeed one component of memory. But what is less well known is that over time, the images one associates with events can change—and even be created through a number of processes. These may consist of exposure

to verbal or written accounts causing the person to generate images of the event, sensory images from other sources (such as pictures or video depictions), or internal processes such as the person's attempts to remember and picture the event or efforts to imagine how things must have happened. Some internal processes are triggered by therapeutic procedures involving active imagination/imaging (for example, guided imagery or hypnosis). Others may occur spontaneously such as dreams or sensory image associations triggered by exposure to reminders of the type of event. They may also be created through conversations with others or interviews, as described more fully in the section on suggestion.

If the person mistakenly attributes the source of such images to the experience of the original event, rather than to the real source, the images may be interpreted as a 'memory'. Indeed, a substantial body of scientific literature has shown that it is commonplace to confuse sensory images acquired independently of the original event (or any event) as 'memories' for the event in question (for reviews, see [24, 30, 51]).

With a foundation of plausibility for abuse, such misattributions become more likely. Mazzoni *et al.* [43], for example, suggested that imagination procedures can create false memories in a three-stage process by which a person first perceives the event as more plausible, then comes to believe the event actually did occur, and finally reinterprets the narrative as actual memories. Imagery is crucial to this process, in that Green and Brock [53] have shown that narratives are persuasive to the extent they evoke imagery of the event.

Imagery in the context of suggestion

Essentially, suggestion involves any statement or action asserting or implying a particular version of an event is true or that others are not true. It may also state or imply that the speaker strongly believes what is suggested and/or the speaker strongly prefers that the listener reports a particular version of events. In effect, suggestion plants an idea in the target's mind about either what might have or probably did happen or what another person wants the target to say or do.

Suggestion can create imagery of events that did not occur and increase belief that the events did occur. Suggestion can also create expectations of more approval/reinforcement for giving specific memory reports and expectations of disapproval/punishment for continuing to give the initial report. These processes have been shown to lead to false memories and false reports of relatively trivial events in the laboratory, as well as of dramatic personal experiences among both children and adults, including false confessions to heinous crimes such as murder of one's own children, parents, siblings, and others [30, 54].

Some common therapeutic techniques are inherently suggestive or are executed in a suggestive manner. They can simultaneously encourage imagery of suggested events and increase plausibility and belief. Guided imagery, for example, may be practised alone or in the context of other suggestive techniques. It involves efforts to induce the client to picture an event through multiple sensory modalities and can involve suggestions for both focus and content. Though sufficient alone to produce false memories, false memories become more likely when guided imagery is combined with other suggestive techniques. Herndon and colleagues [55] tested combined effects of guided imagery and an analogue to survivor group therapy. Each increased false memories and participants' confidence in the memories they reported. But when exposed to both, fully 75%

of participants developed false memories for a suggested early childhood medical procedure (compared to 5% among those exposed to neither and 41–50% among those exposed to one source of suggestion) (for a demonstration of additive effects of guided imagery, peer pressure, and repeated interviewing, see [56]).

One frequently practised memory recovery technique is hypnosis, often used in conjunction with guided imagery or efforts towards age or past life regression. Though hypnosis does increase the amount recalled, even without suggestion, much new information is false. But unless carefully trained otherwise, therapists can be very suggestive with their hypnotic subjects—both through suggested focus and content and through selective reinforcement of expected reports of abuse, satanic ritual abuse, alien abduction, womb, birth, infantile, or past life experiences, etc. They may also be suggestive through directed imagery such as when therapists instruct clients to change the view of the ‘camera’ of memory to focus on a person, action, or location not originally noticed. This not only suggests memory content but also suggests unrealistic processes and abilities of memory. Given widespread public and professional beliefs in the ability of hypnosis to enhance recall, it is not surprising that both place greater confidence in memories recovered under hypnosis (for reviews, see [57–59]). The role of hypnosis in false memories appears to be, in part, rooted in the vulnerability of those who are hypnotized, in that hypnotizability itself is related to vulnerability to development of false memories [60].

These are only a few among many techniques that can alter the components of memory (plausibility, narrative, images, etc.). Others include survivor group participation, journaling and other ‘homework’, and eye movement desensitization and reprocessing (EMDR)—and even use of drugs such as sodium pentothal [3, 17, 18].

Finally, related to the adoption of a ‘survivor’ identity, some research has shown that when led under hypnosis to believe in characterizations of themselves that were inconsistent with their current identities, participants have shown selective attention to, and enhanced memory for, other information consistent with the new characterizations. In addition, they tended to perceive information consistent with the new characterizations as more self-relevant and personally meaningful and to more easily access autobiographical information consistent with the new characterizations. These accessed memories often entail a reinterpretation of previous experiences that seemed to verify the new characterizations (for a review, see [58]).

The role of a memory judgement criterion

An additional step in the development of consequential false memories is that the person must apply one or more criteria to assess whether a new narrative is a memory of a real event.

Generally, the stronger the verbatim images or gist traces and the weaker the memory judgement criterion, the more likely a particular narrative is to be judged a memory. Verbatim images developed and strengthened through the many processes described thus far can be sufficiently vivid and detailed to pass even the most stringent memory judgement criterion. Gist traces (an abuse narrative) can likewise be strengthened by processes such as imagination, exposure to plausibility-enhancing information, the development of

abuse-related personal identities, and others. The more plausible the narrative in light of the person’s general knowledge and beliefs, or the more information of any kind that appears consistent with the narrative in question, the more likely it will be judged an actual memory. Moreover, the sense of familiarity with an image or narrative, which grows stronger the more it is discussed or brought to mind, can be interpreted as memory.

Neither the strength of verbatim and gist traces or their plausibility nor their familiarity are necessary criteria for a person to conclude the memory is real, however. Loftus and Davis [17] described in detail the way in which the criteria one uses to assess whether or not a memory is real may be highly variable and malleable. Some people may require of themselves that they have very clear sensory images of an event in order to interpret or report it as a memory. Others may consider beliefs without images or very vague images to be memories.

These and other memory judgement criteria are malleable and can exert significant influence on reports and behaviour. Some therapists and survivor literature encourage beliefs that dreams can be verbatim replays of actual events, and therefore that a specific dream is a memory of a real event. But given that dreams are most likely to reflect daily events and what is on one’s mind, a person who is exposed to content about abuse or who is thinking a great deal about abuse might dream about abuse for that reason. Beaulieu-Prevost and Zadra [61] provide a recent review of research showing that dreams are a common source of false memories and addressing the conditions under which dreams are most likely to be interpreted as memories, even in the absence of suggestion (and they further demonstrated that false memories for dreams themselves can be planted).

Other therapy-related beliefs promote very liberal memory judgement criteria that can lead clients to classify a variety of questionable experiences as true event memories. For example, Francine Shapiro’s book [62] on EMDR states that any memory that emerges during EMDR is, in fact, true. A therapist may also encourage the belief, already prevalent among laypersons, that all memories that emerge during hypnosis are true. Some therapists and survivor literature have also promoted the belief that bodily sensations are ‘body memories’ of abuse (for example, [63]).

Bass and Davis [7] discussed body memories and promoted liberal memory judgement criteria: ‘You may have forgotten large chunks of your childhood ... yet there are things you do remember. When you are touched in a certain way, you feel nauseated’ (p. 22). The authors suggested that although memories might be hazy, dream-like, or fragmentary, this was not evidence of inauthenticity: ‘if you ... have a feeling that something happened to you, it probably did’ (p. 21). Though the authors recounted stories of those who doubted their new memories, or explicitly said they knew they were not real, they also suggested these feelings did not justify discounting the memories: ‘It’s natural that you have periodic doubts ... But that’s because accepting memories is painful, not because you weren’t abused’ (p. 86).

Beliefs that bodily sensations can be, or reflect, traumatic event memories are widespread among practising therapists, laypersons, and students. From one-third to over three-quarters of therapists in the United States and Canada report beliefs that body pains and other physical symptoms are symptoms of sexual abuse and/or that sensory impressions from early life can represent reliable memories

that can be recovered (for a review, see [64]). Therapists adopting such beliefs may tell patients that a particular bodily sensation is, or reflects, a memory of abuse and thereby justify a series of suggestive therapeutic procedures to unearth a more explicit narrative or sensory ‘memory’.

Summary

Influences that can distort or fabricate memories are well established within the scientific literature. Remaining controversy concerns the nature of events for which false memories can be created. Some argue that memories for traumatic events cannot be planted and laboratory studies of less dramatic false memories are not applicable to sexual abuse. Nevertheless, many accounts of ‘retractors’ (those who reported recovered memories and later recanted them) have suggested that indeed false memories for horrific forms of abuse can be planted (for reviews, see [17, 18]).

While laboratory studies are limited by ethical constraints to avoid attempts to create potentially very consequential false memories, a substantial and growing literature has demonstrated that false memories for a variety of relatively dramatic, sometimes scary, autobiographical events can be planted in mentally healthy participants across the lifespan. And they can be planted by means of procedures used within therapy (such as dream interpretation, hypnosis, guided imagery, and others) or practised by the person (active imagination, reading survivor literature, exposure to abuse accounts in media, and others). Together with suggestion (that abuse may have, or must have, taken place) and loosening of memory judgement criteria, such procedures greatly increase the likelihood of the development of false memories of sexual abuse, satanic ritual abuse, or other seemingly implausible events.

Conclusions

Although our view is that evidence for massive repression is lacking, by endorsing this conclusion, we in no way deny the reality of sexual abuse. All parties in this controversy can appreciate the widespread nature of the problem and the severity of the consequences for many victims. However, we suggest two important conclusions.

Firstly, claims of repressed and recovered memories are inherently suspect. The repression hypothesis has itself proven difficult, and some believe virtually impossible, to test. And it is fundamentally incompatible in many respects with the science of memory. Moreover, a very large and growing scientific literature has shown that common therapeutic procedures and other influences can distort memories or lead to the development of fully fabricated false memories of sexual abuse and other dramatic and/or traumatic life events.

When such claims are litigated, at the very least they should be given significantly reduced weight. There are two possible explanations for a subjectively ‘recovered’ memory: (1) that the memory is real, that it has indeed been repressed for as long as decades, and that it has now been recovered intact; or (2) that the memory was at best distorted—or at worst entirely fabricated—through processes shown across many scientific studies to have such effects. Even continuous memories, whether reported immediately after an event or significantly later, can be distorted. Memories can also be totally confabulated, even if no claim of repression or suspect

memory recovery procedures are involved. But when there is a claim of repression, and particularly when the claimant has been subject to influences shown to distort or fabricate memories, research suggests the claim must be given reduced weight, if not fully discounted. A plausible explanation, one that is arguably much more plausible than the reality of the memory, exists for where the memory came from (for reviews of legal issues entailed in the recovered memory debate, see [65–67]).

Secondly, research suggests that some therapeutic practices should be avoided—prominently direct suggestions and arguments to clients claiming that they have likely been sexually abused, particularly in the absence of clients’ initial memories of abuse or in the face of an absolute denial. Also undesirable are focusing therapy on the issue of abuse with such clients, using memory recovery procedures within therapy focused upon retrieval of memories of abuse, and recommendations for outside activities focused on recovery of such memories (such as reading abuse centred self-help literature, participation in survivor groups, and other ‘homework’). These are all procedures known to increase the risk of memory distortion and fabrication [17, 18, 68].

These recommendations may be controversial, since despite the highly publicized nature of the controversy, belief in repression remains widespread within the therapeutic community and among some clinical or memory scientists (for surveys assessing such beliefs, see [64, 69]). Many popular therapies endorse the idea of memory ‘recovery’ and include techniques for that purpose, for example EMDR, sensorimotor psychotherapy, somatic experiencing therapy, neurolinguistic programming, alien abduction therapy, internal family systems therapy, and others [64]. Many therapists incorporate one or more practices that increase the risks of false memory development. Beliefs supporting such practices are likely to remain widespread for some time to come.

Our hope and expectation is that researchers will continue the rapid development of new research and paradigms to inform the disputed issues and to discourage practices with known risks. While many false memories may be benign, those regarding sexual abuse are highly consequential and toxic for both the accused and the accuser.

Finally, we hope that better education of professionals and the public will improve understanding of memory and that this education will provide inoculation against many faulty claims prevalent in popular culture. Although some widely held beliefs are correct, many respondents across varied populations have endorsed beliefs diametrically opposed to the actual operation of memory (for a review, see [64]).

Core dimensions of anxiety disorders

Nastassja Koen and Dan J. Stein

Introduction

Contemporary clinical approaches to anxiety disorders are based on a categorical approach. The *Diagnostic and Statistical Manual of Mental Disorders*, third edition (DSM-III) [1] provided a key impetus to the field by providing operational diagnostic criteria for a range of different anxiety disorders and by clearly demarcating these conditions from normal anxiety responses. Subsequent decades saw progress in delineating the neurobiology of each of the anxiety disorders, as well as the introduction of specific pharmacotherapies and psychotherapies for the treatment of generalized anxiety disorder, panic disorder, specific phobia, and social anxiety disorder.

However, several factors have also suggested the value of a return to a more dimensional approach to anxiety. First, there is significant comorbidity among the anxiety disorders, and the severity of anxiety symptoms in community and clinical symptoms falls on a continuum [2]. Second, psychobiological research has emphasized that multiple genes of small effect and perhaps common environmental factors are implicated in anxiety disorders, and that overlapping neural circuits and molecular mechanisms underpin these conditions [3]. Third, there is overlap in interventions for anxiety disorders, and there is value in a transdiagnostic approach to treatment [4].

It is important to emphasize that categorical and dimensional approaches can readily complement each other [5–7]. Any dimensional variable can be split to form categories, and categorical constructs can be evaluated with dimensional measures. Categorical constructs may have significant clinical utility, facilitating decision-making and treatment, while dimensional constructs may be particularly important in research settings where fine delineation of underlying mechanisms is needed to advance diagnostic validity. Still, while categorical and dimensional approaches are complementary, it is timely to focus here on dimensions.

This chapter will provide a theoretical basis for approaching the psychobiological dimensions that underpin the anxiety disorders. We first begin with a brief description of categorical approaches. We then outline, in turn, dimensional approaches to the assessment of anxiety, the range of mechanisms underlying anxiety disorders, and transdiagnostic approaches to treatment. Subsequent chapters in this section of the volume will provide additional detail on each of these topics (for example, see Chapters 80, 87, 89, 90, and 92).

Categorical approaches

DSM-II [8] was strongly influenced by the psychodynamic theory and described a number of categories of neuroses, including hysterical neurosis (modifiable symptoms symbolized underlying conflicts), phobic neurosis (fears are displaced from a focus unknown to the patient, to a phobic object), neurasthenic neurosis (characterized by somatic symptoms such as chronic weakness), obsessive-compulsive neurosis, and depressive neurosis. These were viewed as predominantly characterized by anxiety, which produced a range of symptoms (for example, anxious over-concern, panic, somatic manifestations) and which were experienced as subjective distress from which relief was desired [9]. The *International Classification of Diseases*, ninth revision (ICD-9) chapter on neurotic disorders similarly covers a fairly broad range of conditions [10].

DSM-III attempted to take a more atheoretical stance to classification, introducing a chapter on anxiety disorders and providing operational diagnostic criteria for each of these conditions [1]. DSM-III anxiety disorders included agoraphobia, generalized anxiety disorder, obsessive-compulsive disorder (OCD), panic disorder, post-traumatic stress disorder, simple phobia, and social phobia. DSM-IV also emphasized that panic attacks could occur in a range of different anxiety disorders and introduced the constructs of acute stress disorder, anxiety disorders due to a general medical condition, and substance-induced anxiety disorder [11]. The ICD-10 chapter on ‘neurotic, stress-related, and somatoform disorders’ includes these various conditions, as well as a number of additional disorders [12].

In DSM-5 [13] and ICD-11, the category of anxiety disorders has continued to evolve. The development of DSM-5 saw a strong focus on diagnostic validity and the inclusion of neuroscientific data, while the development of ICD-11 has emphasized the issue of clinical utility and considerations of public mental health [14, 15]. Both classification systems have now removed obsessive-compulsive and related disorders and trauma- and stressor-related conditions from the anxiety disorders, and placed them in separate chapters. At the same time, in both classification systems, the new chapters remain adjacent to that on anxiety disorders, and the overlap in their symptomatology is emphasized.

Fear may be described as ‘an emotional response to perceived imminent threat or danger associated with urges to flee or fight’ [13]. This ‘fight-or-flight response’ is characterized by an increased

startle reaction and physiological autonomic alterations [16, 17]. In contrast, anxiety is ‘the apprehensive anticipation of future danger or misfortune accompanied by a feeling of worry, distress, and/or somatic symptoms of tension. The focus of anticipated danger may be internal or external’ [13]. From an evolutionary perspective, fear and anxiety appear to be adaptive responses [18]; and in the clinical setting, it is important to differentiate normal functional anxiety from pathological dysfunctional anxiety.

Since the fourth edition of the DSM, the differentiation of normal and pathological anxiety is crucially dependent on the clinical criterion; disorders are characterized by clinical distress or by significant impairment [19]. The field is unfortunately unable to rely on biomarkers for this differentiation [20]. Instead, clinical judgement is key; considerations such as duration and persistence, frequency or intensity of symptoms, disproportionality of symptoms (given the context), and pervasiveness of symptom expression across contexts all point to evidence of underlying dysfunction and so help differentiate normal and pathological anxiety [21].

Dimensional approaches to anxiety assessment

Although current psychiatric classification systems primarily employ categorical constructs, it is notable that during the development of DSM-5, significant emphasis was placed on dimensional assessments of anxiety disorders [2]. Partly as a result, DSM-5 includes cross-cutting questions to assess anxiety symptoms, emphasizes that panic attacks may occur in a range of anxiety and other disorders, and underscores the value of assessing anxiety severity in depression [13]. In this section, we focus on a number of non-diagnostic constructs that are relevant to the dimensional assessments of anxiety: behavioural inhibition (BI), anxiety sensitivity (AS), and neuroticism.

Behavioural inhibition

BI is a heritable temperamental trait characterized by restraint, caution, or fearfulness and withdrawal in response to unfamiliar or novel people, stimuli, or situations [22, 23]. Approximately 15–20% of young children are born with marked BI, which is usually identified early in life when children transition from the normative developmental stage of ‘stranger anxiety’ and begin to adapt behaviourally to threat stimuli [24, 25, 26]. The temperamental bias categorizing BI may be underpinned by varying responses to novel stimuli by the amygdala [22]. For example, adults previously categorized as behaviourally inhibited in childhood have been found to demonstrate greater amygdala response to novel (vs familiar) faces, when compared to non-behaviourally inhibited controls [27].

Behaviourally inhibited children appear to be at increased risk of developing anxiety disorders in adulthood, particularly social anxiety disorder (SAD) [23, 28]. In their recent meta-analysis, Clauss and Blackford [26] found that BI was associated with a clear increase in the risk of developing SAD (OR = 7.59). This risk remained significant after considering individual study differences in phenotype assessment, parental risk, age of anxiety diagnosis, and other potential confounders.

The conceptualization of BI as a variant of normal (i.e. a temperament) emphasizes the value of a dimensional approach to the spectrum of normal and pathological anxiety. In particular

environments, BI may have adaptive value [29], but increased BI may also increase sensitivity to the development of anxiety disorders. Further work is needed on how particular environments may intersect with BI to increase the risk for such conditions [30, 31]. Research elucidating the neurobiological underpinning of BI, as well as its role in predicting adult anxiety, may ultimately inform primary prevention tools to identify BI in children and to pre-empt the development of subsequent SAD.

Anxiety sensitivity

AS is the fear of anxiety-related sensations, based on the belief that such sensations are harmful [32, 33]. AS may be conceptualized as an ‘anxiety amplifier’ [33], which increases arousal-related sensations, thus worsening anxiety in affected individuals. Individuals with AS are at increased risk of developing anxiety symptoms, particularly those pertaining to panic [34]. One meta-analysis [35] reported greater AS among patients diagnosed with an anxiety disorder vs non-clinical control participants. Further, panic disorder was found to be associated with greater AS, compared to the other anxiety disorders (with the exception of PTSD).

AS is widely believed to comprise three interrelated phenotypic concerns: physical, cognitive, and social [33, 36]. The aetiology of these dimensions may be influenced by additive genetic and/or cumulative environmental effects. Preliminary evidence suggests that AS is heritable in women [33, 37], which may be attributable to hormonally driven gene expression [38].

The Anxiety Sensitivity Index (ASI) [39] is the most widely used tool to assess AS. The ASI comprises 16 items to ascertain an individual’s beliefs about the sequelae of anxiety-related sensations. Again, it is possible that AS and other markers of risk for the development of anxiety disorders could be screened for, and in those at high risk, preventive interventions could be developed and investigated.

Neuroticism

Neuroticism—a personality trait predisposing individuals to higher negative affect—has been rigorously studied for several decades and has been strongly associated with common mental disorders (CMDs) in general and internalizing disorders, including anxiety disorders, in particular [40, 41]. This association is consistent with Clark and Watson’s [42] influential tripartite model which suggested that high negative affect is common to both anxiety and depression (with physiological hyperarousal specific to anxiety, and anhedonia specific to depression). Indeed, an early proposal for DSM-5 was for an emotional cluster of disorders characterized by negative affectivity [43].

A causative model would predict that shared genetic and environmental factors lead to both neuroticism and internalizing disorders [44]. In confirmation, a large population-based twin study found that genetic factors common to neuroticism accounted for up to half of the genetic risk across internalizing disorders [45]. This genetic overlap may also help to account for the extensive comorbidity among the internalizing disorders. Indeed, in their recent meta-analysis of genome-wide linkage scans of anxiety-related phenotypes [46], Webb and colleagues reported a high global correlation between neuroticism and anxiety disorders.

A cross-cutting dimensional (rather than categorical) approach to assessing neuroticism [2] may be useful for the assessment of both

anxiety and non-anxiety disorders, and there are well-validated scales for the assessment of neuroticism [44, 47].

Mechanisms underlying anxiety disorders

Animal models of fear

Pathological anxiety is often characterized by more rapid attentional threat engagement, elevated stress reactivity to potentially threatening stimuli, threat-based assessment of ambiguous stimuli, and impaired disengagement and avoidance of threat stimuli [48–50]. Further, increased amygdala responses to threat stimuli are often noted in pathological anxiety [50]. Fear conditioning and extinction have long been used to develop translational models of anxiety, as discussed in detail in Chapter 87. The amygdala and prefrontal areas of the brain are key components of the neurocircuitry underlying fear conditioning and extinction [51, 52] (see Chapter 90).

Research Domain Criteria approach

The Research Domain Criteria (RDoC) approach [49, 53–55]—developed by the NIMH and described in detail in Chapter 8—is informed by a translational formulation of anxiety disorders as arising from neurobiological, cognitive–affective, and neural circuit dysfunction. This model represents anxiety disorders (and indeed all mental disorders) on a continuum, and not as discrete entities that are separate from mental health and well-being. In contrast to the categorical DSM approach (see Chapter 7), the RDoC approach presents a matrix of key behavioural dimensions or ‘domains’ (represented by rows), as well as a number of analytical tools, as follows (Fig. 86.1) [56]:

- Rows (domains of function): negative valence systems, positive valence systems, cognitive systems, social processes, arousal/regulatory systems, sensorimotor systems.
- Columns (modes of analyses): genes, molecules, cells, circuits, physiology, behaviour, self-report, paradigms.

Thus, psychiatric symptoms represent variation (deviation) in normal traits (ranging from normal to abnormal functioning) across one or more of the RDoC’s functional domains. Currently, the RDoC model holds promise as a research framework for the dimensional assessment of anxiety disorders, rather than as a diagnostic tool. Ultimately, such models—in conjunction with categorical diagnoses that remain integral to clinical practice—may assist in incorporating advances in neurogenetics, behavioural science, and the neurosciences, thus allowing the translation of basic work into clinically useful constructs.

While quite promising as an approach to anxiety disorders, RDoC constructs are potentially no less complex than clinical disorders [57]. Further, the RDoC model has been criticized for an overly reductionist approach to psychiatric disorders, emphasizing the pathophysiological role of discrete neurocircuits and ignoring a range of other possible approaches to the conceptualization of mental illness [58].

Transdiagnostic neural circuitry

Human functional imaging studies have built on the basic constructs of fear conditioning and extinction to address

anxiety-related symptoms and behaviours (see Chapter 90). Broadly, such neuroimaging studies have suggested involvement of the insula, periaqueductal (PA) grey matter, and hypothalamus—which together are responsible for registering negative stimuli, processing resultant emotions, and autonomic regulation—in the neurocircuitry of fear and anxiety [59]. Further, amygdala hyperactivity has been found in response to disorder-specific stimuli in social phobia, specific phobia, and PTSD [60–63].

There are fewer data on the role of the amygdala in panic disorder and generalized anxiety disorder, and OCD and related syndromes are likely underpinned by dysfunctional cortico-striato-thalamo-cortical (CSTC) circuitry (see Chapters 93–100). Nonetheless, hyperactivity of the amygdala in human subjects with certain anxiety disorders is consistent with the neurocircuitry of fear conditioning proposed in animal studies.

In summary, a transdiagnostic neural circuit network, informed by classical fear conditioning paradigms, may underlie a number of the commonly occurring anxiety disorders [64, 65]. Specific functional and structural abnormalities in this large-scale neural circuit may result in biotypes which not only differ from traditional categorical DSM diagnoses, but also overlap, intersect, and interact [66]. Further delineation and validation of this network may be of value in informing novel diagnostic and therapeutic interventions for anxiety disorders, thus potentially bridging the gap between neuroscientific advances and clinical practice and perhaps even ultimately contributing towards precision medicine in psychiatry.

Transdiagnostic neurogenetics

Genetic epidemiological studies have reported anxiety disorders to be moderately heritable, with heritability estimates ranging from 30% to 50% [67]. Further, genetic factors underlying anxiety disorders may be correlated with those underlying related phenotypes such as neuroticism [46] and may be transdiagnostic. Thus, ‘overlapping genes’ may account partially for the lifetime co-occurrence both of anxiety disorders and of related phenotypes. A detailed update on the genetics of anxiety and stress disorders is found in Chapters 80 and 89. However, a brief summary of the major findings will illuminate the dimensional issues described here.

Candidate gene association studies have suggested a number of genes that may be involved in increasing vulnerability both to normal anxiety traits and to pathological anxiety, including those in the serotonergic (for example, 5-HTT), noradrenergic (for example, COMT), and hypothalamic–pituitary–adrenal (HPA) axis (for example, CRHR1, FKBP5) systems [68]. These findings are endorsed and complemented by a large body of work on animal models of anxiety, including a number of mouse studies mapping several genetic loci thought to affect anxiety-like behaviour in rodents [69]. Human and animal studies have also suggested a role for both gene–gene and gene–environment interactions in contributing to the overall risk for anxiety disorders. Further, there is some evidence suggesting a role for epigenetic DNA modifications (for example, DNA methylation) and changes in gene expression in the effect of early life stress—such as poor maternal care—on anxiety-like behaviours in mice. Genetic variants may also confer risk via intermediate phenotypes (endophenotypes) such as BI, AS, and trait neuroticism [46]. Indeed, it is likely that anxiety disorders and phenotypes are polygenic with multifactorial aetiology.

Transdiagnostic approaches to treatment of anxiety disorders

The concept of ‘pharmacotherapeutic dissection’, with different disorders responding to different drugs, was key in delineating different categories of anxiety disorders, including panic disorder [70]. However, there is also long-standing evidence that a range of different psychotropic agents (for example, benzodiazepines, SSRIs, D₂ blockers) are useful across several different anxiety conditions (see also Chapter 92). Somewhat analogously, early interest in specific cognitive behavioural therapy (CBT) treatments for particular anxiety disorders has been replaced by a growing interest in transdiagnostic CBT. Indeed, transdiagnostic CBT interventions are increasingly viewed as efficacious across anxiety disorders, with a large treatment effect size and stable maintenance of improvement during follow-up [4, 71].

More recently, the Unified Protocol for Transdiagnostic Treatment of Emotional Disorders (UP) has emerged as a focus of transdiagnostic CBT studies. The UP comprises five treatment modules to target emotion processing, regulation, and extinction, as follows [72–74]: to increase present-focused emotion awareness; to increase cognitive flexibility; to identify/prevent emotion avoidance and maladaptive behaviours; to increase awareness and tolerance of emotion-related physical sensations; and interoceptive and situation-based emotion-focused exposure.

One small randomized controlled trial of clinical patients with heterogeneous anxiety disorder diagnoses [72] found that immediate UP treatment resulted in significant improvement in outcome measures of general anxiety/depressive symptoms, clinical severity, and functional impairment, as compared with delayed treatment following a waitlist period. Similarly, another study of UP treatment in two consecutive trials [75] reported decreased AS from pre- to post-treatment; and the majority of this change coincided largely with the introduction of interoceptive exposure therapy.

The next step in this area is work on combined transdiagnostic pharmacotherapy and psychotherapy. One study has investigated the effect of SSRIs/SNRIs and sedatives on the efficacy of transdiagnostic 5-week group CBT [76]. These authors found that combined antidepressant/CBT resulted in greater improvement in depressive symptoms when compared to CBT monotherapy (and that the efficacy of combined therapy was less for those patients also treated with sedatives). Nevertheless, given the evident paucity of empirical data on transdiagnostic combined psychotherapy and pharmacotherapy for anxiety disorders, further work is required before such interventions are routinely advised. An even greater transdiagnostic challenge is primary prevention of anxiety disorders, described at length in Chapter 91.

Conclusions

Categorical approaches to anxiety are currently key in the clinical diagnosis and management of DSM-5- and ICD-11-defined disorders. Dimensional approaches may hold promise for future research and clinical innovation. These approaches are informed by a growing body of evidence that dimensional assessments of anxiety and related symptoms are informative, that spectrum approaches to

understanding cognitive–affective mechanisms and the underlying neurocircuitry are useful, and that transdiagnostic treatment interventions are effective. However, dimensional approaches are, for now, a complement to—rather than a substitute for—current categorical approaches to anxiety disorders.

Basic mechanisms, genetics, targets, and animal models for anxiety disorders

Martien J. Kas and Berend Olivier

Introduction

Existing anxiolytic drugs, such as benzodiazepines (BZs) and selective serotonin reuptake inhibitors (SSRIs), have been developed several decades ago, partly as a result of serendipity (BZs), partly because they were primarily targeted at major depressive disorder (SSRIs). Extensive search has occurred in the ensuing decades to find new targets for anxiolytics, based on the known and anticipated neurochemical mechanisms underlying anxiety. However, no real breakthroughs have emerged. Currently, SSRIs remain the preferred drugs for the treatment of anxiety disorders (and augmented with BZs for a limited time interval). Although efficacious, some patients are treatment-resistant, and inherent disadvantages are attached to SSRI use, including lasting side effects. Therefore, in the last decades, preclinical and clinical studies have extensively focused on other mechanisms to target anxiety processes in order to ultimately treat anxiety disorders. Since then, evidence has emerged pointing to a modulating role of corticotrophin-releasing factor 1 (CRF1) receptors, neurokinin 1 (NK-1) receptors, and glucocorticoid receptors (for a review, see [1]). Although the efficacy of such drugs during development often looked promising in the preclinical phase, therapeutic anxiolytic effects were often absent or inferior to the existing drugs. Thus, so far no 'superior' drugs have reached the market that will replace the current treatment choices.

As described in Chapter 86 in the new DSM-5, the former DSM-IV category of 'Anxiety disorders' became three separate categories: 'Anxiety disorders,' 'Obsessive compulsive disorders,' and 'Trauma and stress-related disorders.' This categorization does not create an easier pathway for new drugs or an easier discovery track. Thus, the creation of preclinical models for each individual anxiety disorder is not only impractical, but actually impossible. Therefore, it has been proposed that a classification based on the neurobiological mechanisms underlying anxiety and pathological anxiety (intermediate phenotypes) would enhance drug development [2]. Another classification approach would be based on dysfunctional neurotransmitter systems, for example, abnormal serotonin transporter function [3]. In the present chapter, we mainly focus on what we know on the pharmacology of GABA-ergic and serotonergic

drugs, and we try to outline, focusing on genetic and genomic approaches and innovative animal models of anxiety disorder, how to find putative new targets and some new promising avenues and technologies in the anxiety field.

GABA_A receptor α subunits and anxiety

In the 1950s, BZs were serendipitously found as having therapeutically interesting activity with anxiolysis, sedation, anticonvulsive activity, and muscle relaxation. It took more than 20 years to discover the molecular target of BZs—the GABA_A receptor [4]. It is now known that the GABA-ergic system has ionotropic (GABA_A) and metabotropic (GABA_B) receptors that are ubiquitously expressed and distributed in the CNS [5, 6]. The GABA_A receptor (GABA_AR) is the target of clinically important anxiolytics, including BZs [7]. A role for GABA_BR in anxiety and stress has been found preclinically but has not (yet) led to clinical applications [7, 8].

GABA_ARs are ligand-gated ion channels that mediate fast inhibitory effects on many post-synaptic sites and are ubiquitously present in the CNS, although there is a specific and differential subunit distribution. When the endogenous ligand gamma-aminobutyric acid (GABA) binds to its receptor, chloride ions flow into the neuron, causing hyperpolarization of the cell membrane and inhibiting cell firing. GABA_ARs occur synaptically and extra-synaptically and display large molecular heterogeneity made up via a variable subunit composition. This heterogeneity in composition determines the physiological and pharmacological properties and contributes to the flexibility in signal transduction and modulation [7]. GABA_ARs are always composed of five subunits, a complex that forms a heteropentamer creating a channel permeable to chloride ions. The subunits can be made up, although not randomly, from 19 subunits (α 1–6; β 1–3; γ 1–3; δ , ϵ , θ , and ρ 1–3). Most GABA_A receptors are built from two α , two β , and one γ subunit (Fig. 87.1 from [9]). The endogenous neurotransmitter GABA binds to the GABA site, which is formed by α and β subunits, whereas the binding site for BZs is formed by one of the α subunits (α 1, α 2, α 3, or α 5) and a γ subunit (almost exclusively the γ 2 subunit). GABA_A receptors with α 4 or α 6 subunits do not bind to classic BZs. The most frequent subtype in the CNS is a pentameric complex, consisting of two α ,

Fig. 87.1 Schematic picture of the GABA_A receptor. (a) A global picture of the two α , two β , and one γ subunits and the direction of the chloride influx. (b) A top view with the subunits arranged around a central pore—the chloride channel. The GABA and benzodiazepine binding sites are indicated.

Reproduced under the Creative Commons Attribution License 4.0 (CC BY-NC 3.0).

two β , and one γ subunit. Approximately 60% of all GABA_A receptors are $\alpha 1\beta 2\gamma 2$ subunits, 15–20% $\alpha 2\beta 3\gamma 2$, 10–15% $\alpha 3\beta \gamma 2$, and 5% $\alpha 4\beta \gamma$ or $\alpha 4\beta \gamma \delta$, and <5% have $\alpha 6\beta 2/3\gamma 2$ subunits [10]. GABA_A receptors are the main inhibitory neurons in the CNS, and it is estimated that 20–30% of all neurons in the CNS are of the GABA_A type. BZs do not open the chloride channel in the absence of GABA. Different classes of pharmacological agents act at different sites of the GABA_AR, including the endogenous agonist GABA and various GABA_AR agonists (for example, muscimol) or antagonists (for example, bicuculline). Classical BZs (for example, chlordiazepoxide, diazepam) bind to the GABA_AR BZ modulatory site. Other drug classes also bind to the GABA_AR, including alcohol, barbiturates, and neurosteroids. BZs mediate their action via the modulatory binding site that is present on most, but not all, GABA_ARs. The allosteric binding site for BZs is always formed by two α subunits ($\alpha 1$, $\alpha 2$, $\alpha 3$, or $\alpha 5$), two β subunits, and the $\gamma 2$ subunit. Only if the GABA receptor site is activated (by GABA or external receptor agonists) may activation of the BZ site modulate the opening of the channel (frequency and/or time). Ligands at the BZ binding site are called allosteric modulators. They modify the efficacy and/or affinity of GABA in positive allosteric modulation (PAM) or negative allosteric

modulation (NAM) or have neutral effects by stabilizing different three-dimensional conformations of the GABA_AR complex. Selectivity of a ligand for a specific receptor subtype can be obtained by affinity and/or efficacy changes that determine the potential potency of a ligand [11]. Benzodiazepines have anxiolytic, sedative, hypnotic, muscle relaxant, and anticonvulsive properties. The sedative-hypnotic properties are useful for, for example, insomnia treatment but are unwanted side effects if anxiolysis is the primary indication. Classic BZs (for example, diazepam) are non-selectively activating $\alpha 1$, $\alpha 2$, $\alpha 3$, and $\alpha 5$ subunits, but extensive research, mainly in genetically modified mice in which individual GABA_AR subunits (GABRA) were made insensitive to diazepam binding (by histidine-to-arginine point mutations at a conserved residue in the $\alpha 1$, $\alpha 2$, $\alpha 3$, or $\alpha 5$ subunits, whereas the actions of the endogenous ligand GABA remained intact) showed that the different subunits represent different functions. It has become clear that the broad profile of therapeutic effects of BZs is dependent on activation of selective α -subunits. Strong evidence was gathered that $\alpha 1$ subunits are involved in sedative and anterograde amnesia effects mediated by diazepam ($\alpha 1(H101R)$ mice); $\alpha 2$ point mutations ($\alpha 2(H101R)$ mice) led to absence of the anxiolytic and diminished muscle relaxant action, but intact anxiolytic effects, and in $\alpha 3$ ($\alpha 3(H126R)$ mice) and $\alpha 5$ point mutations ($\alpha 5(105R)$ mice), diazepam did not induce myorelaxation, whereas sedation and anxiolysis were intact. Such data strongly suggest a functional differentiation in the GABA_A receptors, depending on the α subunit composition (for reviews, see [12, 13]).

Classic BZs, still frequently prescribed, have therapeutic activity but, inherent to the activation of all relevant α subunits, come with built-in side effects. If used as an anxiolytic tool, sedation is one of the troubling side effects. Furthermore, upon chronic use, BZs can lead to dependency and tolerance and induce abuse liability, limiting long-term use [14]. Recent efforts have tried to synthesize new drugs that have selectivity and potency for specific α subunits [13], although relatively selective drugs for the $\alpha 1$ subunit are already in use for sedation/hypnotic purposes (zopiclone, zolpidem, (S)-zopiclone, and zaleplone). Compounds that selectively activate the $\alpha 2$ subunits and have no effects on any other α subunit might constitute an ideal non-sedative anxiolytic, although activation of $\alpha 3$ subunits might contribute to an anxiolytic profile [15–17]. L-838417, a partial PAM at $\alpha 2$ -, $\alpha 3$ -, and $\alpha 5$ -containing GABA_A receptors and an antagonist at $\alpha 1$ -containing receptors has a non-sedating anxiolytic profile in mice [18, 19] and primates [20]. Development of this compound has been stopped due to an unfavourable pharmacokinetic profile [21]. TPA023, an $\alpha 2/\alpha 3$ PAM, has anxiolytic and no sedative effects in rodents [22]. TPA023 was evaluated in three phase 2 studies in GAD and proved preliminary indications of anxiolytic activity without sedation [17]. However, this compound had to be withdrawn due to severe preclinical toxicity. A comparable story holds for ocinaplon, having a non-sedative, anxiolytic profile in humans but which also had to be withdrawn due to hepatotoxicity [23, 24]. Several other ligands have been synthesized and tested, mostly restricted to pre-clinical phases. It appears possible to make compounds with some selectivity for specific α subunits, but *in vivo* efficacy is extremely difficult to design; both PAMs and NAMs have been found, and sometimes even mixed PAM/NAM effects on different α subunits are present or no selectivity is present *in vitro*, whereas *in vivo*, some efficacy is found (for example, ocinaplon). MRK-409, an extremely

low partial agonist (PAM) at $\alpha 1$ -, $\alpha 2$ -, and $\alpha 5$ -containing GABA_A receptors, but with higher intrinsic activity at $\alpha 3$ subunit GABA_A receptors, appeared to be anxi-selective in animals but sedative in humans, already at low (<10%) receptor occupancy [25].

Another class of compounds—the neurosteroids (for example, allopregnanolone, alfaxalone)—have modulatory effects (PAM) on the GABA_AR, comparable to BZs. However, due to several differential mechanistic differences, the neurosteroids have not emerged as potent anxiolytics [26].

One of the unresolved issues around subunit selective GABA-ergic compounds is the issue of tolerance and abuse potential. Does activation of all α subunit-containing GABA_A receptors lead to addiction or is that caused by specific α subunits [27]? This is an important issue because the development of medications with potential for misuse may not be possible. There is some evidence that activation of $\alpha 1$ subunits is essential in the addictive properties of BZs [14, 28]. However, the processes of tolerance development are complex and endpoint-dependent [29]. If the therapeutic effects of activation of $\alpha 1$ -containing GABA_A receptors cannot be separated from potential addictive side effects, no further development of $\alpha 1$ subunit-specific ligands can be expected. However, if addictive properties are not entwined in (chronic) activation of the other $\alpha 2$, $\alpha 3$, $\alpha 5$ subunits, new developments in the field

of anxiety (and others like cognition and analgesia) might be expected [9, 29, 30].

The 5-HT_{1A} receptor

The 5-HT_{1A} receptor has been implicated in anxiety because 5-HT_{1A} receptor agonists exert anxiolytic activity in rodent models of anxiety [31, 32], whereas buspirone, a partial 5-HT_{1A} receptor agonist, exerts mild anxiolytic effects in human anxiety patients, particularly in GAD [33]. Although clinically the development of new 5-HT_{1A} receptor agonists for anxiety disorders (for example, ipsapirone, gepirone, tandospirone, flesinoxan) failed, the 5-HT_{1A} receptor has received considerable interest as a critical target implied in anxiety and depression [31–37]. 5-HT_{1A} receptors are G-protein-coupled inhibitory receptors expressed in serotonergic neurons as auto-receptors and in non-serotonergic neurons as heteroreceptors (Fig. 87.2). The somatodendritic 5-HT_{1A} auto-receptor controls serotonergic tone via feedback inhibition in concert with 5-HTT, the target of the most commonly used anxiolytic/antidepressant SSRIs. It has been hypothesized that desensitized 5-HT_{1A} auto-receptors delay the onset of action of SSRIs that act by enhancing brain serotonin levels [38, 39]. 5-HT_{1A} receptors are quite abundantly distributed and expressed, although restrictedly present in some brain areas. Auto-receptors are mainly, if not only, found in the dorsal

Fig. 87.2 Schematic representation of serotonin (5-HT) in the terminal and synapse. G-protein-coupled receptors are located presynaptically [5-HT auto-receptor (5-HT_{1A/1B})] or post-synaptically (5-HT_{1/2/4/5/6/7} receptors). (1) 5-HT is released from the presynaptic neuron and binds to a heterotrimeric G-protein post-synaptic receptor. Heterotrimeric G-protein complexes contain an α , β , and a γ subunit, which, in an inactive state, are bound to GDP. (2) 5-HT acts on post-synaptic receptors and induces a change in the conformation of the post-synaptic receptor. GDP is phosphorylated to GTP and binds to the α subunit, which subsequently becomes active. The β and γ subunits are freed. (3) Extracellular 5-HT is taken up by the SERT into the presynaptic neuron. (4) Back in the presynaptic neuron, 5-HT is broken down by MAO to 5-HIAA (occurs also extracellularly) or is being stored in the vesicles for future release. MAO, monoamine oxidase; 5-HIAA, 5-hydroxyindole acetic acid; SERT, serotonin transporter.

and median raphe nuclei, whereas post-synaptic heteroreceptors are found in high densities in limbic regions (including the hippocampus) and in the frontal, medial prefrontal, and entorhinal cortices.

Genetic and imaging studies in humans suggest that 5-HT_{1A} receptor density or regulation are associated with depression and anxiety, but also with the response to antidepressants [40]. Recently, an association was found between a C(-1019)G polymorphism (rs6295G/C) in the promoter region of the 5-HT_{1A} receptor gene (*Htr1a*) and mood-related variables, including amygdala reactivity [41] and depression [42]. Enrichment with the G-allele is associated with enhanced raphe (presynaptic) 5-HT_{1A} auto-receptor expression, whereas post-synaptically, the reverse occurs with the 5-HT_{1A} heteroreceptor [42]. A clear hypothesis of how such changes contribute to an anxious/depressed phenotype has, however, not emerged yet. More polymorphisms in the *Htr1a* gene are known, but no clear data on their influence on anxiety are present [43].

Studies in rodents found that 5-HT_{1A} receptors modulate anxiety and depression. Three independent research groups generated 5-HT_{1A} receptor knockout (KO) mice [44–46], and all KO strains displayed enhanced anxiety in standard anxiety paradigms. The unanimous finding that inactivation of the 5-HT_{1A} receptor gene (both auto- and heteroreceptor) resulted in an anxious phenotype in all three lines was rather striking. The picture became even more blurred when the anxious phenotype appeared dependent on the paradigm used [47]. Moreover, in one of the strains (Swiss-Webster), the 5-HT_{1A} receptor KO mouse displayed reduced sensitivity to the anxiolytic and sedative effects of diazepam, an α subunit non-selective GABA_A-positive allosteric modulator [48, 49], attributed to changes in some α subunits of the GABA_A-BZ receptor complex. However, this BZ insensitivity was not present in the KO mice in both other genetic backgrounds [49, 50]. Apparently, dysfunction of the GABA_A-BZ system is not a prerequisite for the ‘anxiogenic’ phenotype of the 5-HT_{1A} KO mouse model. Along with the anxiogenic phenotype in the 5-HT_{1A} receptor null mouse, which was unresponsive to SSRIs [51], it appeared that overexpression of the 5-HT_{1A} receptor reduced anxiety [52]. Rescue experiments of forebrain 5-HT_{1A} receptors showed that post-synaptic 5-HT_{1A} receptors are critical in the development of the anxiogenic phenotype in the null mutations [53]. The latter authors showed that transgenic developmental overexpression of 5-HT_{1A} receptors in the rostral brain in the early stages of life (not adulthood) was sufficient to restore normal anxiety levels. Pharmacological blockade of 5-HT_{1A} receptors in early development, but not in adulthood, appeared sufficient to enhance anxious behaviour in normal (wildtype) mice [9, 54]. The complex regulation of anxiety (and depression) processes during development and adulthood illustrates the complexity of the neural substrate, including genetic regulation of anxiety and its pathology, and makes clear that straightforward and simple relationships between the function of a certain receptor and anxiety are not very likely.

By genetic modification, Richardson-Jones *et al.* [55] manipulated the level of presynaptic 5-HT_{1A} auto-receptors at adult age, without changing post-synaptic 5-HT_{1A} heteroreceptors. Mice with higher (1A-high) or lower (1A-low) levels of auto-receptors were tested on their vulnerability to stress and response to antidepressants. The investigators suggested that 1A-low mice showed an enhanced 5-HT tone and decreased depression-like behaviour and still responded

to an SSRI, whereas 1A-high mice had a decreased 5-HT tone and more depressed-like behaviour and were unresponsive to SSRIs. In their modelling, they suggested that 1A-lows reflect human C/C, whereas 1A-highs model G/G carriers of the *Htr1a* C(-1019)G polymorphism. Such genetic mouse models are extremely useful in studying the underlying processes emerging in depression and anxiety disorders. Further molecular biological studies into the role of 5-HT_{1A} receptors implicate, in particular, 5-HT_{1A} post-synaptic receptors in the prefrontal cortex in the expression of anxiety [56]. In the prefrontal cortex, those heteroreceptors are expressed on two antagonistically acting neuronal populations—excitatory pyramidal neurons and inhibitory interneurons. These populations play an important role in the expression of anxiety over the lifespan and may be generating new targets for future therapeutic approaches.

The serotonin transporter (5-HTT)

The 5-HTT has, for a long time, been implicated in the processes underlying mood and anxiety and its associate disorders mainly because the SSRI antidepressants block the serotonin uptake into the neuron thereby increasing the serotonergic output (Fig. 87.2). As outlined in the introduction, polymorphisms in the *5-HTT* gene and its associated transcriptional control region have influence on the functioning of the serotonergic system [57]. Although we restrict ourselves here to anxiety disorders, it is noteworthy to realize that several human behavioural traits and whole-body medical disorders (for example, myocardial infarction, pulmonary hypertension, irritable bowel syndrome, and sudden infant death syndrome) are associated with variations in the *5-HTT* gene (*SLC6A4*), indicating the importance of serotonin neurotransmission in all aspects of our biology [3]. Reduced 5-HTT expression and function associated with the S-allele of the *5-HTTLPR* is associated with anxiety and depression personality traits [58, 59]. In the ensuing decade, it became clear that *5-HTTPRL* and other variations in coding and non-coding regions of the *5-HTT* gene play a wide role in neuropsychiatric disorders, including bipolar disorders, depression, anxiety disorders [also obsessive-compulsive disorder (OCD)], suicide, eating disorders, substance abuse disorders, autism, attention-deficit/hyperactivity disorder (ADHD), and neurodegenerative disorders (for reviews, see [3, 60]). Human 5-HTT maps to chromosome 17q11.2, has 14 exons that span around 40 kB, and produces a 630-amino acid protein with 12 membrane domains. The expression of the gene in humans is modulated by a variation in the length of the 5-HTTLPR, together with two SNPs in this region (rs25531 and rs25332), all located upstream of the transcription start. Moreover, variable numbers of tandem repeat (VNTR) polymorphisms are known in intron 2, as well as several SNPs that influence the structure of the 5-HTT protein. In particular, the rs2551 polymorphism is quite frequent in the population and interacts with 5-HTTLPR in 5-HTT transcription [3]. This makes the modulation of serotonergic transmission via the 5-HTT mechanism highly complex and gives probably an important insight in the factors that play a role in the genetic complexity of any psychiatric disorder. The identification of specific gene variants remains a tricky avenue. It becomes increasingly clear that such variations influence intermediate biological phenotypes, in concert with other (background) genes, epigenetic variation, and environmental and developmental factors, and this complex interaction contributes to risk or resilience to develop a psychiatric condition. One avenue to pursue would be to try to find associations

between specific candidate genes (for example, the *5-HTT* gene) and intermediate phenotypes mediating between a moderating allele and a more complex disease phenotype [61]. Studies on the *5-HTTLPR* gene are now under way that explicitly test gene \times environment and gene \times gene interaction. One study [62] found that a significant interaction between maternal anxiety during gestation and subsequent levels of infant negative emotionality at 6 months of age was modulated by *5-HTTLPR* of the child. S-allele-carrying children showed high levels of negative emotionality, with mothers showing high maternal anxiety during pregnancy, whereas no such association was found in L-allele-carrying infants. In a BOLD-fMRI study, healthy women were threatened with unpredictable electric shocks of uncertain intensity, and activation was measured in several cortico-limbic networks upon threat anticipation [63]. During stress exposure, neural systems enhancing fear and arousal modulated attention towards threat and SS-individuals appeared particularly sensitive towards the stress, suggesting that such a mechanism may underlie the risk for psychopathology. In a different study, deductive reasoning appeared also dependent on the *5-HTTLPR* genotype. Apparently, differences in the functioning of the *5-HTT* renders some individuals more vulnerable to emotional factors, thereby generating a deleterious effect on rational reasoning [64].

In another study, an interaction between the *5-HTTLPR* (measure in LL-variants) and an oxytocin receptor variant (TT variant of the SNP rs2268498) that influences the number of oxytocin receptors was found in individual differences in negative emotionality, indicating a gene \times gene interaction [65]. Such data indicate that serotonergic and oxytocinergic neurotransmission processes are somewhere entwined and seem to play a role in affective disorders. In general, S-alleles of the *5-HTTLPR* are associated with increased risk for a variety of psychiatric disorders, including anxiety. The S-allele is considered a 'risk' or 'vulnerability' allele [66], whereas the function of the L-allele is far less clear, although this allele has been suggested as a potential risk factor for the development of psychopathic traits too [67]. Because every human has either the L or the S allele, or both, and most people do not suffer from psychiatric abnormalities, it must be assumed that the genome includes several 'protective' alleles that make many individuals resilient to stress and pathology. Such protective genes have been suggested, for example the CRF1-receptor variants that have been associated with protection from the extreme stresses of maltreatment during childhood [68] and protective emotional resilience-enhancing effects of the L-allele in students [69]. Belsky and colleagues [70] suggested that S-allele carriers are more vulnerable in general, not only negatively, but also positively. Thus, 'vulnerability genes' or 'risk alleles' seem to make individuals more susceptible to environmental influences—for better and for worse. Homberg and Lesch [71] postulated a similar picture of the functions of the allelic variants in *5-HTTLPR*. They did not portray the S-allele as a 'risk' allele and the L-allele as a 'resilient' allele but took the hypothesis that S-carriers (both in humans and in non-human primates) perform better in cognitive tasks than L-carriers. They argue for a switch from a deficit-orientated connotation of *5-HTTLPR* variants to a cognitive superiority of S-allele carriers (which have enhanced reactivity of the cortico-limbic neural circuitry) and that environmental conditions will determine whether a positive (cognitive) or negative (emotional) response will happen. Part of their support comes from studies in genetically modified mice and rats (heterozygote and homozygote) *5-HTT*

KOs. *5-HTT*^{-/-} rodents show brain and behavioural phenotypes rather similar to S-allele carriers such as increased emotionality, improved cognition, and increased sensitivity to psychosocial factors (reviewed in [72]). This seems present without environmental influence in the homozygote KOs, but in the heterozygotes, early or later life stress is additionally needed to show the same phenotypes [3, 72, 73].

Genetic background of anxiety disorders

Genes certainly contribute to the risk for developing anxiety disorders. An update of the current findings is given in Chapters 80 and 89. No 'candidate' genes have emerged that play a straightforward role in the expression for vulnerability to anxiety or anxiety disorders [74]. This is probably due to the fact that several or more risk factors have individually small effects. Among those neurotransmitter systems which have provided targets to develop anxiolytic drugs are serotonin (5-HT), noradrenaline (NA), glutamate, dopamine, GABA, RGS2, and neuropeptides (corticotrophin-releasing factor, neuropeptide Y, brain-derived neurotrophic factor). Regulator of G-protein signalling proteins (RGS) are key modulators of G-protein-coupled receptor signalling. RGS2 modulates anxiety both in mice [75] and in humans [76]. In mice, a quantitative trait locus (QTL) on chromosome 1 was associated with anxiety-related phenotype [77]; the principal quantitative trait gene for this linkage signal appeared to be RGS2 [78].

In conclusion, it has proved a challenge to find loci involved in anxiety disorders, which is likely due to a complex and polygenic genetic background. Probably many genes influence the risk for developing anxiety disorders, each of them with a small effect. Moreover, epistatic processes, having the ability to mask the phenotype derived from other genes, are also very likely to be involved, whereas environmental factors induce complex gene–environment (G \times E) interactions.

Another strategy has been to study endophenotypes or intermediate phenotypes in man. Such familial or heritable traits are assumed first to underlie relevant disorders and second, more controversially, to be more susceptible to genetic analysis. The amygdala shows enhanced activity in phobias and PTSD, compared to healthy individuals [79]. The function of the amygdala in processing emotion and the mechanisms underlying fear conditioning have provided important paradigms for imaging studies in man (see Chapter 90). The link with genetics has proved more challenging. There was great interest when the *5-HTTLPR* polymorphism was associated with amygdala reactivity [80, 81], implicating the S-allele in the increased amygdala reactivity towards external stimuli [82]. This kind of finding in small samples has proved difficult to replicate (see Chapters 80 and 89).

Preclinical genetic approaches to fear and anxiety

Animal models of anxiety and fear have greatly enhanced our knowledge in the neurobiological mechanisms underlying fear and anxiety. Anxiety and fear represent the most translatable processes from animal to human. Indeed, animal pathology appears to resemble human pathology to a certain (but varying) degree [83]. Such models can be powerful in dissecting putative genes in anxiety and anxiety-associated traits [84, 85]. Apart from large-scale mouse

Fig. 87.3 Traditionally, novelty-induced exploratory behaviour in the open field and the elevated plus maze are assessed to study anxiety-related behaviours in rodent species. In these representative data examples, video-tracking summary plots indicate the location of the mouse during a short session of open field exploration (a, b) or of exploration of an elevated plus maze (c, d). Different inbred strains of mice showed robust behavioural differences in these paradigms, as can be visualized in the data samples given. For example, C57BL/6J mice showed high levels of movement throughout the open field (a) and the elevated plus maze (c). In contrast, A/J mice showed lower levels of movement and stay close to the wall of the open field (b) and preferred the closed arms of the elevated plus maze (d) [closed arms are indicated by dark black lines (c, d)]. Based on the avoidance of the centre of the open field and the open arms of the elevated plus maze, A/J mice are considered to express higher levels of anxiety-related behaviour, when compared to C57BL/6J mice.

crossings for genetic mapping, leading to, for example, localization and identification of one gene *rgs2*, which influences anxious behaviours [76, 78, 86], gene-targeting approaches can be applied in rodents (Fig. 87.3).

Apart from classical searching for an animal model of anxiety, one can also try to use cross-species trait genetics in combination with an endophenotype approach [87, 88]. Using chromosome substitution strains, in which a single chromosome from one inbred strain (donor) is substituted with that of another inbred strain (host), makes it possible to locate a certain parameter or phenotype (such as avoidance behaviour) on a locus of a particular chromosome. Via further genetic crossings, the location can be refined and this may lead to candidate genes [89, 90]. By integrating genetic data from the mouse and from a large human GWAS on bipolar disorder, novel candidate genes for bipolar disorder were unravelled [91] (Fig. 87.4).

In the next section, some examples will be given of established targets involved in anxiety. A target can be defined as a neurobiological or cellular mechanism that, upon systematic manipulation, causes correlated effects on circuit function (in this case, anxiety), as well as behavioural/cognitive processes [92]. Because genomic technology advances rapidly, linkage between targets and neuronal circuitry

and genetic factors involved in anxiety disorders are becoming increasingly elucidated. Fundamental research aimed at these targets may contribute to unravelling novel insights in anxiety processes and consequently engender new opportunities for drug discovery.

Although the 5-HT_{1A} receptor, 5-HTT, and GABA_A receptor complex belong to the most known and discussed targets in the field, human and animal research still continues to find new mechanisms around these targets that opens new possibilities to apply in animal models and human psychopathology. The future needs a strict translational approach; data found in human (anxiety) research, including genetic and environmental factors, should be used to formulate scientific approaches in animals, and vice versa. In animals, we have the opportunity to apply cell-specific inducible KOs or knock-ins. Moreover, new optogenetic technology enables selective manipulation of cellular mechanisms and circuit functions linked to the gene's suggested function [93].

Integration

As genetic studies advance, validated animal anxiety models with translational validity are increasingly needed to study the biological role of genes found and their possible contribution to anxiety. In

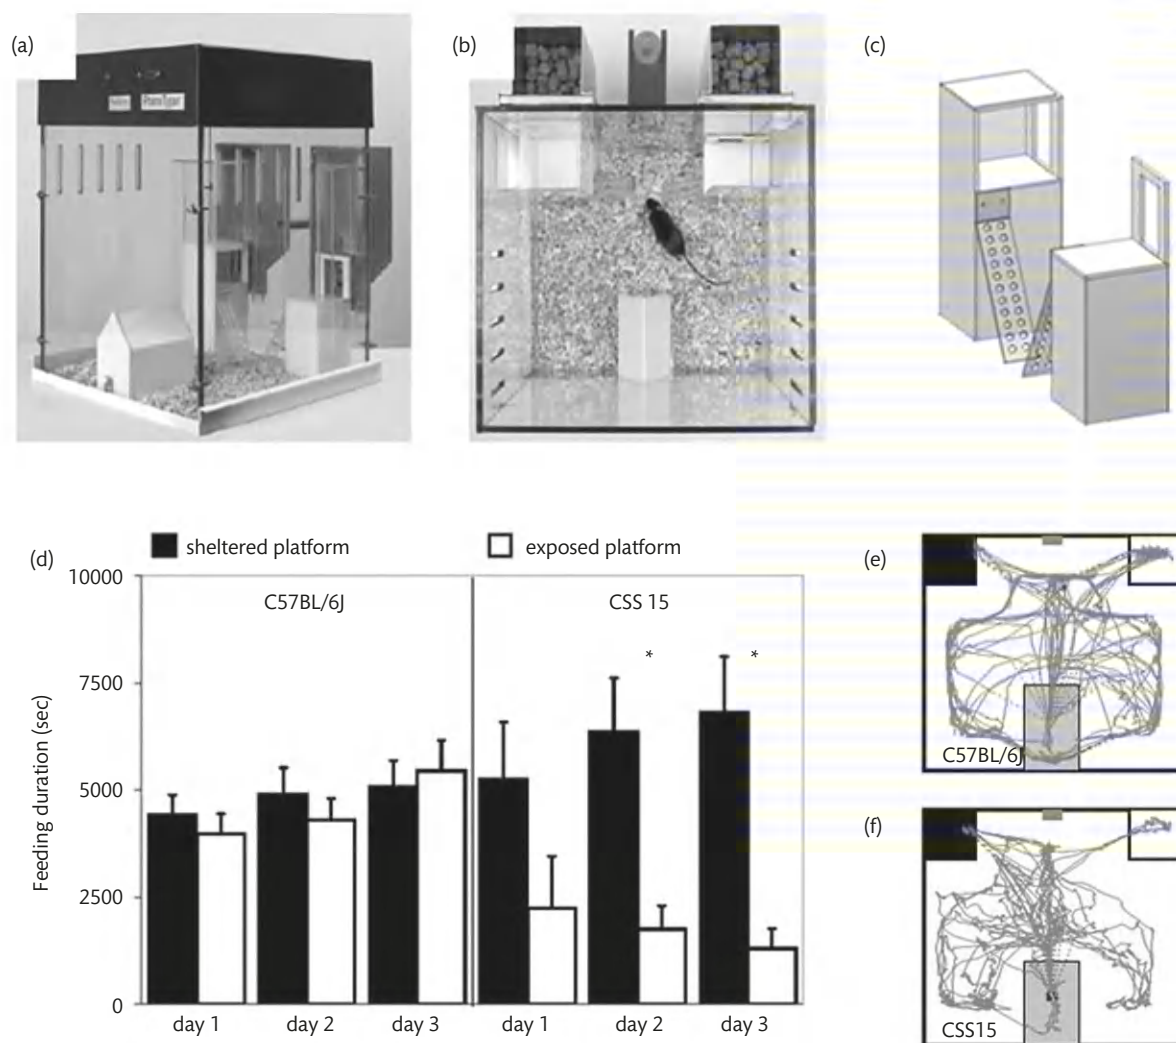

Fig. 87.4 Behavioural screening of a chromosome substitution strain (CSS) panel revealed a locus for avoidance behaviour in an automated home cage environment on mouse chromosome 15. The automated home cage environment is equipped with a home base shelter (in which mice mainly sleep during the light phase) (a, b), a drinking spout, and two feeding platforms—one feeding platform exposed to the environment, and one allowing sheltered feeding (c). The PhenoTyper® top unit contains an infra-red camera and infra-red LED lights, allowing continuous recording, independent of lighting conditions in the test room. C57BL/6j and CSS15 females; feeding duration on the two platforms on 3 days of testing. CSS15 females showed an increasing preference for the sheltered platform over consecutive days (d). * Exposed vs sheltered feeding platform per day; $P < 0.05$. Representative track samples during automated baseline behavioural registration, showing a reduction in visitation of the exposed feeding platform for CSS15 (f), compared to C57BL/6j (e). Further genetic fine mapping of the locus on mouse chromosome 15 revealed a homologous human locus on chromosome 8 previously associated with bipolar disorders.

search for animal paradigms with high translational value, we extensively explored a readout parameter of autonomic nervous system activation—stress-induced hyperthermia (SIH). SIH occurs in animals and man and depends on stress intensity, and individual differences in response to stress are dependent on genetic and environmental factors [94, 95]. In humans, autonomic stress responses correlate with perceived stress levels. Although the SIH response does not specifically model any psychiatric disease, SIH may be very useful as a readout parameter of stress or an anxiety-like response. It can be studied at preclinical and clinical levels, using different and varied stressful experimental conditions. It is highly suitable to detect genetic effects and anxiolytic properties of drugs, for example in 5-HT_{1A} receptor KO mice [50, 94, 96]. The SIH response

can be reduced using GABA_A receptor agonists and 5-HT_{1A} receptor agonists [95, 97]. Baseline body temperature and circadian rhythmicity were comparable, but SIH was lower in 5-HTT KO than in the corresponding wildtypes. Pharmacological studies revealed that 5-HT_{1A} receptors modulating SIH belong to a population of receptors that differ from those involved in hypothermia [98]. Later research found also changed sensitivity in dopamine and NA receptors in 5-HTT KO rats [99]. It might be postulated that the 5-HTT KO rat constitutes an animal model of certain psychiatric disorders, including anxiety disorders. A preliminary study [100] tried to find a genetic basis for the sensitivity of various chromosome substitution mouse strains [101] for diazepam (a non-subunit selective GABA_A receptor agonist) and flesinoxan, a highly selective 5-HT_{1A} receptor agonist

[102], using the SIH paradigm as experimental paradigm. Using the SIH paradigm, eight chromosomal substitution strains (CSS) on a C57BL6/J (host) \times A/J (donor) background were screened to localize chromosomes involved in GABA_A and 5-HT_{1A} receptor sensitivity. Preliminary data indicated that some strains showed clear differences in either diazepam or flesinoxan sensitivity. Further research is ongoing to unravel underlying putative genes.

GABA-ergic and serotonergic mechanisms play an important role in SIH, and rodent and human studies into the underlying brain mechanisms indicate high translational comparability. Mouse genetic mapping studies (by using chromosomal substitution strains) indicated genetic loci involved in the pharmacological mechanisms behind the SIH processes. If such loci and genes can be localized, human counterparts have to be sought in the quest for novel candidate genes involved in anxiety and its disorders.

Besides SIH, other highly valuable translational animal paradigms also have been developed. For instance, the startle reflex methodology can translate animal research into human experimentations, and vice versa. Especially the combination of the startle reflex methodology with Pavlovian aversive conditioning makes it a powerful procedure to develop cross-species studies [103]. The startle reflex is a response to an intense and unexpected stimulus. In animals, this reflex can be measured by assessing the whole body reflex. In humans, the eyeblink reflex is used to measure the amplitude and latency of a startle reflex. Davis and colleagues [104] extensively investigated the fear-potentiated startle, which refers to the increase (potentiation) of the startle reflex during a state of fear. This state of fear is induced by the anticipation of an aversive stimulus (for example, a shock). Animals and humans display similar effects, that is, the amplitude of the startle reflex is greater in the presence of conditioned stimuli than in their absence [104–107]. The advantage of the fear-potentiated startle procedure is that the startle in animals and humans are potentiated by similar procedures. Thus, findings in humans can be replicated in animals, and vice versa, increasing the translational value of animal models of human anxiety. When a new gene is discovered by means of, for example, GWAS, an animal model can be genetically manipulated and used to study the underlying mechanisms or to investigate new potential anxiolytics.

Translational studies into anxiety

Can data on the involvement of serotonin in anxiety and anxiety disorders (here illustrated with the 5-HTT and the 5-HT_{1A} receptor) be used to design translational research that possibly will generate new hypotheses and targets for anxiolytic therapeutics? Recently, Jasinska *et al.* [108] formulated a hypothesis around the involvement of the 5-HTT gene, stress, and raphe–raphe interactions in order to try to explain the risk of depression as a result of gene–environment interactions between the 5-HTT gene and stress. Different populations of serotonergic neurons in the dorsal raphe (DR) nucleus exist that differentially contribute to the response to stress. Although the authors hypothesize this mechanism mainly for depression, there is no a priori reason why anxiety disorders would not be mediated by this or a similar mechanism. The authors propose that the G \times E interaction of the 5-HTT gene and stress depends on the genetically produced variability in serotonin reuptake during stressor-induced raphe–raphe interactions and alters the balance in the amygdala–ventromedial prefrontal cortex–DR circuitry that underlie reactivity to stressors and regulation of emotion. In LL-individuals with an

efficient 5-HT transport, the circuitry is able to normalize, but not so in SS-individuals, potentially leading to abnormal activity and pathology. Whether such a mechanism also acts in human pathology is as yet unresolved but could lead to specific searches for new mechanisms causing pathological anxiety. Next to different functional serotonergic populations in the DR, serotonin transporters appear very dynamically regulated [109] and undergo regulated membrane trafficking, as well as transitions between low and high activity states, with many signalling pathways involved. Moreover, 5-HTT exhibits dynamic associations with cytoskeletal binding proteins; actually, Chang *et al.* [110] found two pools of 5-HTT proteins on the surface of serotonergic cells, with one relatively with free diffusion and the other with restricted mobility due to binding to the cytoskeleton. Whether the serotonergic system exerts this kind of extremely variability, which might lead to new and better understanding of the role of the 5-HTT complex, including its genetic variability, is still a matter of the future, but it remains fully possible that new mechanisms involved in anxiety and its disorders might emerge.

Conclusions

The discovery and development of novel anxiolytic drugs are hampering. The existing anxiolytics have been around for decades, and no subsequent breakthrough has come through. Especially, the lack of innovative and effective novel drug targets is disappointing. The reasons for this lack of progress are not completely clear but may be due to the complex regulatory and financial regulations in the finding of new ‘druggable’ targets (we do not go into many other financial, outsourcing, human, and marketing reasons (see, for example, [111])).

However, central to the continued paucity of new targets for anxiolytic drugs is our limited knowledge of the mechanisms and pathology underlying the various anxiety disorders. We simply do not know what is wrong in the brain of pathologically anxious people and whether the DSM-based anxiety disorders constitute independent entities. Therefore, we have to invest in fundamental research in the neurobiological mechanisms involved in anxiety processes in healthy people and look for what is different in diseased brains. Because intrusive investigations of the human brain are often not (or never) possible, animal research is inevitable and can contribute considerably to find the neural substrates for anxiety and its pathology, although it is not realistic to think that such knowledge is 100% translatable to the human situation. Any strategy to find new targets to modulate aspects of anxiety (and hopefully its pathology) will use genetic and genomic approaches. Our initial hope was that, after elucidation of the human genome, we would be able to pinpoint certain genes as the perpetrator causing the problem. However, it soon became clear that that is an illusion. Notwithstanding a high heritability in many of the anxiety disorders, no single gene or a small number of genes have emerged from a large number of studies on large cohorts of patients thus far. It has become increasingly clear that anxiety disorders, similar probably to the fundamental mechanisms involved in anxiety processes, are caused by action at many hundreds of genes with very complex interactions, including both environmental factors and gene \times gene interactions. It is difficult to expect that one single gene contributes sufficient influence to modulate anxiety processes to a large degree, and no specific drug will

probably be developed for such a target. In the present contribution, three (druggable) targets have been presented, with all three somewhere involved in the (genetic) pathways of anxiety processes (5-HT_{1A} receptor, 5-HTT, and GABA_A receptor). Although it is not known how these three targets are involved in 'normal' or 'pathological' anxiety in the brain, we know at least that they are involved in several aspects of anxiety and may aid in our further understanding of the underlying mechanisms. Whether they represent real direct targets that are changed under pathological conditions or only as primary entrance to influence underlying mechanisms is not clear. In the case of serotonin modulation (via 5-HT_{1A} receptor activation or blockade of the serotonin transporter), an indirect effect is possibly the most logical explanation, because treatment of anxiety disorders with SSRIs or buspirone takes weeks, or even months, before anxiolytic activity is seen. This points to an induction of mechanisms that slowly change and need time to become effective (plasticity changes). Anxiolytic effects after activation of GABA_A receptors seem acute and might point to a primary mechanism directly involved in anxiety-regulating mechanisms. Close collaboration between fundamental academic research into anxiety mechanisms in the brain and drug discovery research and development might lead to breakthroughs in our search for new and better anxiolytics. Clearly, animal models will play an important role in future anxiolytic drug development, but only as a component of a broad and integrated multi-disciplinary approach. To be successful, preclinical researchers need to ensure that novel clinical insights into the aetiology of anxiety disorders are integrated in the design and use of animal models and tests.

Epidemiology of anxiety disorders

Hans-Ulrich Wittchen and Katja Beesdo-Baum

Introduction

For an understanding of anxiety disorders, it is helpful to distinguish anxiety and fear as different, though overlapping and related, constructs. Anxiety is a basic emotion and is typically adaptive, and not pathological. It can be described as a future oriented mood state associated with the anticipation of future threat and possibly its avoidance. Fear is the organism's response to present/imminent real or perceived threat and is associated with autonomic arousal and escape [1]. Clinically relevant anxiety disorders differ descriptively from non-pathological forms of fear and anxiety by being considerably more persistent and excessive, causing significant distress and impairment [2]. It is assumed that various conditioned dysfunctions in the regulation of the complex neurobiological and psychological fear/anxiety circuits are responsible for pathological anxiety [3]. In childhood and adolescence, anxiety often manifests as part of typical development, which can render identification and diagnosis of pathological anxiety difficult. However, it is particularly this sensitive phase of life when initially transient and circumscribed neurobiological, cognitive, affective, and behavioural dysfunctions may generalize and escalate, leading to psychopathologic forms of anxiety associated with distress, impairment, and negative developmental outcomes [3].

Anxiety disorders represent a phenotypically heterogeneous class of disorders. Although the individual anxiety disorders share several clinical diagnostic features (that is, excessive levels of fear or anxiety, physical symptoms, and avoidance behaviour resulting in distress and/or impairment [1, 2, 4]), the specific anxiety disorders (such as separation anxiety disorder, panic disorder, agoraphobia, social anxiety disorder, generalized anxiety disorder, and the specific phobia subtypes animal, natural environment, blood injection injury, situational, and 'other') also differ from each other significantly in terms of their typical focus of fear and anxiety, form, type, and severity of the psychophysiological fear response and the associated cognitions, as well their onset and patterns of course and the clinical and neurobiological correlates, as well as risk factors [1, 5–7]. Moreover, the way fear and anxiety are expressed across different

developmental periods and stages may differ in the various anxiety disorders [8] and may hinder diagnosis [3]. For example, particularly in children, anxiety disorders may manifest in non-specific somatic symptoms or anxiety-related symptoms such as crying, irritability, or tantrums, often resulting in misinterpretation by adults as oppositional or disobedience [9]. However, no separate sets of criteria or classifications exist for children and adults in the most recent international diagnostic classification system DSM-5 [2] ([Table 88.1](#)). Even separation anxiety disorder and selective mutism—traditionally regarded as childhood anxiety disorders—were moved from the previous DSM-IV category of 'disorders usually first diagnosed in infancy, childhood or adolescence' to the anxiety disorder class. Yet, in order to account for differences in the symptom expression of children and adults, the individual diagnostic criteria sets in DSM-5 provide additional notes to guide the clinicians in the diagnostic process [2]. Some noteworthy differences between children and adults are: different symptom presentations (for example, clinging or tantrums in children with social anxiety disorder), duration (for example, 4 weeks in children and 6 months in adults in separation anxiety disorder), symptom type or count (for example, one physical symptom in children and at least three in adults to diagnose generalized anxiety disorder), and level of insight into the excessiveness/inadequacy of fear (children may lack insight).

This chapter summarizes current knowledge on the epidemiology of anxiety disorders across the lifespan, with a particular focus on childhood and adolescence, given the usually early onset of anxiety disorders. It describes the prevalence, onset, course, persistence, comorbidity, and outcome, as well as correlates and risk factors of separation anxiety disorder, specific phobia (and the various subtypes), social anxiety disorder, agoraphobia, panic disorder, and generalized anxiety disorder. We do not address selective mutism because of a lack of data in epidemiological studies, and post-traumatic stress disorder and obsessive-compulsive disorder—despite being closely associated with pathological anxiety—have now been moved from anxiety disorders into separate diagnostic groups in DSM-5 (see Sections 13 and 15).

Table 88.1 Anxiety disorders in DSM-IV and DSM-5, highlighting different symptomatology in youth

DSM-IV-TR		DSM-5		
Disorders usually first diagnosed in infancy, childhood, or adolescence		Anxiety disorders		Different criteria in children (vs adults) <i>Information on childhood anxieties as highlighted in DSM text portion</i>
309.21	Separation anxiety disorder	309.21	Separation anxiety disorder	<p>A5: Children may be unable to stay in or go to a room by themselves. They may also display 'clinging' behaviour, staying near or 'shadowing' the parent around the house, or needing someone to be with them when switching to a different room in the house.</p> <p>A6: Children often have difficulty during bedtime and may insist that someone stays with them till they fall asleep. In addition, they may make their way to their caretaker's bed (or that of a significant other, ex, sibling). Children may refuse or be reluctant to go to camp, attend sleepovers, or run errands.</p> <p>A8: Headaches, abdominal complaints, nausea, and vomiting are common in children. Cardiovascular symptoms, such as palpitations, dizziness, and feeling faint, are less common in younger children. However, they may occur in adolescents and adults.</p> <p>B: Duration is at least 4 weeks in children and adolescents and 6 months or longer in adults. Younger children are reluctant to go or may avoid going to school altogether. They may not express worries or fears about threats to their home, parents, or themselves, because the anxiety manifests only when separation takes place. As they age, they often worry about specific dangers (kidnappings, accidents, muggings, and death) or will have vague concerns about not being reunited with their attachment figures</p>
313.23	Selective mutism	312.23	Selective mutism	<p>In children, when encountering individuals in social interactions, they do not initiate speech or reciprocally respond when spoken to by others. In addition, they will speak in their homes in the presence of immediate family, but not too often in front of extended family or even close friends. They often refuse to speak at school and sometimes use non-verbal means (grunting, pointing, writing) to communicate. They may be more willing and eager to engage in social encounters when speech is not required or necessary.</p> <p>C: In children, duration of disturbance is not limited to the first month of school</p>
Anxiety disorders				
300.01	Panic disorder without agoraphobia	300.01	Panic disorder	B: Adolescents may be less worried about additional panic attacks than young adults
300.21	Panic disorder with agoraphobia			
300.22	Agoraphobia without history of panic disorder	300.22	Agoraphobia	B: 'Other incapacitating or embarrassing symptoms' in children include a sense of disorientation and getting lost
300.23	Social phobia	300.23	Social anxiety disorder	A: Social anxiety must occur in peer settings, not just in interactions with adults
	(Specify if: generalized)		(Specify if: performance only)	C: In children, the anxiety may be expressed by crying, tantrums, freezing, clinging, shrinking, or failing to speak in social situations
				F: Duration of disturbance is at least 6 months, for that aids in distinguishing the disorder from transient social fears that are common, particularly among children. Adolescents display a broader pattern of fear and avoidance, compared to younger children. Older adults display lower levels of anxiety across a broader range of situations, whereas younger adults express high levels of social anxiety for specific situations
300.29	Specific phobia	300.29	Specific phobia	A: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, or clinging
	(Specify type: animal, natural environment, blood injection injury, situational, other)		(Specify if: animal, natural environment, blood injection injury, situational, other)	When a diagnosis of this disorder is being considered, it is important to evaluate the degree of impairment and the duration of fear, anxiety, or avoidance, and the typicality of such behaviour, relative to the child's particular developmental stage. Fear and anxiety are often expressed differently between children and adults. In children, the C criterion (which recognizes that fear is excessive/unreasonable) may be absent. Children are typically unable to understand the concept of avoidance
300.02	Generalized anxiety disorder	300.02	Generalized anxiety disorder	C: In children, one, instead of three, out of six symptoms is required
				In children and adolescents, the anxieties and worries often concern the quality of their performance or competence at school or in sporting events, even when their performance is not being evaluated by others. It is possible for children with this disorder to worry about catastrophic events (such as earthquakes or nuclear war), in addition to mundane habits such as punctuality. Children may be perfectionists, redoing tasks due to dissatisfaction with their own performance. They are, more often than not, eager to seek approval and require a substantial amount of reassurance about their performance and their worries

Prevalence of anxiety disorders

Cross-sectional community surveys conducted in many countries around the globe [10–14] have shown the prevalence of anxiety disorders to be the highest among all classes of mental disorders (that is, mood, substance use, impulse-control, somatoform, and eating disorders) in most countries, with estimates of up to 30% for lifetime and 14% for the past 12 months. The estimated lifetime risk up to age 75 is even higher (up to 41% in the United States [15]). In addition, prospective longitudinal studies that examine mental disorders in the same study cohort at multiple points in time provide consistent evidence that the cumulative rates go beyond 30% when entering early adulthood [16–18]. Thus, anxiety disorders are already the most common class of mental disorders in childhood and adolescence [8, 19–21].

Cross-sectionally, the most frequent anxiety disorders in adulthood are specific phobias, followed in frequency by social anxiety disorder, with 12-month prevalence estimates of up to 10% and 8%, respectively [13, 15]. In children, in addition to specific phobias and social anxiety disorder, separation anxiety disorder is highly prevalent, with quite variable 12-month prevalence estimates across studies, ranging from 2.8% and 8% [8]. It is noteworthy that the National Comorbidity Survey Adolescent Supplement (NCS-A) found that separation anxiety disorder had a low current period prevalence (12 months: 1.6%; 30 days: 0.6%) [22] but displayed a high lifetime prevalence (7.6%) [19]. This might indicate that this early childhood anxiety condition rarely persists into adolescence and adulthood. Consistent with these data, adult surveys have found a relatively low 12-month prevalence of separation anxiety disorder in adulthood of 1–1.5% [23, 24].

The less prevalent anxiety conditions across all ages are generalized anxiety disorder, panic disorder, and agoraphobia. These three anxiety disorders reveal low prevalence estimates in childhood (1% or lower); somewhat higher estimates are found in adolescence (2–3% for panic disorder and 3–4% for agoraphobia and generalized anxiety disorder) (for comprehensive reviews, see [6, 8]).

Onset of anxiety disorders

There is abundant epidemiological evidence that the developmental period of childhood, adolescence, and young adulthood constitutes the core high-risk phase for the onset of anxiety disorders [5, 25–27].

Noteworthy heterogeneity, however, exists in the specific age of onset patterns for the various types of anxiety disorders. The bars in Fig. 88.1 show the cumulative age of onset distribution for specific anxiety disorders by gender, as derived from data from the Early Developmental Stages of Psychopathology (EDSP) study [18, 28]. Separation anxiety disorder and specific phobias are the earliest forms of anxiety disorders, revealing an emergence of 50% of all onsets prior to the age of 8 years; almost all affected cases have emerged by the age of 12. Social anxiety disorder begins to develop later in childhood, showing a steep increase in incidence in early adolescence. Although agoraphobia, panic disorder, and generalized anxiety disorder reveal some onset cases in childhood, their core onset risk period is in later adolescence and early adulthood. Despite differences in prevalence estimates for females and males (the former being more commonly affected than the latter), no remarkable gender differences in the age of onset patterns are observed. Slightly earlier onsets are seen for specific phobias in males, which are due to an earlier onset of the natural environmental subtype of specific phobias in males [8], and for generalized anxiety disorder in females. Similar age of onset findings have emerged in other epidemiologic studies conducted in both adult and adolescent samples [15, 21, 26, 27].

Natural course and outcome of anxiety disorders

Given that current 12-month period prevalence estimates are not considerably lower than the lifetime estimates for most anxiety disorders, we can assume that anxiety disorders typically have a persistent course, either in terms of chronic symptoms or in terms of a waxing and waning or frequent recurrent course [8]. For example, the 12-month/lifetime prevalence ratios in the National Comorbidity Surveys in the United States are higher for anxiety disorders (any: 0.7) than for depressive disorders (0.5), with variations across the anxiety disorders (0.5 for generalized anxiety disorder to 0.8 for specific phobia). The prevalence ratio is highest in adolescents (0.8), as compared to adults (0.6) and the elderly (0.5) [15]. However, this decrease is not uniform across the anxiety disorders, with generalized anxiety disorder (0.4–0.5) and specific phobia (0.7–0.8) showing similar ratios across all age groups [15].

Persistence estimates for anxiety disorders from cross-sectional studies may overestimate the chronicity or recurrence of anxiety

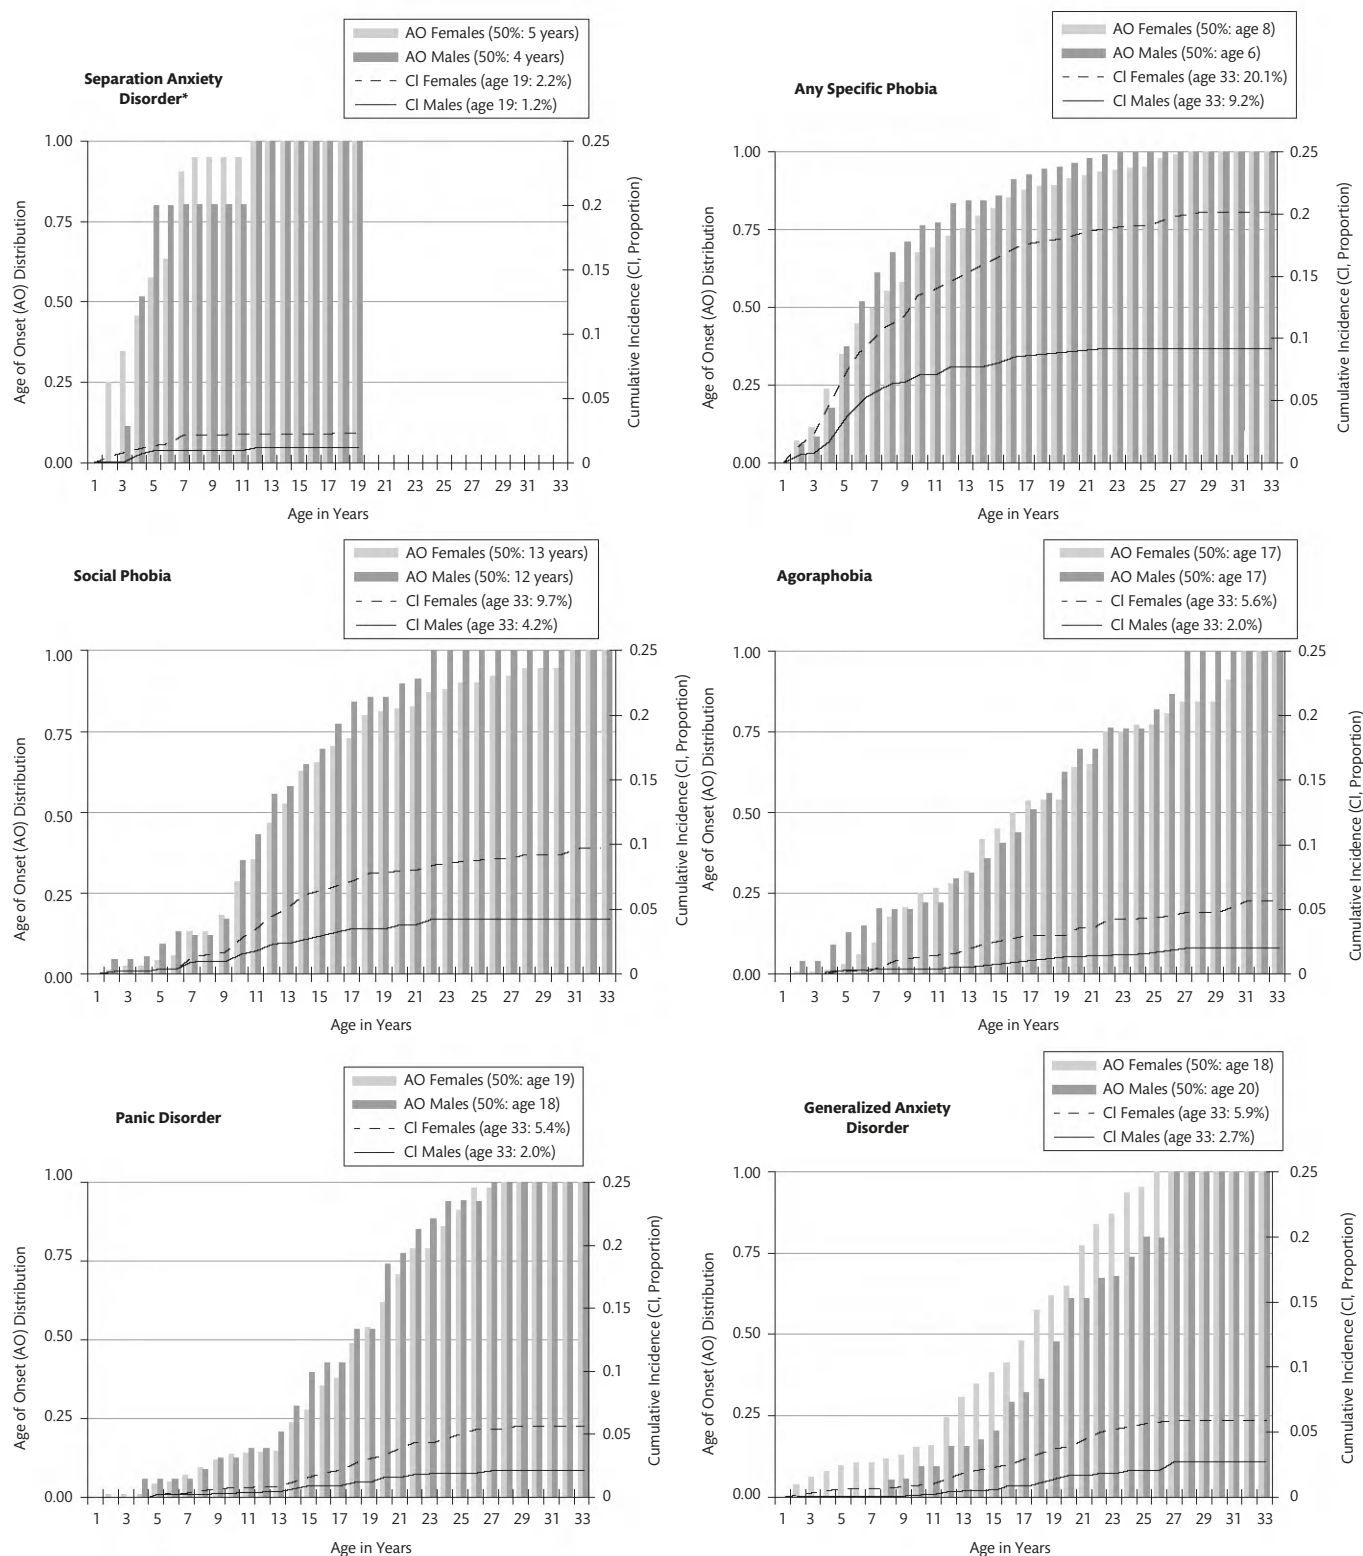

Fig. 88.1 Cumulative incidence and age of onset distribution of anxiety disorders by gender. The EDSP study is a prospective longitudinal study in a representative sample of adolescents and young adults aged 14–24 years from the general population (Munich, Germany; $N = 3021$). Anxiety and other mental disorders were assessed using the standardized and computerized composite international diagnostic interview (DIA-X/M-CIDI), according to DSM-IV criteria, on a lifetime basis at baseline and for the interval period since the last assessment at 1-, 4-, and 8-year follow-up, respectively. Bars in the figure show the cumulative age of onset distribution; lines show the age-dependent cumulative lifetime incidence; in phobias, impairment was required among subjects aged 18 years or older; * Separation anxiety disorder was only assessed once at 1-year follow-up in subjects of the younger age cohort (aged 14–17 years at baseline).

problems in the general population, given the potential memory and recall bias in lifetime symptom reports and the age of onset/recency information [8]. Prospective longitudinal study approaches are able to provide a more reliable picture of the natural course and outcome of anxiety disorders (Fig. 88.2). However, given the considerable efforts and financial resources required for such studies, prospective course data are still scarce, particularly for longer time scales of 10 years or more. The data available indicate that the stability or persistence is probably less pronounced than expected, based on the estimates of cross-sectional studies, at least when focusing on

full-threshold diagnosis (*diagnostic stability*). For example, in the 15-year prospective Zurich Cohort study [29], a low stability rate of 4% was found for pure (non-comorbid) anxiety disorders (generalized anxiety or panic disorder). For children and adolescents with anxiety disorders, Last and colleagues [30, 31] reported that 80% remitted from the anxiety shown initially, over a 3- to 4-year follow-up. The prospective longitudinal EDSP study among adolescents and young adults found that 2 years after the baseline investigation, 19.7% of adolescents with baseline anxiety disorder met the threshold criteria again at follow-up, with the probability

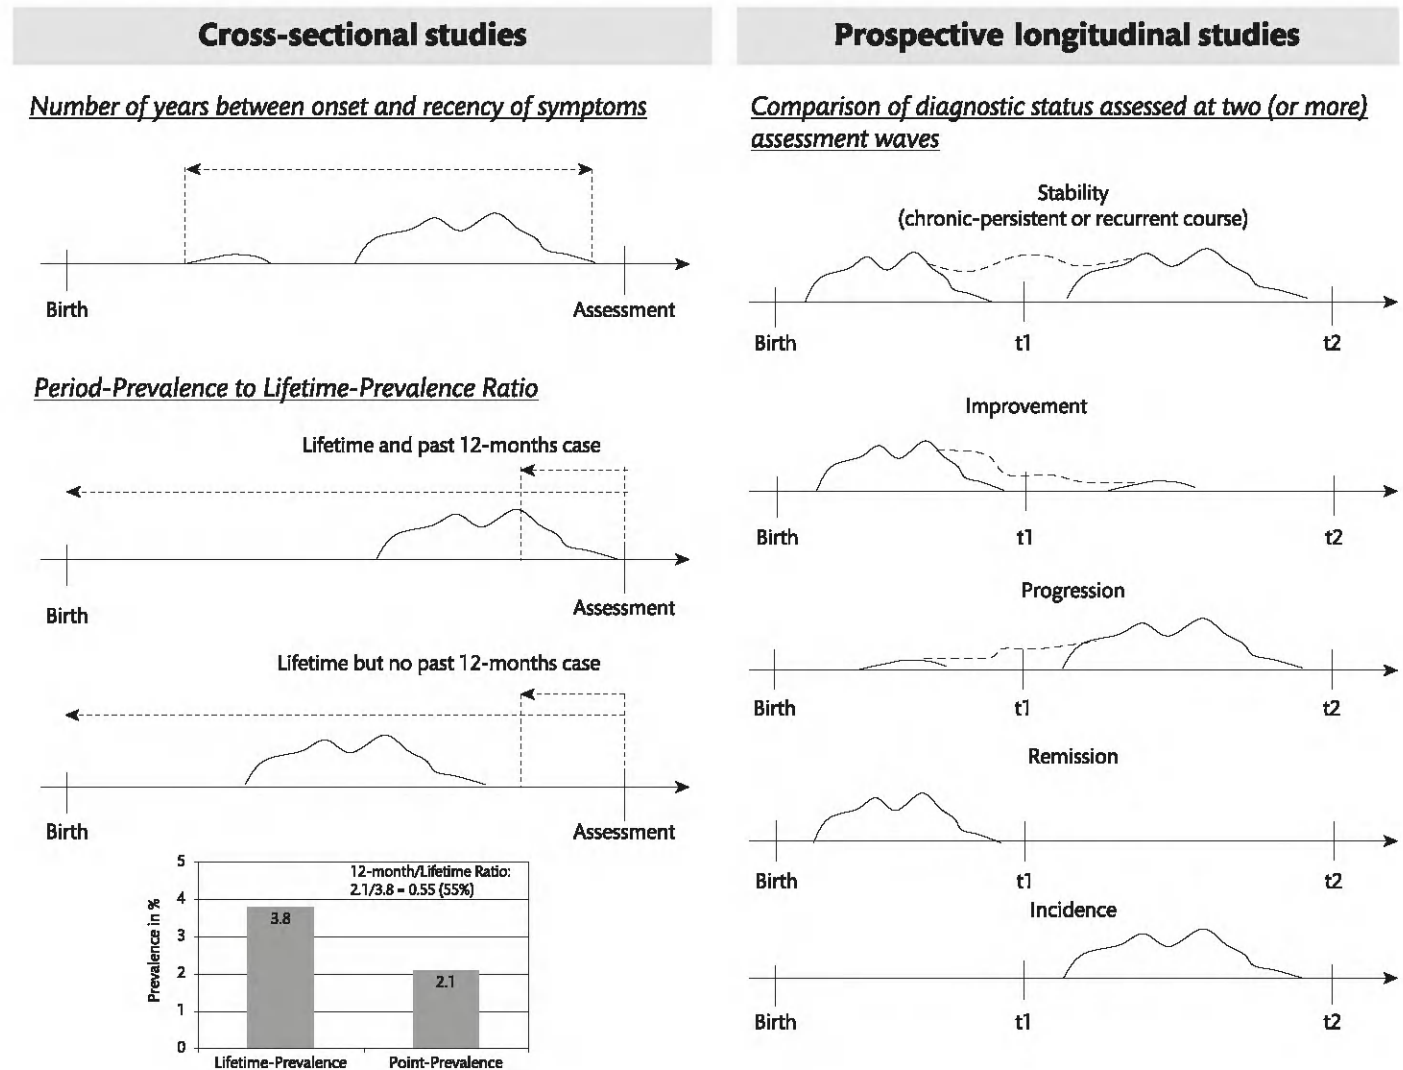

Fig. 88.2 Approaches to the natural course assessment of anxiety disorders in cross-sectional and prospective longitudinal epidemiological community-based studies. Cross-sectional studies most frequently utilize retrospective age of onset and age of recency reports to estimate the persistence of anxiety, as indicated by the duration of a condition in years. This approach assumes the continuous presence of a disorder, neglecting waxing and waning in symptom severity, including symptom-free intervals, and may thus overestimate the stability (or persistence/chronicity). Another indirect indicator of disorder chronicity is the 12-month to lifetime prevalence ratio. The higher the proportion of 12-month cases among lifetime cases, the higher the assumed chronicity of a condition. Because only categorical diagnoses are considered here (no symptomatic improvements below the diagnostic threshold), this may lead to underestimation of chronicity. On the other hand, as lifetime occurrence prior to the past 12 months may have not been reported or remembered by study participants, this ratio may also overestimate the chronicity. Thus, cross-sectional studies only allow for crude estimations of the natural course of anxiety disorders. Longitudinal studies, in contrast, allow for a more realistic and comprehensive course description as 'true persistence', recurrence, progression, improvement, and remission can be mapped using the diagnostic information on a threshold and subthreshold level available from two (or more) assessment waves months to many years apart.

Adapted from *Psychiatr Clin of North Am.*, 32(3), Beesdo K, Knappe S, Pine DS, Anxiety and anxiety disorders in children and adolescents: Developmental issues and implications for DSM-V, pp 483–524, Copyright (2009), with permission from Elsevier Inc.

of a negative outcome increasing as a function of baseline anxiety severity [32]. Considerable variability in stability rates by type of anxiety diagnosis have been observed. For example, when taking threshold and subthreshold anxiety diagnoses from both baseline and follow-up of the EDSP study into account, panic disorder (44%) and specific phobia (30.1%) were found to be the most stable; other anxiety disorders showed lower stability rates, particularly agoraphobia (13.4%) and social phobia (15.8%) [32]. Of course, stability rates at least slightly increase when following up individuals who have been affected for longer periods of time. There is then a higher chance for recurrence to have occurred. For social anxiety disorder in the EDSP study, for example, 15.5% of baseline cases met threshold criteria again at least once during any of the three follow-up assessments conducted over a time period of 10 years, and a further 19.7% had at least subthreshold social anxiety disorder [33].

To summarize, these findings seem to indicate that anxiety disorders in the community are typically not chronic, in the sense that the symptoms are consistently stable above the diagnostic threshold. Instead, the symptoms typically wax and wane over time around the diagnostic threshold, with spontaneous complete remissions being the rare exceptions (Fig. 88.3) [32].

It is also a consistent finding from prospective studies on the course of anxiety that there is a considerable degree of homotypic continuity. This is despite the proportion of youth diagnosed again with the

same anxiety disorder or symptoms thereof being numerically rather low to moderate (for comprehensive reviews of studies, see [8, 34, 35]). Individuals diagnosed with an anxiety disorder, compared to those without, are at a statistically higher risk of having the same disorder (for example, [36–38]) or symptoms of the same disorder [32, 33] at later points in time (*homotypic prediction*) [39]. Moreover, the limited *homotypic continuity* of anxiety disorders observed in prospective longitudinal community studies does not mean that anxiety disorders completely remit (Fig. 88.3). In the EDSP study, only 10% of children and adolescents with (pure or comorbid) specific phobia at baseline had no mental disorder at the 10-year follow-up (*full diagnostic remission*); 41% reported specific phobia again (*strict homotypic continuity*), and overall 73% were diagnosed with any anxiety and/or depressive disorder at subsequent assessments (*heterotypic continuity*) [40]. Similarly, only 13% of baseline social anxiety disorder cases were free of any mental disorder during the 10-year follow-up, while the remaining 87% reported having other types of anxiety disorders or depressive disorders. All of the baseline generalized anxiety disorder cases revealed either homotypic or heterotypic continuity. Other multi-wave, prospective longitudinal studies revealed similar findings [29, 31, 37, 41]. Thus, after onset of the first (that is, pure) anxiety disorder emerges in childhood or early adolescence, a pattern with continuous and frequently variable anxiety develops by later adolescence or early adulthood [6, 42].

Fig. 88.3 The evolution of anxiety disorders.

Adapted from *Compr Psychiatry*, 41(2, suppl. 1), Wittchen H-U, Lieb R, Pfister H, et al., The waxing and waning of mental disorders: evaluating the stability of syndromes of mental disorders in the population, pp. 122–32, Copyright (2000), with permission from Elsevier Inc.

Complications and development of comorbid disorders

A frequent outcome of primary anxiety disorders is the development of a cascade of other psychopathological complications [4]. Anxiety disorders have been consistently shown to contribute not only to the development of further anxiety disorders, but also to depressive disorders, substance use disorders, and suicidality, as well as to other adverse developmental outcomes (such as educational underachievement, early parenthood, and financial disadvantage [25, 43]). Thus, for anxiety cases in which *homotypic continuity* is not observed, there is a substantial degree of *heterotypic continuity* in both cross-sectional and longitudinal epidemiological studies [39]. The longitudinal associations between anxiety and subsequent depression are particularly strong [5, 21, 31, 43–47]. Prospective epidemiological studies investigating particular anxiety diagnoses found that children and adolescents with specific fears and phobias (especially fear of darkness) [48], social anxiety disorder [49–51], and other types of anxiety disorders, such as agoraphobia, panic disorder, and generalized anxiety disorder [5, 38, 51], are all at significantly increased risk for subsequent depression.

There is also consistent epidemiologic evidence that certain clinical characteristics of anxiety disorders, such as greater severity (multiple anxiety diagnoses or more severe impairment of individual anxiety disorders), greater impairment or persistence, and co-occurring panic attacks, are associated with an increased risk of depression [49, 51], suggesting that anxiety disorders may play a causal role in depression development [52].

Substance abuse or dependence is also a frequent heterotypic problem outcome of primary anxiety disorders [43, 45, 53–56], providing some evidence that alcohol or other drug use is possibly motivated by self-medication for pathological anxiety symptoms [57].

Correlates and risk factors

A range of sociodemographic, individual, and environmental factors assessed have been found to be associated with anxiety disorders in epidemiological studies. We will describe these factors as correlates or risk factors, not speculating whether they should be considered as distal or proximal vulnerability factors or risk factors in a strict sense. This is because cross-sectional studies predominate and identify correlates; prospective longitudinal studies are required to evidence risk factor status [58], either for the first onset of an anxiety disorder or for an adverse course after the anxiety disorder has initially developed (chronicity/persistence/progression/recurrence vs improvement/remission) (Fig. 88.3). Course predictors have been less extensively studied, compared to risk factors for first onset; yet both appear crucial, and at least partly different factors could emerge relevant for prevention and early intervention. Moreover, while the correlates overlap, risk factors and course predictors for the individual anxiety disorders or for anxiety vs depressive or other comorbid disorders may be different. They may be implicated in the heterogeneity of the various disorder types and classes in relation to the phenomenology, onset, and course.

Sociodemographic factors

Female gender is the most consistent risk factor for the development of each of the specific anxiety disorders (for a review, see [8]). Gender differences are usually small in childhood and grow with age, reaching a ratio of approximately 2:1 to 3:1 for females vs males in late adolescence. The recent NCS-A found a higher prevalence of anxiety disorders among non-Hispanic black, compared to non-Hispanic white, adolescents, as well as among respondents with divorced or separated parents, compared to married or cohabiting parents [19]. Anxiety disorders are frequently also found among individuals with lower, compared to higher, education (for example, [59]). In NCS-A, low parental education was also shown to be associated with adolescent anxiety disorders. Low household income or precarious financial situations have been shown to be associated with anxiety disorders (for example, [59]), and there is evidence of adverse financial outcomes in young adulthood among children and adolescents with anxiety disorders, particularly generalized anxiety disorder/overanxious disorder [25]. As sociodemographic risks co-occur, Copeland and colleagues [60] identified a moderate-risk class containing low parental education and poverty being associated with offspring anxiety disorders, as well as with depressive disorders, but not with externalizing disorders. After taking into account comorbidity and multiple other risk factors, Shanahan *et al.* [61] found that parental unemployment was associated with anxiety and behavioural disorders, but not with depressive disorders.

Familial aggregation

Anxiety disorders consistently ‘run in families’, with strong associations between parental and offspring anxiety diagnoses [5, 52, 62–65]. A particularly strong risk is present for offspring with two affected parents [62, 65] and for offspring of severely affected parents as indicated by impairment, number of anxiety disorders, and early onset of anxiety disorders [66]. However, not only parental anxiety disorders increase the risk for anxiety in offspring, but parental depression was also found to be associated with offspring anxiety [67, 68]. Investigations into the specificity of the familial aggregation of anxiety and other mental disorders revealed mixed findings, with some evidence for specificity [5, 69, 70]. Furthermore, some specificity appears to exist in the familial aggregation of certain anxiety disorders [5, 71]. The exact mechanism of ‘familial transmission’ of anxiety from parents to offspring is complex and still far from being well understood. Biology in terms of genetic or physiological (intrauterine) factors, the family environment in terms of living with an anxious parent (for example, modelling, anxious rearing, insecure attachment), or both (additive risks or gene–environment interactions) are implicated [72–74]. Twin studies indicate that the genetic liability for specific anxiety disorders, as well as for depression and anxiety, may overlap with different environmental risks, resulting in phenotypically diverse outcomes [74–76]. For more detail on genetic factors, see Chapters 80 and 89.

Temperament/personality

Personality traits such as neuroticism, trait anxiety, or negative affect, as well as temperamental styles often investigated in epidemiological studies in terms of behavioural inhibition are likely overlapping constructs that can be viewed as precursor conditions

to anxiety disorders, with some indications of specificity between anxiety and depression outcomes [5, 77–83].

Environmental factors

Adverse life events and conditions in childhood and adolescence, as well as unfavourable parental rearing styles, have been linked in many epidemiologic studies to the development of anxiety disorders in offspring. Indeed, loss of a parent by death, separation, or divorce, as well as physical or sexual abuse or neglect in childhood, have been associated with almost all mental disorders, including anxiety disorders (for example, [70, 84–86]). In the EDSP study data, there was nevertheless some indication that childhood separation events were specifically associated with pure anxiety, as well as with comorbid anxiety and depression, but not with pure depression [5]. Other negative life events have also not just been evidenced as risk factors for depression [87, 88], but also for anxiety disorders [89]. In particular, threat events tend to precede anxiety disorders (or comorbid anxiety and depressive disorders), whereas loss events tend to precede depression [61, 90–92].

Parenting styles have also been linked in epidemiologic studies with offspring anxiety disorders. For example, in the EDSP study, parental overprotection and parental rejection were associated with increased prevalence of social anxiety disorder in offspring [63, 71]. Overprotection was found to increase the risk for anxiety disorders, but not for pure depressive disorders, while parental rejection was linked with depressive disorder [5]. After adjusting for comorbidity and other putative risk factors, Shanahan *et al.* [61] found harsh discipline to be specifically associated with generalized anxiety disorder or overanxious disorder (among a range of poor emotional and behavioural outcomes); overintrusive parenting was revealed as a non-specific risk factor for anxiety and behavioural disorders.

Course predictors

Sociodemographic, individual, and environmental factors have been less frequently examined as course predictors for anxiety disorders, particularly when based on prospective longitudinal data [35]. Contrasting to correlates and risk factors for onset, sociodemographic factors are not consistently associated with an adverse course of anxiety disorders. In a cross-sectional study among adolescents in the United States, for example, female gender was the only demographic variable found to be associated with a higher persistence of most anxiety disorders, while race/ethnicity, family income, or family composition were not consistently implicated [22]. Symptom severity and duration of illness are the best prognostic indicators for anxiety in both epidemiologic and clinical studies [8]. For example, the prospective longitudinal EDSP study revealed several clinical features, such as early age of onset, the generalized subtype, a high number of catastrophic anxiety cognitions, severe avoidance, and impairment, as predictors for higher persistence, as well as prospectively assessed diagnostic stability for social anxiety disorder [33]. Comorbidity with other disorders was not found to predict the course of social phobia, with the exception of co-occurring panic attacks that were associated with both higher persistence and diagnostic stability of social anxiety. Established vulnerability characteristics for the onset of anxiety conditions, such as parental social anxiety disorder and depression, as well as a behavioural inhibited temperament, were related to poor prognosis. Thus, besides gender and clinical diagnostic information, familial

and temperamental characteristics may inform estimates of prognosis for anxiety disorders and appear useful to target treatment interventions.

Summary and implications

Anxiety disorders are frequent clinical conditions with an early onset in life, associated with considerable developmental, psychosocial, and psychopathological complications. Early anxiety syndromes in children may remit spontaneously, but most children and adolescents with an anxiety disorder continue to suffer from anxiety or other psychopathological problems for the major part of their subsequent life. This persistent course is causally related to a tremendous personal, economical, and societal burden [11, 93, 94]. Recent EU-wide calculations rank anxiety disorders as the third most burdensome group of disorders [3]. Although effective cognitive behavioural and pharmacological treatments exist for anxiety disorders and related conditions, the vast majority of anxiety disorders typically never receive any appropriate treatment and the majority remains undiagnosed and untreated, even in the most advantaged countries. Evidence suggests that treatment only occurs after many years when additional psychopathological complications like depression have developed. The degree of often lifelong non-recognition, underdiagnosis, and undertreatment has been related to the tremendous burden caused by anxiety in the United States, the EU, and worldwide [11]. Given that available treatments are highly effective and cost-efficient, timely and earlier treatment has the potential of substantially reducing the burden (see Chapter 92). Moreover, given the early onset of anxiety disorders, the burden of anxiety on the population level might be substantially reduced by concerted action, with targeted preventive interventions in children and adolescents, before the disorder becomes persistent and before comorbid complications arise (see Chapter 91). In order to work towards these goals, considerably more basic research is needed to identify the most powerful and specific risk factors for the first onset, as well as poor course of anxiety disorders, and to delineate the complex underlying psychological, behavioural, and biological mechanisms and interactions [3, 95–97]. Focusing on ‘optimal outcomes’ of anxiety problems experienced by children and adolescence is a core societal challenge [98].

Genetics of anxiety disorders

Michael G. Gottschalk and Katharina Domschke

Introduction

The present chapter provides a review of the current state of genetic studies across the spectrum of anxiety disorders, including specific phobias (SP), social anxiety disorder (SAD, also referred to as social phobia), agoraphobia (AP), panic disorder (PD), and generalized anxiety disorder (GAD), with a special focus on genome-wide association studies (GWAS), candidate gene studies, gene–environment studies, and recent advances in epigenetics. Given the interrelatedness of mental disorders in general and of anxiety disorders in particular, we will expand upon the genetics of intermediate phenotypes, crossing classic categorical disorder definitions, and give a critical assessment of related upcoming clinical challenges and future perspectives.

Genetics of anxiety disorders

Family studies and twin studies

Anxiety disorders show significant familial aggregation, with a meta-analysis of epidemiological family studies calculating substantial summary odds ratios for SP and SAD (4.1), PD (5.0), and GAD (6.1) in first-degree relatives [1]. Heritability of PD, as determined by a meta-analysis of twin studies, was 0.43 and of GAD 0.32, with mainly non-shared environmental influences contributing to the remaining variance in liability for PD [1]. GAD appeared to display a significant influence of shared environmental influences in females [1] (Table 89.1). Heritability for phobic disorders has been estimated to range between 0.43 and 0.63 [1] (Table 89.1), and factor analysis suggested one common genetic factor underlying SP and one shared factor underlying SAD and AP [2]. However, the influence of genetic factors on anxiety disorders has been suggested to decrease from childhood towards adolescence, while the influence of shared environmental factors has been reported to increase [3]. This could be explained by an increased direct environmental transmission from parents to their adolescent offspring, in line with developmental theories of fear–anxiety learning [4].

Other studies have reached similar heritability estimates, although very rarely have they corrected for the unreliability of a single lifetime assessment that is most commonly used in these investigations.

When accounting for variability in the recall of unreasonable fears and interviewer bias towards which fears constitute phobias, twin resemblance due to genetic factors of phobias was determined to be 0.46–0.59 for SP, 0.51 for SAD, and 0.67 for AP [5]. This hints at a universal underestimation of the true genetic contribution at least in phobic disorders [5]. Unsurprisingly, both family studies and twin studies in the anxiety spectrum have acknowledged that the influence of genes respects neither hierarchic diagnostic disease boundaries nor the threshold between rational and irrational pathological anxiety or fear. Comparing genetic correlations from twin studies among SAD, AG, PD, and GAD, the lowest correlation of pairwise comparisons with 0.65 was found to exist between SAD and AP, while PD and GAD reached an almost perfect correlation coefficient of 0.98 [6]. This position is further supported by the fact that when twin data of SP, SAD, PD, AP, and GAD were combined in one single analysis, the latent liability to all anxiety disorders was more heritable than for any individual disorder [7].

In summary, the classic genetic studies of anxiety disorders suggest the potential for success in identifying the genes involved. The current landscape includes interesting findings from structural and rare variant studies, genome-wide association studies (GWAS), and candidate gene studies.

Structural and rare variant studies

A genome-wide copy number variation (CNV) association study in 535 PD cases and 1520 control subjects yielded Bonferroni-corrected significant common duplications in the pericentromeric region of 16p11.2, including genes like the immunoglobulin heavy locus (*IGH*) and solute carrier family 6 member 8 (*SLC6A8*, creatine transporter 1) [8]. Furthermore, a meta-analysis of PD linkage studies amounting to over 700 analysed subjects reported significant bins on chromosomes 1, 5, 15, 16, and 22 [9].

The follow-up with GWAS or next-generation sequencing studies appears to be a promising avenue for future rare variant research efforts. For example, the transmembrane protein 132D (*TMEM132D*) locus, a gene previously associated with PD and anxiety severity (see GWAS, candidate gene, gene–environment interaction, and ‘therapy genetics’ studies, p. 929), has a 40-kb region spanning all exons now fully sequenced in a cohort of 300 anxiety disorder patients, including 262 PD, compared with 300 healthy controls [10]. A total of 371 variants were identified, most of which (76%) had a minor

Table 89.1 Heritability of anxiety disorders

	a ²	95% CI	c ²	95% CI	e ²	95% CI
SP ^a	0.46–0.59	NA	–	–	0.41–0.53	NA
SAD ^a	0.51	NA	–	–	0.48	NA
AP ^a	0.67	NA	–	–	0.33	NA
PD ^b	0.43	0.32–0.53	–	–	0.57	0.47–0.68
GAD ^b	0.32	0.24–0.39	0.17	0.03–0.29	0.51	0.41–0.64

Heritability estimates not adding up to 1.0 are derived from rounding up/down effects.

SP, specific phobias; SAD, social anxiety disorder; AP, agoraphobia; PD, panic disorder; GAD, generalized anxiety disorder; CI, confidence interval; a², additive genetic factors; c², shared environmental factors; e², unique environmental factors; NA, information not available in the respective study.

a [5].

b [1].

allele frequency of under 5%, with an overrepresentation of functional coding variants in control subjects, suggesting that putatively protective *TMEM132D* variants decreased the risk to be affected by an anxiety disorder [10].

GWAS, candidate gene, gene–environment interaction, and ‘therapy genetics’ studies

Within the anxiety disorder spectrum, PD has received the most attention in GWAS. Initially, two single-nucleotide polymorphisms (SNPs) within *TMEM132D* (rs7309727 T allele, rs11060369 A allele) were discovered as top hits in independent and combined GWAS approaches in three samples of patients with PD or PD and AP diagnoses (totalling 909 cases and 915 controls) [11]. The variants were associated with the severity of anxiety symptoms in patients affected by PD or panic attacks, and post-mortem studies revealed an increased expression of *TMEM132D* mRNA in the frontal cortex [11]. Subsequently, these results were replicated in a meta-analysis combining cases with primary PD (patients without major psychiatric comorbidities, 1039 cases and 2411 controls), which confirmed the rs7309727 T risk allele and a combined T/A rs7309727–rs11060369 risk genotype [12]. An independent meta-analysis further supported the PD ‘risk’ allele status of the rs7309727 T allele (2630 cases, 3294 controls; and 1867 cases, 2527 controls, respectively) and the rs11060369 C allele (2609 cases, 3279 controls; and 1852 cases, 2516 controls, respectively) in samples of primary PD and European PD [13].

Based on the assumption that different diagnostic definitions reflect alternative expressions of a common underlying anxiety diathesis, a recent meta-analysis of GWAS totalling over 18,000 unrelated individuals followed a dual approach by comparing cases (SP, SAD, PD, AP, and GAD, combined into one group of subjects with any anxiety disorder) to controls and employing, as a phenotypic score, an overall latent anxiety disorder factor [14]. The case-control design revealed a so far uncharacterized non-coding RNA (ncRNA) locus on chromosome 3q12.3 (*LOC152225*), with the rs1709393 T allele as a ‘protective’ factor against any anxiety disorder diagnosis, while analysis of the quantitative factor score highlighted a linkage disequilibrium block on chromosome 2p21 spanning three genes coding for the neutral and basic amino acid transport protein rBAT (*SLC3A1*), the prolyl endopeptidase-like protein (*PREPL*), and the calmodulin-lysine *N*-methyltransferase (*CAMKMT*), exceeding genome-wide significance, with the *CAMKMT* rs1067327 minor G allele as the top hit ‘risk’ SNP [14].

Candidate gene association studies of anxiety disorders have been based on the mechanism of action of anxiolytic drugs, preclinical models, or GWAS results for categorical or dimensional anxiety disorder traits. Within anxiety spectrum conditions, studies of common genetic variation have mainly investigated the serotonergic system, including its transporter and receptors, enzymes related to the synthesis or degradation of catecholamines and other neurotransmitters, or components of neuropeptide and hormonal systems.

The implication of the serotonin transporter (*SLC6A4*, chromosome 17q11.2) polymorphic region (5-*HTTLPR*) in animal models of anxiety [15] sparked interest in the evaluation of genes related to serotonergic neurotransmission in the human anxiety spectrum. The more active (higher transcription rate) long allele (l) has been associated with lower anxiety-related personality traits and implicated as a protective factor against the development of a depressive episode due to an individual’s experienced amount of lifetime stress [16]. Conversely the short (s) allele was claimed to be associated with increased anxiety-related traits (neuroticism and harm avoidance) and vulnerability for an affective disorder diagnosis [15, 16]. The less active forms of the 5-*HTTLPR* have been associated with a variety of clinical phenotypes in anxiety disorders, for example increased blushing propensity in SAD patients [17], increased and more persistent activation of the amygdala during an auditory habituation paradigm [18], and increased amygdala activation during exposure to happy faces [19] (for a review of imaging genetic effects on amygdala responsiveness in anxiety disorders, see [20]).

Unfortunately, several studies have not shown a direct association between 5-*HTTLPR* variation and categorical PD (see, for example, [21]), and a meta-analysis of candidate gene studies failed to find supporting evidence for a significant effect [22]. Somewhat similarly, in a therapy-genetic approach, the 5-*HTTLPR* genotype was successfully included, alongside other factors like gender and comorbid mood and externalizing disorders, in a risk index predicting the response of children (384 cases) to cognitive behavioural therapy (CBT) for primary anxiety disorders [23]. However, replication of the association between the short 5-*HTTLPR* variant and increased response to CBT in a cross-cohort meta-analysis (1044 cases) failed for primary anxiety disorders, albeit s/s allele carriers were more likely to be free of any anxiety disorder post-CBT treatment [24]. Positive results have been reported in pharmacogenetic studies focusing on selective serotonin reuptake inhibitors (SSRIs), with the l variant predicting an increased reduction of SAD symptoms [25] and a significant reduction of panic attacks in female PD patients [26].

A recent systematic literature review of neurobiological markers of treatment response in anxiety disorders supported the role of a functional polymorphism within the *l* variant of the polymorphic region (5-*HTTLPR*/rs25531; the minor G allele renders the *l* variant transporter expression levels more closely to the 'risk' *s* variant [27]) in the prediction of therapy outcome [28]. The ultimate status of the 5-*HTTLPR* gene as a successful candidate remains to be definitively established in larger studies or by meta-analysis of smaller studies with sufficiently similar designs.

The G/G genotype of the serotonin receptor 1A gene (*HTR1A*, chromosome 5q12.3) rs6295 polymorphism (also referred to as -1019C/G, due to its position in the transcriptional control region) has been associated with increased escape behaviour during an avoidance task prior to CBT in patients suffering from PD with AP, as well as increased amygdala activity towards threat and safety cues and reduced self-initiated exposure to aversive stimuli following CBT [29]. Correspondingly, the G allele predicted a significant persistence of panic attacks in PD patients treated with SSRIs [30]. Nonetheless, the pharmacogenetic study was relatively underpowered.

Monoamine oxidase A (MAOA) is responsible for the oxidative deamination of serotonin, noradrenaline, dopamine, and xenobiotic amines; its gene on chromosome Xp11.3 has a functional polymorphism in the promoter region. The relevant location of the variation is commonly referred to as the upstream variable number of tandem repeats (uVNTR); it can take several forms generally distinguished in short (low transcriptional activity) or long alleles (high transcriptional activity), the latter of which has already been shown to occur significantly more frequently in female PD patients than in corresponding control samples [31]. Meta-analytical evaluation (1115 cases, 1260 controls) of candidate gene studies exploring the MAOA uVNTR validated a female-specific allelic association between the long, high-expression gene variants and PD [32]. Remarkably, a controlled and randomized multi-centre analysis (283 cases) discovered that the long alleles of the MAOA uVNTR resulted in significantly worse outcome measurements on dimensional scales of anxiety, following CBT, in patients suffering from PD with AP [33]. Inferior therapy outcome among long allele PD carriers, as compared to short allele carriers, was also accompanied by increased heart rate and reported fear during a behavioural avoidance task involving agoraphobic conditions and impaired habituation to the task upon repeated exposure [33]. Also, the T allele of the T941G polymorphism in the MAOA gene sequence has been possibly linked to GAD [34].

The catechol-*O*-methyltransferase (*COMT*, chromosome 22q11.21) is essential for the degradation of catecholamine neurotransmitters via the S-adenosyl methionine-coupled methylation of a hydroxyl group. It displays a SNP at base pair position 472 replacing a G with an A (rs4680, commonly referred to as the val158met polymorphism), causing a 3- to 4-fold lower overall *COMT* activity [35]. Initial association analysis revealed the G allele (that is, the valine/high-activity variant) to be overrepresented in female PD patients [36]. A recent meta-analysis (1130 cases, 1783 controls), including Asian and European-Caucasian samples, confirmed the 'risk' status of the rs4680 *COMT* G allele in European PD samples, regardless of gender [13]. Interestingly, the 158met/met genotype has been suggested to profit less from exposure-based CBT for PD, as compared to carriers of at least one val allele, who reported higher symptom intensity prior to CBT [37]. Additionally, while the *COMT* val variant

has been linked to SP [38], internalizing disorders, including SAD and GAD, have been associated with other genetic variation related to the catecholaminergic system, including the sodium-dependent dopamine transporter (*SLC6A3*) [39].

Given the pivotal role of corticotropin-releasing hormone (CRH) in the hypothalamic–pituitary–adrenal (HPA) axis, and therefore as a regulator of cortisol release in the stress response, the CRH receptors CRHR1 and CRHR2 have been an additional focus in the exploration of anxiety disorder genetics, particularly in PD. A joint cohort approach genotyping nine *CRHR1* (chromosome 17q21.31) SNPs in 531 matched PD case-control pairs delivered evidence of four SNPs (rs7209436, rs12936181, rs17689918, and rs17689966) to be associated with PD in at least one subsample, with the minor A allele of rs17689918 remaining statistically significant in PD females across all cohorts, even following conservative post hoc correction [40]. Multi-level evidence suggests the rs17689918 A allele is associated with decreased *CRHR1* mRNA expression in the frontal cortex and amygdala of post-mortem brains, aberrant differential conditioning in the prefrontal cortex, and impaired safety signal processing in the amygdala in an imaging paradigm [40]. Furthermore, the risk allele caused carriers to show less escape tendencies in a behavioural avoidance task, yet increased levels of nervous apprehension and anxiety sensitivity [40]. This suggests reduced *CRHR1* expression to be linked to an increased susceptibility to anxious sensations accompanied by feelings of sustained fear [40]. Additionally, an investigation of several anxiety disorder candidate gene effects on serotonin–noradrenaline reuptake inhibitor (SNRI) treatment response in GAD supported an association of *CRHR1* SNPs with therapy outcome [41].

Among the neuropeptide class and their respective receptors, genetic variation of neuropeptide S (*NPS*) and the NPS receptor (*NPSR1*, chromosome 7p14.3) correlates psychopathological processes relating to stress, arousal, and fear, and to their mediation in particular, with anxiety-related behaviour and anxiety disorders (Fig. 89.1) [42]. Upon binding of NPS, the G-protein coupled *NPSR1* promotes the mobilization of intracellular calcium stores and thereby affects second messenger signalling [43]. In independent, as well as joint, analyses of case-control cohorts (766 cases and 776 controls), the *NPSR1* rs324981 T allele (replacing an asparagine in amino acid position 107 with an isoleucine [Asn¹⁰⁷Ile], leading to receptor hyper-responsiveness) has been significantly associated with PD with and without AP in females in a categorical analysis approach and, dimensionally, with increased levels of anxiety sensitivity [44]. Evaluations of the *NPSR1* rs324981 T allele in PD females demonstrated increased heart rates and other symptom measures during a behavioural avoidance task and decreased activation of the anterior cingulate cortex top-down control following exposure to emotionally relevant fear stimuli [44]. The status of *NPSR1* as a PD 'risk' gene has been highlighted recently by a replication of the *NPSR1* rs324981 T allele association with PD in samples of European ancestry in a meta-analysis of candidate gene studies (914 cases, 1028 controls) [13]. For a review of the *NPSR1* gene in mechanisms of anxiety, also see [45].

A further valuable candidate gene strategy targets mediating models of anxiety proneness, for example increased sensitivity to carbon dioxide. Hypercapnia reliably elicits a panicogenic effect in PD patients. Following linkage evidence for the chromosomal region 12q13 and PD [46], further studies expanded upon a

Fig. 89.1 Multi-level evidence linking the neuropeptide S receptor 1 gene (*NPSR1*) to anxiety disorders and anxiety-related cross-disorder intermediate phenotypes. The *NPSR1* rs324981 T allele was chosen as seed node. Arrows represent domain interrelations of systems analysis mediating interactions between genetic and environmental factors, potentially leading to observable meta-phenomena crossing classic nosological boundaries and connecting different spectra of psychopathology. Refer to the individual sections in this chapter for detailed supporting literature. ACC, anterior cingulate cortex; AMY, amygdala; CCK-4, cholecystokinin tetrapeptide; CTQ, Childhood Trauma Questionnaire; DLPFC, dorsolateral prefrontal cortex; FPC, frontoparietal cortex; LC, locus coeruleus; LTE, list of threatening experiences/lifetime events; OFC, orbitofrontal cortex; PFC, prefrontal cortex.

potential role of the acid-sensing ion channel 1 (*ACCNI*, chromosome 12q13.12) in mediating the detection of brain acidosis/hypercarbia and acting as a chemosensor triggering fear-related behaviour. *ACCNI* SNPs rs685012 (C allele) and rs10875995 (C allele) have been associated with PD in a case-control analysis, with a particularly strong association in either early-onset PD or PD with primarily respiratory symptoms [47]. There was also an increased amygdala volume and reactivity to emotional stimuli in a cohort of healthy subjects [47]. Interestingly, following the recent interest in carbon dioxide-induced acidosis related to *ACCNI* in patients suffering from PD, an investigation in mice established that exposure to early-life adversity induced separation anxiety-related behaviour and hyperventilation upon carbon dioxide inhalation [48]. This phenotype was further associated with epigenetic histone modifications and a gene expression network in the medulla oblongata, not only confirming increased expression of the murine *ACCNI* orthologue, but also affecting biological processes related to neurodevelopment and emotionality, as well as actual drug targets in the form of the mammalian/mechanistic target of rapamycin (mTOR) signalling pathway [48].

Epigenetic studies

Given the substantial impact of gene–environment interactions in the aetiology, disease course, and treatment of psychiatric disorders [49], the rising field of epigenetics has the potential to expand our

knowledge of systemic biological alterations underlying anxiety-related inter-individual differences. Given the implied intrinsic mechanistic capacity for plasticity, and therefore reversibility, the potential for treatment innovation is particularly exciting.

Assessments of epigenetic DNA methylation patterns spanning the transcription regulatory site and exon 1/intron 1 region of the *MAOA* gene in PD patients and matched controls revealed significantly reduced methylation levels in female PD patients [50]. Notably, across patients and controls, the occurrence of recent negative life events resulted in relatively decreased *MAOA* methylation levels, while positive life events were associated with increased methylation levels [50]. The potential clinical relevance of this dynamic epigenetic state of *MAOA* methylation was supported by the hypomethylation pattern in female PD patients and the correlation of decreased methylation levels with increased panic attack frequency and heightened agoraphobic avoidance in the absence or presence of a trusted person [51]. Exceptionally, following CBT, the average methylation of therapy responders increased to a level indistinguishable from that of healthy controls, while methylation of non-responders remained unchanged or even declined [51]. Further evidence for an epigenetic role in the serotonergic system was provided by a study assessing methylation levels upstream of the *SLC6A4* promoter region in children with a variety of anxiety disorders pre- and post-CBT, with one CpG site differentiating responders with increasing methylation, along

with treatment success, from non-responders with decreasing methylation [52].

Oxytocin has repeatedly been implicated in social functioning and potentially SAD (for a review of oxytocin's role in anxiety disorders, see [53]). Epigenetic screening of a CpG island just downstream of the oxytocin receptor (*OXTR*, chromosome 3p25.3) exon 3 translation start site in a cohort of 110 medication-free SAD patients and 110 gender-matched controls revealed a decreased methylation pattern in SAD patients, with both overall and CpG3 methylation negatively correlating with SAD symptom intensity in patients, as well as dimensional social anxiety in controls [54]. *OXTR* methylation negatively correlated with the cortisol response to the Trier Social Stress Test (TSST) in healthy controls and amygdala activity levels upon exposure to social phobia-related words in SAD patients [54].

Finally, decreased *CRHR1* promoter methylation was associated with PD in a case-control design and with heightened anxiety ratings in an independent sample of healthy volunteers [54]. A functional luciferase assay linked an unmethylated *CRHR1* promoter region to increased gene expression, implicating *CI* hypomethylation and a resulting *CRHR1* overabundance in a dysfunctional stress response as possibly pathogenetically relevant in PD [55].

Genetics of cross-disorder anxiety phenotypes

Family studies and twin studies support the genetic clustering and heritability of SP, SAD, AP, PD, and GAD, along with post-traumatic stress disorder (PTSD) [56–58]. In line with their epidemiological, as well as nosological, overlap and their shared genetic background, anxiety disorders and trauma- and stress-related disorders represent closely interrelated diagnostic constructs. They exist beyond a threshold where subsyndromal anxiety and fear responses grade into degrees of psychopathology. Accordingly, genetic investigations of cross-disorder anxiety and post-traumatic stress phenotypes have explored temperamental traits considered to mediate the susceptibility of children, adolescents, and adults to suffer from the respective disorders; these include neuroticism/negative affectivity, introversion, anxiety sensitivity, behavioural inhibition, insecure attachment styles, and harm avoidance. Further relevant cross-disorder phenotypes are expanded upon in Chapter 80.

Several GWAS have reported on genome-wide significant associations for neuroticism. One approach (106,716 samples) implicated risk genes like the glutamate ionotropic receptor kainate type subunit 3 (*GRIK3*, rs490647) and *CRHR1* (rs111433752), as well as a 4-Mb region on chromosome 8 spanning more than 36 genes [59]. Another genome-wide analysis of 170,911 subjects identified 11 other variants associated with neuroticism; a genetic correlation based on linkage disequilibrium score regression between five different neuropsychiatric phenotypes and neuroticism was highest for anxiety disorders (0.88) [60]. Furthermore, a GWAS twin study in 730 monozygotic and dizygotic twin pairs, exploring the genetic basis of anxiety sensitivity estimated a heritability of 0.44 and identified a top hit within the coding region of the RNA binding protein fox-1 homolog 1 gene (*RFXO1*, rs13334105) [61]. Notably, a genome-wide genetic linkage of neuroticism quantitative trait loci (QTLs) in extremely discordant and concordant sibling pairs established a locus on chromosome 1 spanning the regulator of the G-protein

signalling gene (*RGS2*) [62]. This proved to be syntenic with a QTL modulating anxiety-related behaviour in mice [63], marking a rare occasion of inter-species QTL concordance. Moreover, the *RGS2* rs4606 C allele (hypothesized to lead to increased mRNA stability, and therefore higher expression levels) has been associated with increased incidence rates of PD [64] and GAD [65].

Based on a PD- and AP-related dimensional intermediate phenotype (Agoraphobia Cognition Questionnaire [ACQ]), a GWAS in healthy German probands (1370 samples) found genome-wide associations between increased agoraphobic scores and SNPs in the glycine receptor subunit beta (*GLRB*), one of which (rs7688285) was successfully replicated in an independent dimensional sample and a case/control sample [66]. The minor rs7688285 A allele was subsequently demonstrated to be linked to increased *GLRB* expression in the midbrain of post-mortem tissue, reduced startle habituation and increased startle potentiation and generalization, as well as stronger amygdala and insula activation, during the acquisition phase and thalamus, putamen/pallidum and skin conductance responses, following the acquisition phase in a fear conditioning paradigm [66]. A comparable dimensional GWAS approach in a Hispanic community sample (11,456 samples free of antidepressant or anxiolytic medication) detected a genome-wide significant association between a self-constructed GAD symptom score and the thrombospondin 2 gene (*THBS2*, rs78602344) [67]. Despite these encouraging advances with regard to personality dimensions and psychometric scores, so far, no genome-wide significant associations have been reported for a continuous measure of phobic anxiety [68], anxiety-related behaviour in childhood [69], or harm avoidance [70].

Serotonergic system

Complementary to GWAS, candidate gene, and gene–environment studies outlined previously, the serotonergic system, and therein particularly the 5-HTTLPR, has been a focus of attention in the investigation of cross-disorder and dimensional anxiety-related phenotypes. Anticipation of an unpredictable shock following a long phase of expectation resulted in increased neuronal activation of the amygdala, hippocampus, anterior insula, thalamus, pulvinar nucleus, caudate nucleus, precuneus, anterior cingulate cortex, and medial prefrontal cortex and increased positive coupling between the medial prefrontal cortex and physiological anxiety experience based on insular activity in 5-HTTLPR s/s homozygotes, while in l allele carriers, a negative coupling was observed [71]. Additionally, increased activation of the dorsomedial prefrontal cortex in 5-HTTLPR short allele carriers mediated increased psychophysiological reactions in anticipation of future aversive events, explicitly by increased skin conductance and startle reaction [72]. The low-expression 5-HTTLPR risk alleles have also been implicated in an increased amygdala response to sad emotional faces [73]. Furthermore, healthy controls homozygous for the 5-HTTLPR l allele reacted with increased amygdala and insula activity towards the presentation of fearful faces, if they were treated with citalopram, as compared to placebo treatment, yielding interesting insights into the often reported ‘jitteriness’ phenomenon accompanying SSRI treatment during the titration phase [74].

Moreover, decreased *SLC6A4* promoter methylation levels have been linked to increased cortisol secretion, following the TSST in 5-HTTLPR s allele carriers in a dose-dependent fashion, while no such association was detectable in s allele carriers with high methylation levels [75].

Catecholaminergic system

In healthy female subjects, the *COMT* 158val allele conferred increased amygdala responses to fearful and angry facial stimuli, as well as heightened activation of the ventral visual stream and the lateral prefrontal cortex, pointing to a gender-specific effect of altered catecholaminergic activity on emotional processing [76]. Focusing on cross-generational interaction and neuronal development, it has also been shown that increased antenatal maternal anxiety was significantly positively correlated with ventrolateral prefrontal cortex thickness in neonates when carrying the *COMT* val/val genotype, suggesting a complex genetic interaction between maternal susceptibility to anxiety disorders and *in utero* development of anxiety-relevant cortical areas [77].

Neuropeptide systems

The multi-level disease framework depicted in Fig. 89.1 reflects the converging evidence for a role of the NPS system in categorical anxiety diagnoses and cross-disorder intermediate phenotypes. Additional evidence for a key function of this system in panic-related anxiety emerges from a challenge approach, allowing for studying an unfolding panic attack by injection of the panicogenic pharmacological agent cholecystokinin tetrapeptide (CCK-4) [78]. Following CCK-4 injection, healthy *NPSR1* rs324981 T allele carriers showed lower levels of excitatory neurotransmitter abundance in the anterior cingulate cortex, as measured by magnetic resonance spectroscopy, during the course of a panic attack [79]. This suggests reduced inhibitory top-down control, allowing maladaptive behavioural responses [79]. A further pertinent link between the NPS system and phenotypes with particular relevance to anxiety-related disorders has been established by an imaging genetics approach; the *NPSR1* rs324981 T risk allele has been associated not only with increased amygdala activation in response to fear-relevant stimuli, but also with increased harm avoidance traits, potentially connecting the *NPSR1* risk allele to disorder-specific neuronal processes shaping pathological fear reactions in the limbic system [80]. Furthermore, study of event-related potentials uncovered intensified response inhibition and error monitoring to be associated with the *NPSR1* rs324981 T allele, with the latter also mediating increased levels of anxiety sensitivity [81]. Similarly, higher activation patterns in the prefrontal cortex and the locus coeruleus region during an alerting condition and increased activations in fronto-parietal regions during an executive control condition in T/T genotype carriers correlated with heightened anxiety sensitivity scores [82]. This hints at an influence of the *NPSR1* rs324981 polymorphism on neuronal processes of anxiety-relevant attentional functioning [82]. Remarkably, analysis of fronto-limbic connectivity during brain development revealed a higher connectivity between the middle frontal gyrus and the amygdala in older adolescents carrying the *NPSR1* rs324981 A allele, while T/T homozygosity was linked to a reduced connection between the medial frontal gyrus and both the amygdala and insula [83]. Hence, the *NPSR1* genotype has a potential role in dysfunctional development of cortico-limbic interaction during a crucial time window of anxiety disorder onset [83]. The effect of the *NPSR1* rs324981 genotype on anxiety sensitivity revealed that T/T homozygosity and high levels of childhood trauma resulted in increased levels of anxiety sensitivity, particularly concerns about mental incapacitation and physical sensations, while acute somatic concerns interacted with the *NPSR1* genotype and the amount of

recent life events [84]. Interestingly, from the perspective of innovative future treatment strategies, intranasal NPS administration has been shown to reach the anterior olfactory area, nucleus accumbens, thalamus, hypothalamus, and particularly the hippocampus where it modulates synaptic transmission and plasticity, next to exerting anxiolytic properties in multiple behavioural tests [85].

Moreover, the influence of a less secure attachment style on increased levels of social anxiety may be partially modulated by the *OXTR* rs53576 A/G polymorphism, with the A allele exerting a significantly greater negative influence of insecure attachment on SAD-related dimensional traits, as compared to the G/G genotype [86]. The potential for a paradigm shift from 'risk' genes towards a notion of 'plasticity' genes is exemplified by a neuroimaging study assessing *OXTR* gene-environment interactions for the very same polymorphism previously linked to protective, as well as maladaptive, properties. *OXTR* rs53576 G/G homozygotes exhibited a significant reduction of bilateral ventral striatum grey matter volume interacting with the extent of childhood trauma suffered and increased amygdala reactivity towards emotional facial stimuli [87]. In turn, decreased ventral striatum grey matter volumes were also associated with the prosocial trait of lower reward dependence in G/G homozygotes [87]. Thus, the G allele may not only mediate the vulnerability of limbic structures to adverse childhood events but could also confer resilience in the form of increased limbic responsiveness to emotional interaction [87].

Clinical challenges and future perspectives

The establishment of the genetic variation influencing anxiety disorders is an ongoing process. Recent advances converge on a cross-disorder explanation of psychopathology, pointing towards the need for a revised understanding of mental disease frameworks (Fig. 89.1), which may be translated into novel clinical tools. Specifically, the field of psychiatric genetics/epigenetics holds the promise to catalyse a paradigm shift in drug discovery, treatment response prediction, individual risk evaluation, and nosological conceptualization, by ultimately answering questions regarding the molecular plasticity of anxiety and fear, experience and trauma, and resilience and susceptibility [45].

The inspection of a given gene, or rather a gene set, in relation to biological pathways and processes yields the potential to uncover *innovative molecular treatment targets* and pioneer alternative mechanisms of action. This is why especially the follow-up of unbiased GWAS by candidate gene studies and functional *in silico* enrichment analyses represents a pivotal step in the identification and prioritization of therapeutic objectives. The greatest present challenge is the consistent replication of findings. However, as reviewed in detail previously, several genes (for example, *NPSR1* or *ACCN1*) and systemic processes (for example, glucocorticoid or oxytocinergic signalling) have accumulated considerable evidence for their modulation of disease-relevant traits like fear generalization or perseverative thought patterns.

In addition to the provision of novel therapeutic targets, psychiatric genetics may also contribute to the discovery of clinically valid phenotypes, exploring the molecular characterization of patient subgroups that would allow for an improved pairing of patient and treatment in an *individualized precision medicine approach*. Future steps might comprise the combination of several or even many

SNPs, as well as the inclusion of environmental factors to account for the phenotypic heterogeneity observed in anxiety disorders. A polygenic risk score of environmental sensitivity based on within-pair variability in emotional problems of monozygotic twins has been found to significantly moderate the effect of parenting on emotional problems in an independent group [88]. It also predicted a better response to CBT for childhood anxiety disorders in individual, rather than in group, sessions, suggesting that, in line with the differential susceptibility hypothesis, individuals with greater environmental vulnerability are at an increased likelihood to develop emotional problems in an adverse environment but correspondingly benefit more from an intense form of treatment [88].

Finally, as summarized, a growing body of evidence suggests *dynamic epigenetic changes* in chromatin structure and methylation patterns to underlie anxiety-related phenotypes, their pathophysiological signature, their disease course, and perhaps most strikingly—in a possibly mechanistic way—their clinical response to psychotherapeutic or psychopharmacological interventions. For

example, increased *MAOA* methylation levels following successful CBT might not only constitute a plastic epigenetic marker of therapy response [51] but could also pave the way for personally tailored therapy augmentation. This could be provided in the form of monoamine oxidase inhibitors (MAOIs) as an adjunct to psychotherapy in order to supplement for the degree of *MAOA* hypomethylation in patients suffering from PD. Although the particular attractiveness of epigenetic risk markers lies in their inherent capacity for reversibility, permanent (for example, SNPs), as well as transient (for example, methylation), changes to the DNA strand might not always be reducible to ‘risk’ and ‘resilience’ markers, but rather be viewed in the perspective of *differential susceptibility*. Thus, individuals most vulnerable to environmental adversity due to their genetic loading might simultaneously be most receptive to beneficial experiences, which would consequently result in their nomenclature being re-labelled as ‘*plasticity*’ genes [89]. Following their consistent validation in longitudinal studies of diagnosis and treatment, epigenetic signatures like methylation patterns could eventually meet the

Table 89.2 Overview of genetic variants implicated in anxiety disorders and cross-disorder anxiety phenotypes. The overall degree of confidence was ranked from ‘+’ = ‘low’ to ‘++++’ = ‘high’, based on the reviewed evidence (refer to the individual sections in this chapter for detailed supporting literature)

Gene	Top risk variant	Evidence from structural, rare variant, GWA, candidate gene, gene - environment, and epigenetic studies	Overall degree of confidence
<i>MAOA</i>	Upstream variable number of tandem repeats (uVNTR) Long allele	Candidate gene association with PD in females [31] Meta-analytical candidate gene association with PD in females [32] Association with decreased PD CBT treatment response [33] Reduced methylation in the transcription-regulatory region in female PD patients [50] Negative life events resulted in decreased <i>MAOA</i> methylation levels; positive life events were associated with increased methylation [50] Decreased methylation correlated with increased symptom measures in female PD patients [51] Response to PD CBT was linked to increased methylation [51]	++++
<i>NPSR1</i>	rs324981 T allele	Candidate gene association with PD in females [44] Increased symptom measures during behavioural avoidance and decreased anterior cingulate cortex top-down control towards fear-relevant stimuli [44] Gene-environment interaction with childhood trauma associated with increased anxiety sensitivity [84] Meta-analytical candidate gene association with PD [13] Lower anterior cingulate cortex excitatory neurotransmitter levels during a panic attack [79] Increased amygdala response to fear-relevant stimuli and increased harm avoidance [80] Increased frontal and locus coeruleus activation in the neuronal alerting network [82] Increased fronto-parietal activation in the executive control network correlating with anxiety sensitivity [82] Reduced development of neuronal fronto-limbic connectivity [83]	++++
<i>TMEM132D</i>	rs7309727 T allele	Rare functional coding variants protective of PD [10] Top hit in PD/PD+AP GWAS [11] Confirmed in follow-up candidate gene association [12] Meta-analytical candidate gene association with PD [13]	+++
<i>COMT</i>	rs4680 G allele (val158met, val variant)	Candidate gene association with PD in females [36] Meta-analytical candidate gene association with PD [13] Increased amygdala response to negative emotional stimuli [76]	+++
<i>SLC6A4</i>	Serotonin transporter polymorphic region (5-HTTLPR) short allele	Increased neuroticism and harm avoidance [15] Increased blushing propensity in SAD [17] Increased amygdala activation during auditory habituation [18] Meta-analysis of PD candidate gene studies found no association [22] Contradictory findings of association with anxiety disorder CBT treatment response in children [23, 24] Association with decreased SSRI treatment response [25, 26] Increased coupling of insular activity and physiological anxiety [71] Increased amygdala response to sad faces [73] Decreased methylation levels linked to increased cortisol response to social stress [75]	++
<i>CRHR1</i>	rs17689918 A allele	Cross-cohort candidate gene association with PD in females [40] Increased anxiety sensitivity and impaired safety signal processing in the amygdala [40] Different SNP (rs111433752) implicated in neuroticism GWAS [59] Decreased promoter methylation associated with PD [55]	++

AP, agoraphobia; SAD, social anxiety disorder; PD, panic disorder; CBT, cognitive behavioural therapy; GWAS, genome-wide association study; SNP, single nucleotide polymorphism.

clinical need for an easily accessible peripheral biomarker, allowing the stratification of patients in susceptibility classes. Subsequently, regular quantitative observations could guide the development and provision of targeted, and thus the most effective, preventive, as well as interventional measures. The next generation of psychotherapeutic and psychopharmacological treatments might also be evaluated by the speed, strength, and permanence with which they alter the multilocus impact of environmental stimuli and traumata on the epigenetic architecture of anxiety disorders.

Conclusions

Anxiety disorders display a distinct familial clustering, and heritable factors contribute significantly to their disease burden. Large-scale unbiased GWAS and meta-analyses have begun to reach the necessary sample sizes to uncover meaningful SNP associations and have been complemented and extended by candidate gene and gene–environment studies implicating the serotonergic and catecholaminergic, as well as neuropeptide and hormonal, systems (Table 89.2). The polygenic nature of anxiety disorders suggests that the still incompletely unravelled molecular signature of anxiety might transcend traditional hierarchical diagnostic boundaries. Facing the complexity of potential pleiotropic effects and their interactions with each other, systems–biological methods could facilitate the mapping of candidate genes and functional pathways onto cross-cutting symptom measures and uncover their interface with temperamental, developmental, and environmental variables. One of the emerging key mechanistic processes potentially unifying these components appears to be psychiatric epigenetics. Given the dynamic nature of chromatin structure and methylation patterns related to environmental influences, as well as psychotherapeutic and psychopharmacological interventions, epigenetics may explain part of the missing heritability of anxiety disorders, constitute a mechanistic link between stress and biological vulnerability, and finally—in synopsis with genetic and other risk factors—inform personalized treatment and indicated prevention in anxiety disorders.

Neuroimaging of anxiety disorders

Gregor Leicht and Christoph Mulert

Introduction

The development of neuroimaging techniques, such as functional magnetic resonance imaging (fMRI), has enabled neuroimaging researchers to identify structural and functional patterns in the brain underlying mental disorders. Thus, neuroimaging has helped to shed light on the neurobiological basis of anxiety and the pathophysiological mechanisms in anxiety disorders [1]. A large body of research has been conducted on experimentally induced anxiety in healthy individuals. Fear conditioning and fear generalization paradigms serve as models for the development and maintenance of pathological anxiety and for the maladaptive overgeneralization of fear [2, 3]. Studies investigating pharmacologically induced panic in healthy individuals tried to exemplarily resemble symptoms of patients with panic disorder (PD) [4]. Neuroimaging studies investigating patients with anxiety disorders have attempted to disentangle the neurobiological characteristics specific to each disorder [5]. Furthermore, more and more effort is focused on understanding the neural mechanisms of successful treatment of anxiety disorders [6].

The present review attempts to introduce a comprehensive overview of the current neuroimaging findings from research on anxiety disorders. In the following, we discuss evidence from neuroimaging studies on experimentally induced anxiety in healthy subjects, results of studies investigating neuronal patterns in patients with anxiety disorders, and finally findings from neuroimaging research on treatment effects in anxiety disorders.

Neuroimaging of experimentally induced anxiety in healthy individuals

The functional neuroanatomy of anxiety in healthy humans has been investigated using experimentally induced anxiety. Such studies considerably enhanced the knowledge on pathophysiological aspects of anxiety disorders and offer the possibility to develop new treatment strategies. Mainly two different approaches of anxiety induction in healthy subjects have been applied in the recent past: fear conditioning paradigms and pharmacologically or respiratory-induced panic. In classical fear conditioning studies, a previously neutral stimulus becomes 'conditioned' after repeatedly pairing it with an

aversive stimulus which elicits an autonomic fear response. After several paired presentations, the previously neutral stimulus elicits the autonomic fear response by itself [7]. For instance, this was done by conditioning neutral faces with an unpleasantly loud tone [3]. Thus, conditioned neutral faces elicited brain activity in a 'fear network' comprising the anterior cingulate cortex (ACC), the anterior insula, and the amygdala. Activity within this network evoked by aversive conditioned stimuli has repeatedly been shown in several fear conditioning studies [8, 9]. Moreover, this 'fear network' is also known to be active during symptom provocation in patients with anxiety disorders.

The idea of fear conditioning in healthy subjects has recently been used in neuroimaging studies investigating the neurobiological mechanisms involved in fear generalization. Healthy organisms tend to generalize conditioned fear responses to a certain stimulus and transfer it to perceptually close events in order to adapt behavioural responses to complex real-world situations by means of fear learning [10]. A maladaptive overgeneralization of fear is considered as a core pathophysiological mechanism of anxiety disorders [11, 12]. A first fMRI study investigating neurobehavioural mechanisms of human fear generalization revealed brain activity within regions also involved in the acquisition of conditioned fear in response to stimuli resembling an aversive conditioned stimulus. Activity within this network comprising the insula, caudate, thalamus, and ACC increased with growing similarity of the probe stimulus to the aversive conditioned stimulus, whereas the ventromedial prefrontal cortex (PFC) showed increased activity in response to a stimulus resembling a non-conditioned stimulus [13]. These results were replicated by studies presented in [2] and [14]. Additionally, Lissek *et al.* showed an increase in the involvement of the hippocampus and its connectivity to the ventromedial PFC with increasing similarity of the stimulus to a cue representing safety (in contrast to the danger-conditioned cue). The functional connectivity between the hippocampus and the amygdala, as well as the insula, increased in response to stimuli more and more resembling the danger-conditioned cue [14]. On basis of these findings, a fear generalization model has been proposed, suggesting that sensory information on stimuli resembling danger-conditioned cues is directly forwarded from the thalamus to the amygdala, bypassing the sensory cortex. Thus, conditioned fear is rapidly expressed via connections between the amygdala and, for example, the insula. Furthermore and according

to this model, the hippocampus is suggested to contribute processes of pattern completion in case of presentation of stimuli resembling danger-conditioned cues, which initiates the conditioned fear response. On the other hand, in case of pattern separation processes in the hippocampus due to presentation of a cue not resembling the danger-conditioned cue, the ventromedial PFC is activated and downregulates the amygdala [15]. However, in view of the results of their recently published fMRI study, Onat *et al.* suggest that fear generalization is not only passively dependent from the perceptual similarity of a stimulus to a danger-conditioned cue, but also a mechanism which enables the human brain to actively transfer the threat classification to perceptually similar stimuli, using additional variables besides perceptual similarity [16].

In order to expand the understanding of neurobiological mechanisms of psychotherapeutic interventions in the treatment of anxiety disorders, fear conditioning paradigms also were used to investigate processes of fear extinction in neuroimaging studies [8]. Therefore, fear extinction has experimentally been modelled by repeatedly presenting a previously neutral, but aversive, conditioned stimulus without the aversive stimulus. Thus, the conditioned fear response can gradually be eliminated. There is evidence for activation in the ventromedial PFC and the hippocampus during fear extinction that might reflect a regulating inhibition effect on the amygdalar fear reaction [17]. Fear conditioning is differentiated from extinction learning by an anti-correlated dynamic competition between the large-scale functional networks underlying conditioning (amygdala-thalamo-cortical network) and extinction (hippocampal-prefrontal network) [18]. Moreover, a contribution of the cerebellar vermis to the extinction of conditioned fear has been shown [19]. Eckstein *et al.* recently found that oxytocin facilitates the extinction of conditioned fear by increasing PFC activity and inhibition of amygdalar responses during extinction [20].

An experimental model of the relapse of anxiety symptoms after successful therapeutic intervention in anxiety disorders is provided by a number of studies using return of fear experiments. For this purpose, the aversive event is re-presented after extinction [21]. Return of fear processes critically involve brain structures within the hippocampus and the ventromedial PFC [22]. The return of fear could be prevented experimentally by administration of the dopamine precursor L-3,4-dihydroxyphenylalanine (L-DOPA) [23], intake of the β -blocker propranolol [24], or REM sleep [25], which, in all cases, was accompanied by alterations of activity in return of fear-related brain regions.

The experimental induction of panic attacks with panicogenic substances in healthy subjects is another approach of modelling human anxiety. Different substances have been used to elicit panic symptoms in healthy individuals. For instance, the respiratory induction of panic symptoms has been conducted using lactate or carbon dioxide administration simulating life-threatening hypoxia. Pharmacological approaches involved noradrenergic (for example, yohimbine) and serotonergic (for example, meta-chlorophenylpiperazine) panic induction strategies. However, the most commonly used panicogenic agent is the synthetic neuropeptide cholecystokinin-tetrapeptide (CCK-4), a synthetic analogue of the endogenous neuropeptide cholecystokinin. It is considered as an ideal, safe, and valid experimental model of panic, serving as a useful approach to study the pathophysiology and neurobiology of PD [26]. CCK-4 induces symptoms closely resembling spontaneously

occurring panic attacks in patients with PD [27]. Additionally, antipanic pharmacological treatment like imipramine reduces CCK-4-induced panic symptoms [28]. To this day, several neuroimaging studies have used the CCK-4 panic model in healthy participants in order to characterize brain regions which might be involved in the generation of panic attacks. The first studies investigating the functional neuroanatomy of CCK-4-induced panic in healthy participants using positron emission tomography (PET) showed an increase in cerebral blood flow (CBF) in the ACC, the claustrum-insular-amygdala region, and the cerebellar vermis [29, 30]. These results were confirmed by a first fMRI study contrasting brain activity induced by CCK-4 vs placebo administration [31]. However, the authors did not report amygdala activation elicited by CCK-4. In contrast, Eser *et al.* showed significantly stronger amygdala activation after CCK-4, in comparison to placebo administration, and five out of 11 healthy subjects with high amygdala activity reported more pronounced fear symptoms, in contrast to subjects with low amygdala activity. According to the authors' discussion, these findings indicate that the extent of amygdala activation might modulate the experience of CCK-4-induced fear, emphasizing the role of this structure in fear and anxiety. Moreover, CCK-4, in comparison to placebo, elicited large responses in several other brain regions, for example, the ventral ACC. In contrast, anticipatory anxiety in expectance of CCK-4 administration led to increased activity in the dorsal part of the ACC. Eser *et al.* interpreted this differential activation of the ACC as a correlate of a diverse functional neuroanatomy between cognitive anticipation and real autonomic and affective responses to CCK-4 in healthy subjects [32]. Using a data-driven fMRI analysis approach called tensorial probabilistic independent component analysis, Dieler *et al.* identified strong increases of activity in 12 different brain networks being active only after CCK-4, but not after placebo, administration or showing a significant increase in activity after CCK-4 administration, compared to placebo. The way of analysis in this study additionally allows to explore the time courses of each activated network and could enable future studies to quantify and visualize changes in CCK-4-activated neural networks, for example, elicited by pharmacological treatment of CCK-4 induced panic [33]. The CCK-4 model of PD was used not only to reveal the functional neuroanatomy of panic attacks, but also to investigate putative genomic risk factors for anxiety [34]. For instance, using magnetic resonance spectroscopy, Ruland *et al.* showed that the brain glutamate/glutamine levels in bilateral ACC during an acutely occurring CCK-4-induced panic attack is dependent on the neuropeptide S receptor gene variation [35]. Neuropeptide S is suggested to be involved in the pathogenesis of anxiety and PD. Accordingly, the CCK-4 panic challenge might be able to help to uncover genetic mechanisms influencing anxiety brain networks.

Imaging neural correlates of anxiety disorders

Symptom provocation is the most commonly used procedure for the investigation of anxiety disorders in neuroimaging studies. For this purpose, anxiety-specific brain activity is induced by negative emotional stimuli such as, for example, angry faces [36], trauma-related visual or auditory stimuli [37], or pictures of phobia-related contents [38]. Most of the studies revealed increased activity of the 'fear network' comprising the amygdala, insula, ACC, and medial PFC [7] in

patients with anxiety disorders, compared to healthy control groups, during symptom provocation. The appearance of anxiety symptoms seems to involve a pathologically hyperactivated amygdala under insufficient frontal top-down control [39].

The amygdala is considered to be involved in grading the biological significance of a stimulus [40]. Thus, it plays a crucial role in the processing of emotionally and socially relevant information [41]. The insula is another brain structure which is related to the processing of emotional contents [42] and interoceptive awareness [43]. Mechanisms of fear learning critically involve the medial PFC [44]. Thus, the crucial relevance of these regions for fear and anxiety may arise from its engagement in 'the processing of emotions as they relate to the self' [45].

Patients with generalized anxiety disorder (GAD) show a deficient ability of regulating their emotions. The results of the neuroimaging studies investigating this cognitive dysfunction in GAD patients suggest that the dysregulation of emotions is related to a malfunction of the medial PFC and alterations of its connectivity to the amygdala in terms of an insufficient top-down control [46]. This frontal control may be realized by means of theta oscillations, for example during emotion regulation [47]. Reduced mPFC activity was found in GAD patients during viewing emotional faces [48], suppressing worries [49], and reappraising emotional responses to negative pictures [50]. In a fear generalization experiment, the mPFC was not sufficiently recruited during fear inhibition in GAD patients [51]. Moreover, the connectivity between the mPFC and the amygdala has been shown to be altered in GAD patients [52].

The first functional neuroimaging studies investigating patients with PD have reported alterations of the blood flow in hippocampal brain regions [53, 54]. Results of fMRI studies investigating the processing of emotional stimuli suggest that hyperactivity of several different brain regions, including the amygdala, dorsolateral and medial PFC, ACC, insula, inferior frontal gyrus, orbitofrontal cortex, striatum, and hippocampus, are involved in the pathophysiology of PD [55, 56]. For instance, stronger activations were found in the bilateral ventral striatum and the left insula in PD patients during the anticipation of agoraphobia-specific pictures [57]. Increased anxiety sensitivity, which is known to be an important component of PD, has been linked to activity in regions encompassing the PFC, ACC, and insula during emotional processing [58]. A neural correlate of the altered interoceptive processing in patients with PD

might be represented by an increased functional connectivity between the somatosensory cortex and thalamus in the resting state brain [59]. The hypersensitivity of PD individuals to inhaled carbon dioxide goes along with alterations of the acid-sensing ion channel ASIC1a, and ASIC1a risk allele carriers showed increased amygdala volume, as well as task-evoked amygdala reactivity to fearful and angry faces [60]. Domschke *et al.* showed a reduction of effective connectivity between the middle frontal gyrus and both the amygdala and the insula, reflecting an impaired frontal top-down control of limbic structures in adolescent carriers of a variant in the neuropeptide S receptor gene which has been associated with PD [61]. Another imaging genetics study investigated the influence of the corticotropin-releasing hormone receptor gene *CRHR1* as a risk factor for PD on brain activity during fear conditioning. Risk allele carriers showed aberrant activity predominantly in bilateral prefrontal regions and the amygdala, implicating altered generalization of fear processes [62].

Post-traumatic stress disorder (PTSD) has been associated recurrently with amygdala hyperactivity [63, 64] and hypoactivity in the medial PFC [65] in functional neuroimaging studies. Moreover, a lack of negative connectivity between the amygdala and the subgenual ACC has been observed (Fig. 90.1) [66]. Among others, one established model of PTSD assumes that amygdala hyperactivity reflects permanently increased fear responses, whereas the observed hypoactivity in frontal regions might be a correlate of an aberrant ability of top-down regulation and fear extinction [67]. Moreover, a reduction of hippocampal activity has been observed in PTSD patients [68], which has been interpreted as a disturbed ability of the hippocampus to provide context information, especially with respect to the identification of safe contexts [69]. This exemplary conception is further strengthened by structural changes in several brain regions, including the hippocampus, amygdala, and medial PFC observed in PTSD patients [65, 70, 71]. Interestingly, some studies report increased activity in the dorsal part of the ACC and dorsolateral PFC which might be the correlate of an increased recruitment of top-down attentional control [72]. Disturbances of fear generalization processes in military veterans with PTSD have been linked to an increase of amygdala connectivity with sensory brain regions and the thalamus and a decrease of connectivity between the amygdala and the ventromedial PFC [73]. Spielberg *et al.* reported an association between PTSD re-experiencing symptoms

Fig. 90.1 (see Colour Plate section) Absent negative connectivity between the centromedial (CM) amygdala and the subgenual anterior cingulate cortex (sgACC) in trauma-exposed youth. (a) Anatomically defined seed region of interest for the connectivity analysis within bilateral CM amygdala. (b) Tukey's boxplots depicting connectivity values by group centred on the sgACC peak. The middle line indicates the median, the vertical line the range, and the limits of the box represent the upper and lower quartiles.

Reproduced from *Soc Cogn Affect Neurosci.*, 10(11), Thomason ME, Marusak HA, Tocco MA, *et al.*, Altered amygdala connectivity in urban youth exposed to trauma, pp. 1460–8, Copyright (2015), with permission from Oxford University Press.

and a weakened connectivity in a hippocampus–PFC network involved in providing contextual information [74]. The fact that exposure to a traumatic event does not necessarily lead to the development of PTSD raises the question of whether the structural and functional abnormalities predispose to or follow the development of PTSD [75]. For instance, a smaller hippocampal volume has been shown to predict pathological vulnerability to psychological trauma [76]. On the other hand, hippocampal grey matter loss is predicted by the duration of PTSD [77].

Neuroimaging studies investigating the neural alterations underlying specific phobia mainly focused on the animal subtype, particularly spider phobia subjects. These studies consistently reported hyperactivation in fear-relevant structures such as the amygdala, dorsal ACC, PFC, thalamus, and insula [5]. For instance, spider-phobic subjects showed stronger responses of both amygdalae during exposure to pictures of spiders. The magnitude of amygdala responses was positively correlated with the intensity of disorder-related vigilance for threat [78]. At the same time, there are reports on reduced activity in both the dorsolateral PFC and the lateral orbitofrontal cortex during conscious perception of phobia-related pictures. Taken together, these results have been suggested to reflect an increased activation of the fear circuit, accompanied by an insufficient top-down control in response to phobia-related stimuli [79]. The exaggeration of the expectancy to be faced with the phobic threat was shown to be related to decreased activity in the lateral PFC, precuneus, and visual cortex, reflecting irrationality in encounter expectancies and deficiencies in cognitive control and contextual integration [80]. The overestimation of the relationship between fear-relevant stimuli and aversive consequences, the so-called covariation bias, was found to be predicted by connectivity between the paracentral lobule (PCL) and sensory cortices, whereas reduced covariation bias was predicted by connectivity between the PCL and the PFC [81]. In contrast to the phasic fear responses to threatening stimuli associated with increased amygdala activity, sustained anxiety in phobic patients has been related to increased activity in the bed nucleus of the stria terminalis (BNST) and the ACC, as well as to enhanced connectivity between the BNST and the amygdala [82]. Increased activity of the ACC has also been linked to anticipatory anxiety in phobia patients [83]. Moreover, structural brain abnormalities of fear-related brain regions in patients with specific phobia have also been reported [84].

Neuroimaging of treatment effects in anxiety disorders

Neuroimaging techniques offer the opportunity to monitor structural and functional neuronal changes as a result of psychotherapy in anxiety disorders or to predict the efficacy of psychotherapeutic interventions. For example, behavioural changes in patients with social anxiety disorder after mindfulness-based stress reduction (MBSR) therapy seem to be reflected by distinct patterns of neural activity [85]. Hölzel *et al.* demonstrated that GAD patients with higher amygdala activity in response to neutral faces than healthy participants showed a decrease in amygdala reactivity following 8 weeks of MBSR. Moreover, the activity in the ventrolateral PFC and the functional connectivity between the amygdala and PFC regions

increased after MBSR, in comparison to a stress management education active control group (Fig. 90.2) [86].

Cognitive behavioural therapy (CBT) is known to be an effective first-line intervention in the treatment of patients with PD. Neuroimaging studies have shown that neural activation patterns predict and moderate the therapeutic success of CBT in PD [87]. For instance, CBT in patients with PD led to a significant greater reduction in bilateral amygdala activation during the processing of agoraphobia-related pictures than treatment with selective serotonin reuptake inhibitors (SSRIs) [88]. Another sample of PD patients revealed normalization of PFC hypoactivation and hyperactivation of the amygdala and hippocampus after CBT, when panic-related symptoms had improved [89]. In a fear conditioning study, patients with PD showed a CBT-induced reduction of activity in the left inferior frontal gyrus (IFG) during the conditioned response and an increase of connectivity between the IFG and regions of the ‘fear network’ such as the amygdalae, insulae, and ACC after CBT. The change of neuronal patterns was correlated with a reduction in agoraphobic symptoms [90]. An increase of activation of the hippocampus and a decrease of its connectivity with the IFG have also been reported as an effect of successful CBT in PD [91]. Moreover, neuroimaging data were able to predict the treatment response to CBT in PD with high accuracy on single-patient level [92]. For instance, improved response to brief CBT was predicted by increased pretreatment activation in bilateral insulae and the left dorsolateral PFC during threat processing [93]. Lueken *et al.* showed an association between treatment response to CBT and increased right hippocampal activation, as well as inhibitory functional coupling between the ACC and the amygdala [94].

Studies investigating the functional neuroimaging correlates of PTSD treatment have shown a correlation between improvement of PTSD symptoms after trauma therapy and alterations of activity in different brain regions such as the amygdala, insula, hippocampus, ACC, and dorsolateral PFC [95–98]. Treatment with eye movement desensitization and reprocessing (EMDR) in PTSD patient has been shown to modulate activity in limbic and prefrontal regions [99, 100] and to increase the amygdala volume [101], along with significant improvements in PTSD symptoms. The functional connectivity within the fear extinction network seems to be modified by PTSD treatment with repeated exposure to the traumatic memory, which emphasizes the relationship between human fear extinction and trauma memories [102]. Studies applying neuroimaging measures in order to predict trauma therapy responses in PTSD patients have revealed relationships between the degree of symptom reduction and the pretreatment activity of bilateral amygdalae [103], the cortical thickness in the subgenual ACC [104], or the hippocampal volume [105].

There is strong evidence for high efficacy of exposure therapy during CBT in the treatment of specific phobia patients [106]. The neural mechanisms underlying the reduction of anxiety symptoms after CBT have been extensively investigated in recent neuroimaging studies showing that processes of fear extinction and the corresponding mechanisms in the brain might play a crucial role. Different studies demonstrated a decrease in amygdala activity and normalization of insular and ACC activity after successful exposure therapy in specific phobia patients [107]. Reductions in amygdala responsiveness have been associated with self-reported symptom improvement [108]. An improvement in the effectiveness

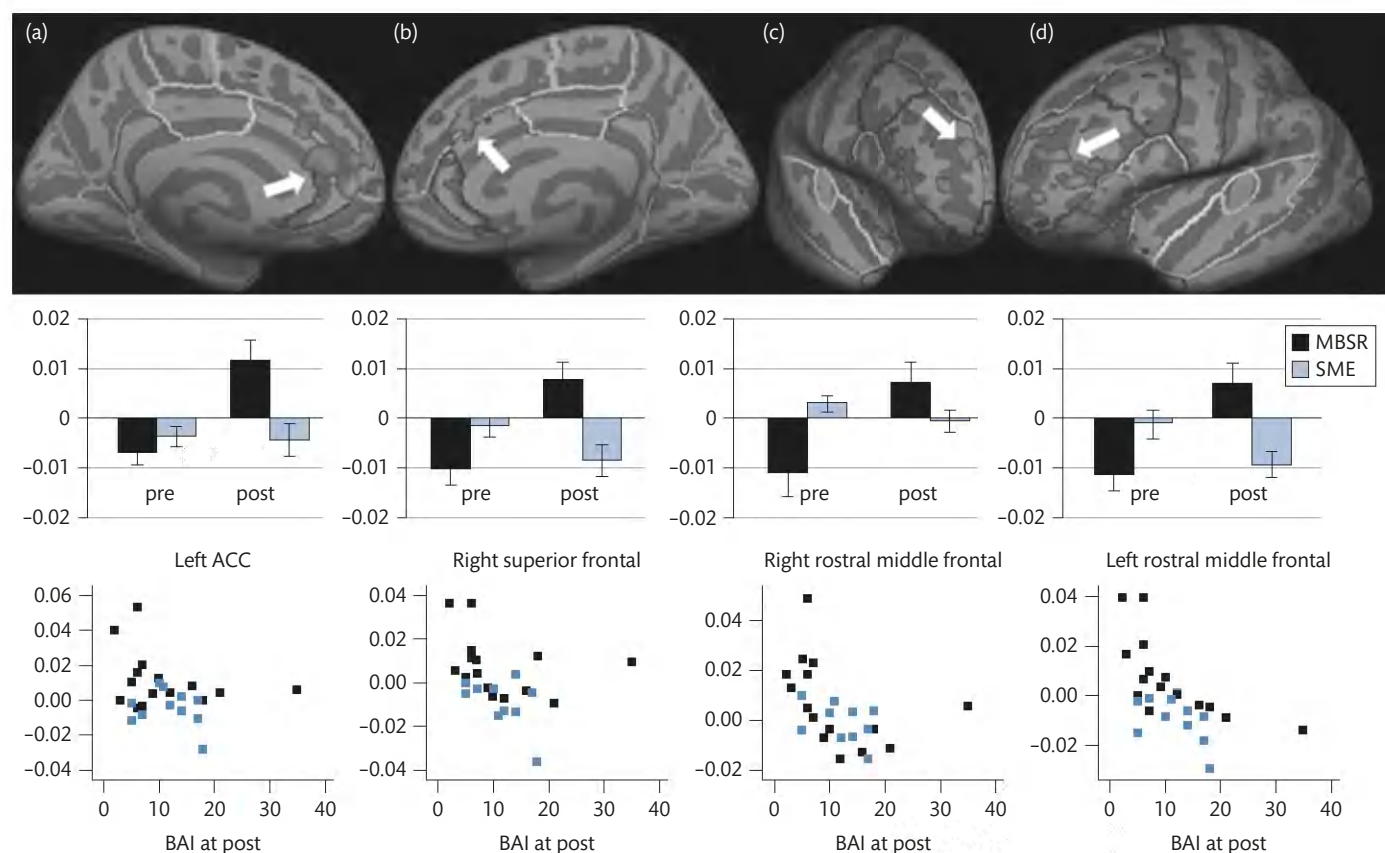

Fig. 90.2 (see Colour Plate section) Functional connectivity between the seed region in the right amygdala and several regions in the frontal cortex increased from pre- to post-intervention with mindfulness-based stress reduction (MBSR) therapy in patients with generalized anxiety disorder, but not in control subjects who underwent a stress management education (SME) class. Top row: anatomical location displayed on an inflated surface. Middle row: regression coefficients extracted from the clusters from MBSR (black) and SME (blue) participants at pre- and post-interventions. Bottom row: scatter plots for correlations between pre- to post-increase in connectivity (y-axis) in the frontal cortex region and Beck Anxiety Inventory (BAI; x-axis) for MBSR and SME participants at post-intervention. ACC, anterior cingulate cortex.

of exposure therapy via faster fear extinction processes has been reported for the application of D-cycloserine, a partial *N*-methyl-*D*-aspartate (NMDA) receptor agonist, in combination with exposure-based therapy [109]. This might be due to enhancement of activation in regions involved in cognitive control and interoceptive integration, such as the PFC, ACC, and insula, during symptom provocation [110]. A novel psychotherapeutic approach is provided by applying neurofeedback techniques during training of anxiety regulation by cognitive reappraisal. fMRI neurofeedback has recently been shown to enable spider-phobic patients to downregulate insula activation levels by cognitive reappraisal strategies, accompanied by lower anxiety levels. Feedback had been provided, based on activation in the left dorsolateral PFC and the right insula. The achieved changes in insula activation levels seemed to be based on a learning mechanism and predicted long-term anxiety reduction [111].

Psychopharmacological treatments of anxiety disorders have also been shown to alter abnormal neural processes that were found to be key characteristics of fear and anxiety in neuroimaging studies. For instance, SSRI treatment attenuated activity in prefrontal regions, the striatum, the insula, and paralimbic regions during listening to worry sentences in GAD [112], reduced amygdala and enhanced

ventral medial PFC reactivity to emotional faces in social phobia patients (113), and increased activation in the dorsolateral PFC during emotion regulation (114), as well as increased mean hippocampal volume in PTSD patients (115). The anxiolytic effect of benzodiazepines, such as alprazolam, seems to involve a reduction of rostral ACC activity and changes of its connectivity with the dorsolateral PFC and the amygdala, as revealed by means of CCK-4 panic challenge in healthy subjects (Fig. 90.3) [4].

The use of the neuropeptide oxytocin has been suggested as a promising approach for the facilitation of psychotherapy effects in anxiety disorders. Recent neuroimaging studies have extensively illustrated its stress-reducing, anxiolytic, and prosocial properties [116]. For instance, oxytocin attenuated the exaggerated amygdala activity [117] and enhanced the functional connectivity of the amygdala with the insula, medial PFC, and ACC [118, 119] in pathological social anxiety. Furthermore, intranasal application of oxytocin normalized the amygdala functional connectivity to the dorsal ACC and the ventromedial PFC in PTSD patients, indicating suppression of the anxiety and fear expression of the amygdala via increased top-down control of the ventromedial PFC or decreased salience processing of the dorsal ACC [120]. In summary, recent evidence from neuroimaging findings suggests that oxytocin could

Fig. 90.3 (see Colour Plate section) Contrasts of functional magnetic resonance imaging responses compared between different treatment conditions. Group analysis ($n = 16$) of the blood oxygen level-dependent response (functional magnetic resonance imaging) to challenge with cholecystokinin-tetrapeptide after alprazolam vs placebo pretreatment (Talairach co-ordinates: $x = -1$, $y = 30$). Activation of the rostral anterior cingulate cortex was reduced after pretreatment with alprazolam, but not after pretreatment with placebo. potentially enhance treatment response in PTSD by modulating the fear network.

These lines of research suggest that neuroimaging techniques could potentially identify the mode of action of anxiety treatment drugs and therefore facilitate the development of new pharmacological treatment options for anxiety disorders. Furthermore, there is evidence that pretreatment patterns of functional neuronal activity might predict the treatment response to pharmacological interventions. For instance, the treatment response to venlafaxine was predicted by greater pretreatment ACC activity and lesser reactivity in the amygdala in GAD patients [121, 122].

Conclusions

In the present article, we have provided an overview of the results of current neuroimaging studies in fear and anxiety. Human models of anxiety in healthy individuals serve as an experimental tool for the investigation of neural processes underlying the pathophysiology of clinically relevant anxiety disorders, for example, with respect to the expression of fear during symptom provocation or fear generalization. Moreover, neurobiological aspects of therapeutic interventions have been uncovered in fear extinction studies. Studies in human models of anxiety, as well as investigations in anxiety disorder patients, consistently demonstrated the pathophysiological role of a 'fear network' comprising the amygdala, insula, medial PFC, and ACC. Symptoms of anxiety are considered to be due to a pathologically hyperactivated amygdala and insufficient top-down regulation by frontal brain regions. Moreover, a disturbed function of the hippocampus with respect to processes of pattern completion, pattern separation, and integration of contextual information seems to crucially contribute to the development and maintenance of anxiety disorders.

Effective psychotherapeutic and pharmacological treatments of anxiety occurring along with normalization in patients' perception and behaviour seem to specifically alter patterns of brain activation in these structures. Neuroimaging techniques might enable therapists and researchers to continuously monitor treatment success and thus may contribute to the refinement of existing approaches and the development of more effective therapeutic options. Furthermore, neuroimaging parameters can help to predict the success of certain treatment strategies. Thus, clinicians might prospectively be able to assign the most promising treatment option to individual patients.

The primary prevention of anxiety disorders

Aliza Werner-Seidler, Jennifer L. Hudson, and Helen Christensen

Introduction

Anxiety disorders comprise the most prevalent class of psychological disorders across the lifespan. Onset frequently occurs early in life, with a median age of onset at 11 years [1]. The 12-month prevalence estimates exceed 10% [2] and affect approximately 8% of youth in a 12-month period [3]. Anxiety disorders are also highly comorbid with other mental disorders such as behavioural disorders, substance use disorder, and eating disorders [4], and frequently co-occur with depression, even in youth [5]. There has been some suggestion that anxiety in childhood acts as a precursor and risk factor for the subsequent development of depression [6, 7]. A more detailed description of the epidemiology is given in Chapter 88.

The adverse consequences of anxiety disorders are well documented and cause impairment across social, emotional, and academic domains [8, 9]. For example, young people with anxiety disorders have lower self-esteem, are more likely to be socially isolated, and perform worse academically than their non-disordered counterparts [10]. The economic impact of anxiety disorders is substantial, with current estimates of £9.8 billion per year in the United Kingdom in terms of lost productivity and direct costs to the health system [11]. This picture is mirrored in the United States, with costs reaching \$42.3 billion per year during the 1990s [12]. The financial and societal burden posed by anxiety disorders has been recognized by world health authorities who have identified it as a public health priority [13].

One way to address this burden is via prevention. While effective treatments for anxiety disorders exist, the shift towards prevention has been driven by increased recognition of the shortcomings of treatment. It has become clear that the demand for mental health services far exceeds the availability of such services and that these services are costly and often inaccessible to many [8]. Additionally, more than half of individuals with mental health disorders do not receive clinical treatment [14], and of those who do, many fail to respond or they terminate treatment prematurely [8, 15]. Young people have particularly low levels of help-seeking, for reasons that include stigma, confidentiality concerns, and beliefs about the value of treatment [16]. Accordingly, there is a legitimate case for developing preventive interventions for anxiety disorders, which may avert some of the aforementioned limitations associated with treatment.

Conceptual issues and definitions

Three levels of prevention were first described by public health researchers in the 1940s: primary, secondary, and tertiary. Primary prevention refers to a reduction in the incidence of a disorder by intervening in advance of disorder onset. Secondary prevention seeks to reduce the prevalence of psychopathology once symptoms have been identified but are not yet severe or do not meet the threshold level for the disorder, while tertiary prevention involves the treatment of disorders and relapse prevention [17, 18]. Although this classification system is pervasive in public health domains, the conceptual overlap between prevention and treatment has led to inconsistencies in how prevention is discussed and examined in the literature. As a result, the Institute of Medicine (IOM) [19] developed a definitional system specific to mental health research, which suggested that prevention should comprise programmes designed at reducing incidence rates, that is, delivered in advance of disorder onset. Three types were described: universal, selective, and indicated prevention. Universal prevention is delivered to all individuals within an identified population, regardless of risk. For example, universal prevention programmes for youth anxiety are typically delivered on a large scale in the school environment to every child in the grade [20]. Selective prevention refers to delivering interventions to individuals who have an increased risk profile for a specific disorder. Risk factors can be conceptualized as a characteristic, an experience, or an event that increases the likelihood of an adverse outcome, relative to the general population [21]. A sound knowledge of risk factors is therefore necessary to inform selective prevention efforts. Several comprehensive reviews document the risk and protective factors of anxiety disorders [8, 22], which include genetic (for example, family history), individual (for example, temperament, anxiety sensitivity), and environmental factors (for example, parental divorce, exposure to violence and crime). Finally, indicated prevention refers to approaches that are delivered to individuals who have subclinical symptoms but do not yet have a clinical disorder.

The present chapter aims to provide a systematic review of the psychological interventions that aim to prevent anxiety. This review is broader than previous reviews that either have focused individually on specific prevention settings, such as school environments [20], community settings [23], workplaces [24], or primary care settings

[25], or have examined specific age groups [26]. Although broad, with respect to setting, we restrict our focus on studies which specifically measure anxiety outcomes, rather than include studies measuring a less specific range of psychopathology, health, or well-being.

Chapter outline

Firstly, we will review the existing research studies examining primary prevention. We believe it is important in a textbook such as this one to establish firmly the effectiveness of prevention for anxiety disorders, to consider the size of the effect, and to indicate for which population groups prevention may be of most use. Healthy scepticism about anxiety prevention is useful, but if these interventions result in a reduction of anxiety in a percentage of the population, there is an imperative to begin to systematically apply them. Secondly, we then consider the key elements common to effective prevention programmes, before thirdly considering barriers to the implementation of prevention programmes. Fourthly, we conclude with a summary of the current challenges facing the field and suggestions for future research.

Systematic review of effectiveness

Adopting Mrazek and Haggerty's IOM conceptualization, primary prevention is defined here as interventions delivered in advance of the onset of anxiety symptoms or disorder and thus include universal and selective prevention approaches. It excludes indicated approaches targeting specific individuals with symptoms, which could be considered early intervention. By including universal approaches that target the whole population, it is assumed that approximately 8% of those included will already be experiencing an anxiety disorder [3]. Although a reduction in incidence is the gold standard for prevention studies, we have opted to include studies which focus on the total population group, including those universal studies that do not explicitly exclude individuals who may already have a diagnosis of anxiety. In large universal studies, screening for anxiety diagnosis or elevated symptoms prior to study entry is often impractical and expensive, and prevention interventions delivered in real-world situations are likely to include the full population cohort. For these practical reasons, studies that relied on continuous symptom measures, rather than diagnostic assessment tools, were included, although it is acknowledged in the case of some participants already experiencing the disorder that this could be considered early intervention.

A systematic review of prevention of anxiety studies

Methods

Search and screening procedures

PsycINFO, PubMed, and the Cochrane Library databases were electronically searched for articles with the key search terms 'prevent*' AND 'anxiety' OR 'anxious' OR 'internalising' OR 'internalizing' AND 'control*' OR 'random*' OR 'trial'. Reference lists from relevant reviews were hand-searched for additional articles.

The criteria for study inclusion were the following: (1) the clearly stated goal of the study was to prevent the incidence of anxiety or reduce symptoms; (2) the presence of anxiety disorder or symptoms was the primary outcome (or one of two or three outcomes in the absence of identified primary outcomes); (3) a universal or selective approach was employed; (4) the study was a randomized controlled trial (RCT); and (5) the study was published in a peer-reviewed English language journal. Studies were excluded if: (1) the focus was on medical or dental anxiety or trauma, post-traumatic stress disorder, or acute stress disorder; (2) the study targeted general mental health or well-being, operationalized by the inclusion of anxiety as one of more than three outcomes when no primary outcome was identified; (3) the study focused on transitory changes in state anxiety; and (4) the study conducted a diagnostic assessment or screening measure at baseline and allowed those with current or past disorder or those with high symptom levels to remain in the study (for example, indicated prevention/early intervention). Selective prevention studies that did not involve a screening procedure were permitted. There were no restrictions in terms of the setting, target group, intervention type, or control condition type. Studies were examined according to inclusion criteria using a checklist and were coded by the first author. Decisions about borderline trials ($N = 4$) were made by the first author and were then discussed with the final author. All decisions made by the first author were endorsed, and complete agreement reached.

Effect size calculations

Standardized effect size estimates for continuous outcomes were calculated using Cohen's d [27] whereby d is calculated by subtracting the mean score of the intervention group from the mean score of the control group at post-test or follow-up, and dividing by the pooled standard deviation. Effect size estimates are reported for between group differences at post-test and follow-up intervals. According to Cohen, effect sizes of 0.20, 0.50, and 0.80 are considered small, medium, and large, respectively. Standardized effect size estimates for dichotomous outcomes were first transformed into \ln (the natural logarithm of the odds ratio) and then converted into a standardized effect size equivalent to Cohen's d , using the method described by Chinn [28]. Where diagnostic and continuous outcomes were both included in a study, both effect size estimates are reported. In studies where follow-up occurred at very short intervals (for example, every month), data were extracted for key follow-up periods (for example, 6, 12, and 18 months).

Results

Study selection

The search returned a total of 5276 articles after duplicates were removed ($n = 367$). The titles and abstracts of the 5276 articles were screened for relevance. Completely irrelevant articles that were unrelated to the topic were excluded at this stage, while relevant articles were retained and full texts were examined ($n = 128$). Of these, 42 articles describing 38 trials met inclusion criteria. The remaining 86 articles were excluded due to: not universal or selective prevention ($n = 36$), not anxiety-focused ($n = 21$), not prevention ($n = 16$), not an RCT ($n = 12$), and no full text available ($n = 1$). See [Tables 91.1 and 91.2](#) for details of included universal and selective prevention studies, respectively.

Note:

Risk profile: COPD, chronic obstructive pulmonary disease.

Programs: FRIENDS, Friends Program; AOP-PTS, Aussie Optimism Program-Positive Thinking Skills Program; PIAS, psychosocial intervention targeting anxiety sensitivity and smoking.

Content: CBT, cognitive behavioural therapy; MBCT, mindfulness-based cognitive therapy; MBSR, mindfulness-based stress reduction; FS, family support; PST, Problem Solving Therapy.

Control group: WL, wait-list control; NI, no intervention control or usual care; AC, active control.

Outcome measures: SCAS, Spence Children's Anxiety Scale; MASCS, Multidimensional Anxiety Scale for Children; DASS, Depression Anxiety Stress Scale; STAI, State-Trait Anxiety Inventory; STAI(T), State-Trait Anxiety Inventory Trait Subscale; SCID-GAD, Structured Clinical Interview for DSM Disorders; Generalised Anxiety Disorder Module; HARS, Hamilton Anxiety Rating Scale; MINI, Mini International Neuropsychiatric Interview; HADS-A, Hamilton Anxiety and Depression Rating Scale; ADIS, Anxiety Disorder Interview Schedule; PA, panic attacks; PD, panic disorder.

Effect size key:

* Between-group difference.

^a Between-group differences at post-test or follow-up not reported in manuscript.

^b Insufficient data reported for effect size calculation.

M, months.

Study characteristics

There were 38 unique studies identified in the current review, which included a total of 23,772 participants. Sample size of the included studies varied considerably from between 40 participants [29] to 7741 participants [30], with a median of 188 participants. Included studies were published between 1997 and 2016, with 50% between 2010 and 2016 (and only two studies prior to the year 2000). A majority of studies were delivered either in Australia (11; 29%) or in America (9; 24%), with a further seven across mainland Europe (18.5%), four in Canada (10.5%), four in the United Kingdom (10.5%), two in Asia (Taiwan and Korea; 5%), and one in Iran (2.5%).

Prevention type

Twenty-two of the studies were universal prevention trials (58%), and 16 were selective (42%). Of the 16 trials delivered to selective groups, risk was defined as: anxiety sensitivity ($n = 2$), having a negative attributional style ($n = 1$), attending a low socio-economic school ($n = 1$), having a parent with a past or current anxiety disorder ($n = 2$), being an undergraduate student for a high-risk profession (teacher, $n = 1$; nurse, $n = 2$), having a high-stress job ($n = 1$), having a physical chronic illness such as stroke, cancer, or hypertension ($n = 5$), or being the primary carer of someone with dementia ($n = 1$).

Population and setting

Recipients of more than half ($n = 20$) of the programmes were children or adolescents (53%); two programmes were delivered to families (5%); eight were delivered to university students (21%); one was delivered to carers (3%); five were delivered to patients with a physical illness (13%), and two were delivered to the general adult population (5%). Of programmes delivered to children and adolescents, effect sizes could be calculated for 18 studies, and of these, eight (45%) reported significant reductions in symptoms of anxiety ($ES = 0.15-0.66$), while ten found no difference relative to the control condition. Of the trials delivered to university and college students, four of the five studies for which effect sizes could be calculated (90%) reported positive effects on anxiety prevention ($ES = 0.51-1.51$). The two studies delivered to families prevented the onset of an anxiety disorder over the 12-month follow-up period ($ES = 1.22-1.42$). The intervention delivered to carers was not effective in preventing anxiety, and of the five programmes delivered to individuals with a physical illness (including stroke, hypertension, chronic obstructive pulmonary disease, and cancer), effect sizes could be calculated for four. Of these, three (75%) were effective in preventing depression ($ES = 0.58-1.79$). Of the two programmes delivered to the general adult population, one study reported positive effects ($ES = 0.66$), while the other did not. The most common setting in which prevention was delivered was the school environment ($n = 20$; 53%), of which 90% were delivered universally. Eight trials targeted university and college students and were delivered in the university setting (22%). A single study was conducted in the workplace (3%), and three studies were conducted in general community-based settings (8%). Six trials were conducted in hospital or clinic settings (16%), and these were predominantly delivered to patients with a chronic illness.

Content

A majority of trials ($n = 26$) delivered a prevention intervention based on cognitive behavioural therapy (CBT; 68.4%) or incorporated at least some element of CBT, blending it with problem-solving

therapy ($n = 2$; 5.3%). Of the programmes based on CBT, effect sizes could be calculated for 24, and 15 of these (62.5%) were effective in preventing anxiety or reducing symptoms ($ES = 0.20-1.79$). The median effect size for all programmes evaluating CBT (regardless of outcome) was 0.25. The programme receiving the most attention was the FRIENDS programme (evaluated in ten studies), which is a manualized face-to-face programme for children and adolescents that can be delivered by teachers or mental health professionals. Four of these studies found FRIENDS to be an effective intervention at post-test ($ES = 0.20-0.66$), while six did not ($ES = -0.18$ to 0.20). Two studies evaluated the Aussie Optimism Programme, which is another standardized CBT school-based programme designed to teach young people about the connection between how they think, feel, and behave. Neither of these studies found significant effects ($ES = -0.19$ to 0.17). Other CBT prevention interventions included MoodGYM, eCouch, Dominique's Handy Tricks, Learn Young Play Young, Cool Kids, Taming Worry Dragons, and ThisWayUp Schools. Ten studies investigated approaches that were not CBT-based. Two of these tested a mindfulness intervention, one derived from mindfulness-based cognitive therapy and the other from mindfulness-based stress reduction (5.3%). Two studies ($n = 2$; 5.3%) involved relationship-focused therapy, delivering the Prevention and Relationship Enhancement Programme (ePREP). The remaining therapeutic approaches included a meditation programme, a tai chi programme, a relaxation programme, support and counselling, problem-solving therapy and escitalopram (an antidepressant medication), and a standardized anti-bullying programme known as KiVa based on education and skill development (each making up 2.6%). Of the ten trials that delivered therapeutic techniques that were not CBT-based, eight reported enough data for effect size calculation at post-test, of which six studies (75%) [30-35] were effective ($ES = 0.41-1.10$) in preventing anxiety.

Programme format, length, and mode of delivery

More than half ($n = 23$, 60.5%) of the included programmes were delivered in a small group format (typically of groups comprising 6-10 individuals), and three programmes (7.9%) involved a group component, combined with individual sessions ($n = 2$) or combined with a self-directed computer-delivered programme ($n = 1$). Six programmes (15.8%) were delivered entirely individually face-to-face, and six programmes were delivered by computer (15.8%). Programme length ranged considerably from a single intervention session to 22 sessions, with most programmes (90%) being delivered in between 6 and 12 sessions (median = 8 sessions), usually on a weekly or a fortnightly basis. There was substantial variability in the duration over which these programmes were delivered, ranging from between a single session to 52 weeks (median = 8 weeks), although it needs to be noted that three studies delivered a single session, followed by 7 weeks of reminder emails encouraging participants to implement the skills they acquired during the session [35-37]. Sessions ranged in duration from 35 to 120 minutes, with the exception of one study where day-long workshops were delivered [38] and one study that did not report on session length [34].

In terms of personnel delivering the programme, ten studies were delivered exclusively by psychologists or mental health professionals (26%); five studies were delivered by researchers or graduate students (13%), and three programmes were delivered by either psychologists or graduate students (7.9%). One study

was delivered by a t'ai chi instructor (3%), and one by a specialist physician (3%). Of these 20 studies delivered by professionals, effect sizes could be calculated for 18, and of these, 13 studies (72%) reported a significant preventive effect on anxiety ($ES = 0.20-1.79$). Nine of the included studies were delivered exclusively by teachers or school staff within the school environment (23.5%), of which two (22%) were effective ($ES = 0.13-0.66$). Two school-based studies involved both school and external staff, comparing a school-led version of the programme to a health professional-delivered version [39, 40]. In the Barrett and Turner study [39], the personnel delivering the intervention did not impact effect size, with both health- and school-led delivery producing significant reductions in anxiety (health $ES = 0.32$; teacher $ES = 0.31$). Conversely, a difference between school-led and health-led prevention was detected in the Stallard *et al.* study [40], with health-led programmes producing significant preventive effects at 12 months ($ES = 0.20$), while teacher-led prevention had no effect ($ES = 0.03$). Of the six computer-delivered programmes, two (5%) were delivered in the school environment and supported by teachers and one (3%) involved a comparison between a school-supported version to a version supported by a mental health organization [41]. The remaining three (7.9%) computer-based programmes were entirely self-directed and delivered to adults. Of the six computer-delivered programmes, four of the five (80%) for which effect sizes could be calculated were effective ($ES = 0.15-1.51$). One study (3%) did not report on personnel delivering the programme [42].

Evaluation control groups

Seventeen of the included studies (45%) compared the prevention programme to either a no-intervention control group or usual care (NI), nine studies involved a wait-list control group (WL; 23.6%), seven studies used an attention control group (AC; 18.4%), and six studies involved more than one control group (15.7%). Of these six studies involving more than one comparison, three included an NI and an AC arm, and two involved a WL arm and an AC condition. Usual care typically involved regular class attendance in school-based programmes or standard care (education, check-ups) in medical settings. Attention control conditions are used to control for extraneous factors (such as attention, exposure to educational material, and non-specific prevention factors such as being in a group) that could feasibly impact preventive outcomes. Of the studies that included an attention control condition, 60% reported significant effects on anxiety ($ES = 0.20-1.22$), while 58% of trials employing NI or WL groups found a significant reduction in anxiety ($ES = 0.15-1.78$).

Outcome measures

Anxiety symptoms were measured as outcomes on all but two of the included studies (95%). Two studies used diagnostic instruments exclusively, and five studies included both diagnostic and symptom outcomes. Of the studies using diagnostic tools, three studies (43%) used the Anxiety Disorder Interview Schedule [43], three used the Structured Clinical Interview for DSM-IV disorders [44], and the final study (14%) employed the MINI International Neuropsychiatric Interview [45]. Anxiety symptoms were measured most frequently with the Spence Children's Anxiety Scale (22%) [46], followed by the Multidimensional Anxiety Scale for Children (14%) [47] and the State-Trait Anxiety Inventory (14%)

[48], followed by the Beck Anxiety Inventory (11%) [49] and finally the Revised Children's Manifest Anxiety Scale (8%) [50].

Overall outcomes

From the 38 studies included in this review, eight studies did not include enough information for effect sizes to be calculated or did not collect data at post-test (for example, some studies included follow-up data only). Of the 30 (79%) studies for which effect sizes could be calculated, three of these reported change score analyses only, and so group differences at post-test could not be ascertained. Out of the 27 (71%) remaining studies, 17 (63%) trials reported that the prevention programme significantly improved anxiety outcomes ($ES = 0.15-1.79$), while ten (37%) trials did not ($ES = -0.19$ to 0.21). Twenty-one studies (55%) collected follow-up data, for which effect sizes and between-group differences could be calculated for 19 (50% overall). Of these, 12 (63%) studies reported significant effects on anxiety ($ES = 0.25-1.78$), while seven (37%) did not ($ES = 0.00-0.33$). Of the studies that included follow-up periods, 15 studies (39%) did not follow up beyond 12 months, two studies included a final follow-up at 18 months (5%), and only three studies followed up individuals for longer than 2 years (8%).

Universal programme outcomes

Effect sizes could be calculated for all but two of the 22 universal trials, but a further three did not report between-group outcomes at post-test and/or follow-up. Of the 17 (53%) trials for which effect sizes and group differences could be ascertained, 11 trials (65%) found positive outcomes on anxiety ($ES = 0.15-1.51$), while six did not ($ES = -0.19$ to 0.32). Eleven studies included follow-up data, for which group differences were reported for nine. Six studies (67%) reported an impact of anxiety prevention at follow-up ($ES = 0.25-1.01$), while three trials did not ($ES = 0.03-0.33$).

Selective programme outcomes

Effect sizes for the 16 selective prevention programmes could be calculated for ten of the studies and ranged from 0.08 to 1.78. Of these ten studies, six (60%) found a significant preventive effect on anxiety ($ES = 0.60-1.79$), while four did not ($ES = 0.08-0.21$). Ten selective studies reported follow-up information, with six finding a positive effect of anxiety prevention ($ES = 0.58-1.78$) and four reporting no difference between groups on anxiety at follow-up ($ES = 0.01-0.22$).

Effectiveness of the primary prevention of anxiety

Overall, this review suggests that there is legitimate value in pursuing primary prevention of anxiety disorders using both universal and selective approaches, with a median effect size for all included studies of 0.21. More than half of the trials (63%) found that the prevention programme either prevented onset of an anxiety disorder or reduced anxiety symptoms, both at post-test and at follow-up. Small (0.15) to large (1.78) effect sizes were reported for both universal and selective interventions. As might be expected, 80% of the studies included were delivered to children, adolescents, or university students, which is appropriate, given that anxiety often develops early in life. Preventive interventions delivered to young people have the greatest chance of preventing first onset, which can have implications for the trajectory of disorder across the lifespan.

Studies that involved prevention in adults and the elderly were more likely to be selective prevention programmes, delivered to those at risk for disorder development (for example, diagnosis of cancer, experience of stroke).

There has been considerable debate in the literature about whether universal or targeted prevention approaches are more effective, and to date, there does not seem to be a clear advantage of one over the other (for example, [18, 20, 51]). A common argument against universal prevention is that programmes are delivered to large samples with relatively low levels of need. However, the counter-argument is that unless prevention is universal, individuals who are on the trajectory to disorder but do not yet meet a given definition of being 'at risk' will not be captured. Furthermore, anxiety disorders can be extremely difficult to detect in children by parents and teachers, relative to other disorders [52], making universal approaches delivered in the school environment particularly attractive in terms of reaching these individuals. Another advantage of school-based universal approaches is that they minimize stigma and are usually easier for school administrators to schedule by directly integrating them into the school curriculum. Although universal programmes are associated with advantages for delivery in schools, outside of this environment, universal implementation is more difficult—we identified only a single community-based universal programme [38] and three universal programmes delivered in university settings [35–37].

Control group type did not appear to influence effectiveness outcomes. It is encouraging that approximately 32% of the studies included an active control group, which is double what has been reported previously [20]. This may reflect an increasing awareness of the importance of active control conditions to control for non-specific factors associated with the prevention programme, something which prevention researchers have been calling for [53]. There was virtually no difference in the proportion of studies reporting significant preventive effects on anxiety as a function of control group type (60% of studies with an active condition found effects, while 58% of those employing inactive control group types reported positive effects).

There was substantial variability in effect size estimates, and this likely reflects the heterogeneity in study variables (for example, setting, age, content). The fact that most selective prevention programmes screened participants for a history of anxiety or mental disorder and excluded participants on this basis, while universal prevention studies did not involve a screening process, is likely to have impacted effect sizes. Furthermore, the quality of the research methodology also varied significantly, which is very likely to have influenced effect size estimates. For example, many studies did not report attrition rates or whether fidelity measures were used (for example, independent coding of therapy tapes).

Although our results provide consistent evidence for the effectiveness of anxiety prevention programmes, findings need to be interpreted in the context of several limitations, including the fact that three studies reported only change scores, so between-group effect size estimates at post-test and follow-up could not be calculated. A further five studies did not report enough information for effect sizes to be calculated. Therefore, the effect size estimates from this review are based on 30 studies, and not the 38 that met inclusion criteria. Finally, a single rater (the first author) screened and extracted the data, without an independent coder.

Key elements common to effective prevention programmes

A consistent finding from both the literature and the current review is that programmes can be effective in preventing anxiety. What is now needed is insight into the elements of consistently effective prevention programmes. There is not yet enough existing research to confidently address this issue, although there are some emerging patterns.

Much of the research that has been carried out in the field of anxiety prevention has tested psychological approaches and, most frequently, CBT. More than 70% of the included programmes in the current review delivered at least some component of CBT, including several trials delivering automated, computer-delivered CBT. CBT typically involves a range of different cognitive and behavioural strategies, meaning that the active ingredient and corresponding mechanisms of change cannot be identified when the overall package is examined. Dismantling studies will help to address this issue, which may inform the development of more effective prevention programmes in the future.

Drawing on the existing literature and the results from the current review, factors such as age, gender, prevention type, and setting have not consistently been associated with effect size outcomes (for example, [20, 26]). Notably, personnel delivering the programme may impact outcome. Existing evidence and data from the current review suggests that programmes delivered by mental health professionals could be more effective than those delivered by teachers [26], although this finding has not been consistently replicated [20, 51]. In our review, programmes that were delivered by mental health professionals (including psychologists, psychiatrists, doctors, graduate students, or researchers) or by computers were associated with a higher percentage of successful preventive outcomes than those delivered by teachers. However, fewer than one-third of included studies were delivered by teachers, and so a relatively low number of teacher-delivered programmes precludes strong conclusions about the effectiveness of these programmes being drawn. Of note, two studies directly compared teacher- vs mental health professional-led face-to-face prevention programmes, of which one noted superiority in the professional-delivered programme, while the other did not [39, 40]. More research is required to resolve this issue, and regardless of outcome, future studies should focus on identifying ways to improve the effects of programmes delivered by school staff, which may involve the development of teacher training and support structures to scaffold teacher competence in delivering mental health programmes.

Barriers to the implementation of prevention programmes

Engagement and fidelity

Engagement is a key barrier to delivering effective prevention programmes. These programmes are notoriously challenging to make appealing and relevant to the target audience, who might not perceive the need for the material or appreciate its value, particularly when there is no obvious immediate benefit. A discussion about prevention necessarily includes a focus on young people, and the

emergence of programmes that use technology may have greater appeal to young people, particularly those involving gamified and interactive components (for example, [41, 54]). These programmes also lend themselves to being updated and incorporating technological innovations that may be particularly appealing to young people, such as completing mood ratings on their own digital device, rather than in a classroom setting. Systematic evaluation of engagement factors is likely to inform how prevention programmes might best be delivered at a population level.

Evidence-based anxiety prevention programmes are unlikely to be effective if they are not delivered as intended. Poor adherence to the protocol could reflect inadequate training or competence on the part of the provider or an overall lack of engagement with the programme. In the current review, most studies did not report on how fidelity to the programme was measured (if it was at all), and it is important to keep in mind that fidelity is likely to be higher in a rigorous research trial than under real-world conditions. One way this barrier might be overcome is for implementation and effectiveness–implementation hybrid trials to systematically examine factors that are associated with higher levels of engagement and fidelity to the programme and how these relate to effectiveness, uptake, and completion rates.

Organizational priority and fit

A related issue is the compatibility of the prevention programme to the culture in which it is being delivered. In the example of school settings, the fit within the school culture and the willingness of school administrators to schedule time in the school curriculum for delivery are likely to influence outcomes. There are many demands placed on an already crowded school curriculum, and one of the key emerging barriers from our work in the field is willingness of school executives to prioritize mental health prevention programmes over other valid educational programmes. One way to overcome this is to align school prevention programmes with curriculum outcomes, such that teachers can fulfil teaching requirements by delivering mental health prevention programmes without having to find extra time in their schedule. Issues of fit and priority against competing demands are likely to apply more broadly to general workplace settings as well where it might be expected that initiatives and programmes that fit with the culture of a workplace would be prioritized. Mediating factors likely to influence implementation in a particular context include the attitude of the organization to the programme, existing stigma, and the attitude and skills of the provider. Empirical investigation into these factors as a way to promote engagement and adherence to the programme is now needed.

Cost and sustainability

The delivery of prevention programmes is expensive. It requires investment in terms of paying professionals to deliver the programme or training non-mental health specialists to deliver the programme. Programmes delivered by lay people, including school staff, provide information about whether a programme is likely to be effective and suitable for sustainable, large-scale implementation because these programmes ultimately need to be delivered by individuals who will be available to do so over the long term. Technology-based approaches show tremendous promise in providing a low-cost and potentially sustainable avenue through which large-scale rollout might occur. Individuals with minimal training in the community

can support a computer-delivered programme at much lower cost than undergoing training themselves to deliver complicated psychological therapies.

Current challenges facing the field and suggestions for future longer research follow-up

Most of the research in the field of anxiety prevention has been conducted over the past decade. Although growing, the existing evidence base is relatively scarce, compared to the treatment literature, and even research into the prevention of depression. What this means is that we do not yet know what the longer-term impact of delivering prevention programmes is, and the field now needs studies that assess participants over longer follow-up periods. To detect a true preventive effect, a difference in the incidence of disorder or symptoms needs to be identified as differentially increasing between prevention and control groups. The use of latent growth curve modelling techniques may help to identify the impact of prevention programmes on trajectories towards disorder over time. The impact of prevention is hypothesized to be long term, and yet there are not enough data available to address this question, with only three of the included studies following participants over 2 years or longer. Researchers are encouraged to assess participants over significantly longer periods, so that genuine long-term effects can be detected. The increase in the use of digital technology may assist in the ease with which participants may be contacted and followed over longer periods.

More rigorous research methods

Many of the studies in this review, together with previous prevention reviews, were of poor methodological quality. For example, 47% of the included studies involved less than 200 participants, suggesting inadequate power to detect preventive effects, while fewer than half of the studies in the current review did not conduct intent-to-treat analyses. These statistics are not unique to the current review and are broadly consistent with what has been reported previously (for example, [20, 51]). Given some of these methodological weaknesses, it is possible that effect size estimates are inflated, and so results need to be interpreted cautiously. The increasingly common requirement to publish protocol papers in advance of completing an RCT and to adhere to Consolidated Standards of Reporting Trials (CONSORT) guidelines [55] is likely to enhance the overall quality of RCTs moving forward.

Cost estimates

An important next step in this line of research is to identify the cost-effectiveness of delivering anxiety prevention programmes in these environments. We know of one study that has examined the cost of delivering the FRIENDS programme universally in schools, with researchers reporting no evidence for its cost-effectiveness [56]. This is clearly an important issue from a public health perspective that future work will need to address. Again, the issue of cost may be addressed, at least in part, by the emergence of new, effective

digital platforms through which prevention programmes might be delivered.

Final comment

A common criticism of prevention programmes is that they are associated with modest effect sizes. Prevention studies require very large sample sizes to detect effects because of relatively low base rates of disorder incidence found in unselected samples [3, 57]. The picture emerging from the literature is that with enough statistical power, genuine small preventive effects may exist. Even small effect sizes are likely to be associated with meaningful and clinically important improvements at a population level. The current review found a median effect size of 0.21 at post-test, which includes all studies meeting inclusion criteria (not just those with significant between-group differences). This estimate is in line with mean weighted effect sizes reported in a previous meta-analysis of youth anxiety where Cohen's d at post-test was 0.18 (for example, [26]). Specifically, the median effect size for CBT programmes, the most widely studied approach, was 0.25 at post-test. Effect sizes of this magnitude may be of practical significance, as they apply to a whole population. Adopting the Kraemer approach [58] to estimate the number needed to treat, approximately 9.2 individuals would need to be delivered the prevention programme for a favourable prevention outcome in one individual. It is not possible to know exactly how many people are needed to prevent onset, as the reliance in the studies reviewed largely rely on symptom measures, for which we cannot be sure what reduction is needed to prevent incidence. However, given that comparable effect sizes in studies using diagnostic vs continuous measures (and specifically those included in this review), this suggests that 9.2 is a valid estimate. Considering that participants included universal, non-selected samples, the potential impact of prevention is substantial, particularly if prevention can be delivered to large samples at low cost, possibly using digital technologies. The successful prevention of anxiety disorders has important implications at both an individual and societal level, and investigation into the factors that promote the successful implementation of prevention programmes, together with more attention to factors which moderate outcomes and whether they are sustained, is now warranted.

Treatment of anxiety disorders

David S. Baldwin and Nathan T.M. Huneke

Anxiety symptoms and anxiety disorders

Anxiety is an understandable response to perceived threat or experienced stress and is typically fleeting and controllable. It can be conceptualized as an 'alarm', allowing a physical and mental response to perceived danger (the 'fight-or-flight' response). Anxiety symptoms are mostly mild and transient, though many individuals experience severe and persistent symptoms that cause considerable personal distress and impair social and occupational function. A distinction is often made between physical (or 'somatic') symptoms, which mainly result from autonomic arousal or muscular tension (for example, shortness of breath, palpitations, tremor, and headache) and psychological (or 'psychic') symptoms, including apprehension, irritability, and worrying.

Anxiety symptoms are common among patients undergoing examination, investigation, and medical or surgical treatment but are also frequent in community settings in physically well individuals. If distressing and impairing anxiety exceeds specified severity thresholds and persists beyond minimum duration requirements, and providing its symptoms are not explicable by another condition, an anxiety disorder can be diagnosed. These disorders share common psychological and physical symptoms but differ in the characteristic features that aid specific diagnosis ([Table 92.1](#)), for example recurrent unexpected panic attacks in panic disorder or the fear of embarrassment and humiliation in social anxiety disorder. Accurate delineation of a suspected anxiety disorder can be challenging, but a simple algorithm can aid diagnosis ([Fig. 92.1](#)). Differential diagnosis from depression and other mental disorders is usually simple ([Table 92.2](#)).

Treatment need and treatment choice

Some people with anxiety receive unnecessary or inappropriate treatment, as mild symptoms of recent onset and associated with stressful events will often improve spontaneously. However, the persistence and associated disability of anxiety disorders means that most patients who meet criteria for diagnosis are likely to benefit from pharmacological or psychological interventions. Unfortunately, many patients who could benefit from treatment are

not recognized. The need for treatment should be determined by ascertaining the severity and persistence of symptoms, their impact on everyday life, the level of coexisting depressive symptoms, and other features such as a previous good response to medication or psychotherapy [1].

The choice of treatment is influenced by clinical characteristics, patient and doctor preferences, and the local availability of potential interventions. There is much overlap across anxiety disorders for evidence-based effective therapies—such as prescription of a selective serotonin reuptake inhibitor (SSRI) or a course of individual cognitive behavioural therapy (CBT)—but there are

Table 92.1 Characteristic features of anxiety disorders

Generalized anxiety disorder	Prolonged excessive worrying that is not restricted to particular circumstances. Worries often centre on possible physical ill health affecting themselves or family members, and patients can repeatedly present with medically unexplained physical symptoms or craving reassurance or requesting medical investigations.
Panic disorder	Recurrent unexpected surges of severe anxiety ('panic attacks'), which typically reach a peak within 10 minutes and last around 30–45 minutes. Patients may believe they are in imminent danger of death or collapse and seek urgent medical attention.
Agoraphobia	Fear and avoidance of public spaces and other situations (crowds, transportation) from which immediate escape may be difficult; in clinical samples, most patients also have expected panic attacks and some have comorbid panic disorder.
Social anxiety disorder (social phobia)	Marked and persistent fear of being observed or evaluated negatively by other people, in social or performance situations. Many avoid consulting doctors, but some present with physical symptoms (such as excessive perspiration) or psychological symptoms (such as fear of vomiting in public).
Simple phobia	Excessive or unreasonable fear of (and restricted to) single people, animals, objects, or situations (for example, dentists, spiders, lifts, flying, seeing blood), which are either avoided or are endured with significant personal distress.
Separation anxiety disorder	Fear or anxiety concerning separation from those to whom an individual is attached; common features include excessive distress when experiencing or anticipating separation from home and persistent excessive worries about potential harms to attachment figures or untoward events that might result in separation.

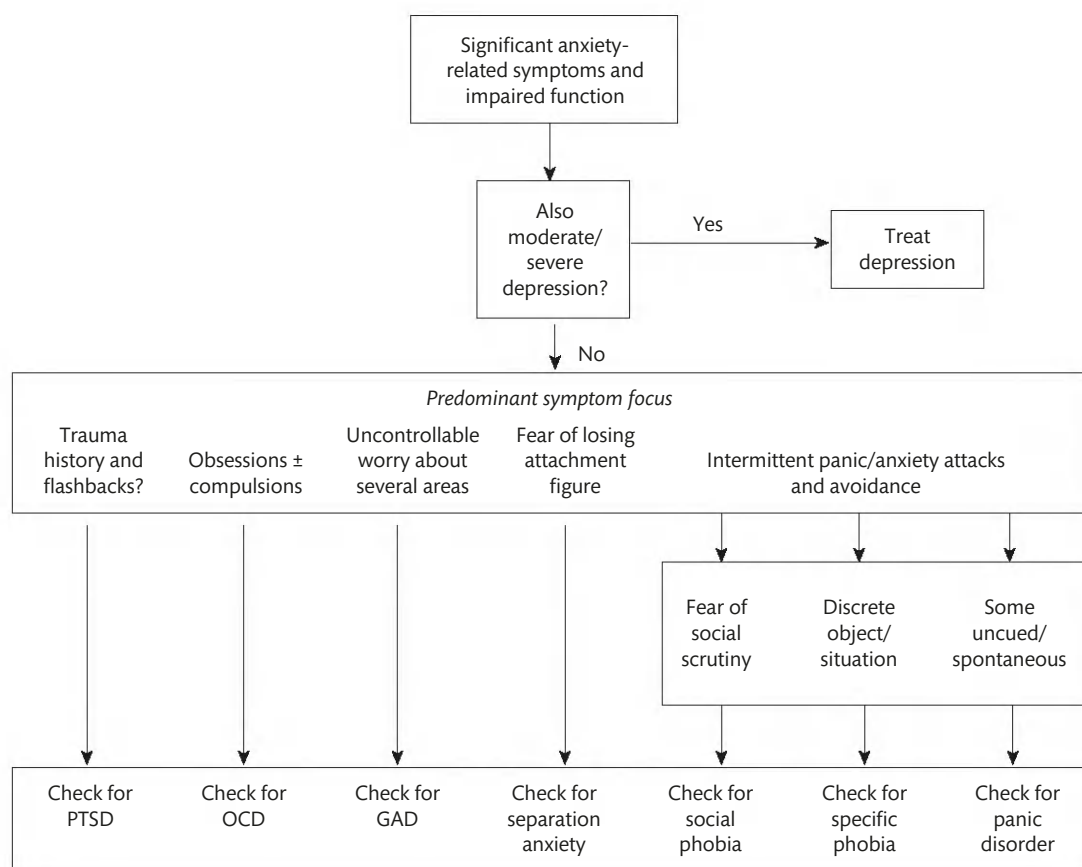

Fig. 92.1 Suggested scheme for exploring a suspected anxiety disorder.

differences in treatment response between disorders, and it helps to be familiar with the evidence base for each condition (Table 92.3). Depressive symptoms often accompany anxiety disorders; around one-third of people with anxiety disorders also fulfil diagnostic criteria for a depressive episode. Treatment of depression will usually relieve anxiety symptoms when depression is the primary diagnosis, but if depression is comorbid or follows an anxiety disorder, each condition requires separate consideration and often specific treatment [1].

Pharmacological and psychological treatments

The overall efficacy of psychological and pharmacological approaches in acute treatment of anxiety disorders has been regarded as broadly similar, although the findings of a recent meta-analysis have questioned this assumption [2]. The strongest evidence for acute treatment is for judicious prescription of an SSRI or undertaking manualized CBT delivered by trained and supervised staff. It is uncertain whether combining these approaches is associated with greater improvement than with either treatment given alone, at least in some disorders. Sequential steps in patient management, such as the 'stepped care' approach recommended by the National Institute for Health and Care Excellence (NICE), are recommended if a patient does not respond to first-line approaches [3]. Continuation treatment, following a satisfactory response to acute treatment (ideally resulting in remission of symptoms), is needed in all patients with anxiety disorders to consolidate the response and reduce the risk of relapse. It has been argued that psychological treatments

may be more effective than pharmacological treatments in keeping patients well, though the evidence to support this view is limited and has been questioned.

Many patients worry about starting and continuing pharmacological treatment, fearing problems such as unwanted sedation, weight gain, or the potential risk of becoming dependent on prescribed medication. By contrast, others are reluctant to engage in a psychological treatment that is often limited in availability, emotionally intrusive, and time-consuming. Regardless of the recommended treatment modality, patients should be advised that transient worsening of symptoms can occur and that prolonged efforts are needed to consolidate and maintain an initial response to treatment.

Access to treatment and referral to psychiatric services

Stigma influences the perception of psychiatric illness and its treatment. Patients with anxiety disorders may fear being dismissed as having minor 'lifestyle' complaints and can be discouraged from seeking help and undergoing treatment. Many patients may receive conflicting messages about the benefits and risks of pharmacological treatment. Similarly, access to evidence-based psychological treatments is often prioritized for those with 'severe and enduring mental illnesses' such as schizophrenia, though this rationing reflects the widespread failure to recognize the impairment and chronicity of many anxiety disorders.

Most patients with anxiety disorders can be managed effectively within primary care, but some need the extra expertise of secondary

Table 92.2 Important common differential diagnoses in anxiety disorders

Condition	Differentiation from anxiety disorder
Depressive illness	Early morning waking, feeling worse in the morning, loss of capacity for pleasure, constipation, guilty thoughts, and suicidal thoughts all suggest depression, rather than anxiety. Depressive symptoms in anxiety disorders tend to develop after the psychological and somatic symptoms that characterize the anxiety disorder (for example, anticipation of embarrassment, anxiety, and avoidance in social phobia).
Psychotic illness	Delusions, hallucinations, and thought disorder are not seen in patients with primary anxiety disorders.
Psychostimulant use	Use of amphetamines, ecstasy, cocaine, and hallucinogens can all result in agitation and severe anxiety, including panic attacks. Primacy of drug-seeking behaviour and physical signs of intoxication (such as stereotypic movements with amphetamine use) support the diagnosis of drug dependency. Excess consumption of caffeine-containing drugs can result in physical and psychological symptoms of anxiety. Many novel psychoactive substances can cause anxiety, but their full effects are still not established.
Drug withdrawal	Abrupt withdrawal of opiates, alcohol, barbiturates, benzodiazepines, or antidepressants can result in agitation, tremor, dizziness, gastrointestinal upset, and insomnia. Anxiety disorders are not associated with acute confusional states or with marked autonomic instability. Characteristic physical signs are seen after withdrawal from certain drug classes such as pupillary dilatation when withdrawing from opiates.
Physical ill health	Anxiety symptoms are common in many physical health problems and can be the presenting feature (for example, in thyrotoxicosis, recurrent hypoglycaemia, complex partial seizures, paroxysmal tachycardia, and phaeochromocytoma).

care mental health services. Referral criteria will vary, depending on service availability. It seems reasonable to expect that patients should be referred by general practitioners to secondary care services when there is uncertainty regarding a possible underlying diagnosis (such as schizophrenia), after the non-response to two evidence-based acute treatment approaches, when there has been a recurrence of symptoms despite continuing treatment, when anxiety disorders are comorbid with other disorders (for example, depression or substance use), when there is a risk of suicide, or when there is a need for specialist intervention (for example, dopamine antagonist augmentation after a partial response to an SSRI) [1].

Generalized anxiety disorder

Generalized anxiety disorder (GAD) is characterized by excessive worrying, lasting more than 6 months and not restricted to particular circumstances (for example, only when attending a social gathering). Common features include apprehension, tension, and difficulty in concentrating, and autonomic symptoms such as dry mouth and abdominal discomfort. GAD is one of the most common mental disorders in primary care but is often not recognized, possibly because only a minority of patients present with its characteristic psychological symptoms. The most important differential diagnosis is depressive illness (although GAD and major depression often occur together), and patients should be asked about key depressive symptoms such as reduced interest, loss of weight, and suicidal thoughts, but distinction between the two conditions can be difficult.

Psychological and pharmacological treatments have broadly similar efficacy. Based on efficacy, safety, and tolerability, first-line pharmacological treatment will usually involve an SSRI, a serotonin–noradrenaline reuptake inhibitor (SNRI), or pregabalin (a calcium channel modulator). Once a drug is started, patients should be treated for a minimum of 4 weeks before deciding whether or not that treatment is working. If no response is seen after this time, increasing the dosage or switching to an alternative treatment may be advisable. The optimal duration of any drug treatment remains unclear, but a minimum of 12 months' further treatment is recommended in patients who have responded to medication [1].

A meta-analysis suggests fluoxetine may be the most likely drug for achieving response and symptomatic remission, while sertraline is the best tolerated [4]. Neither is currently licensed for treatment of GAD in the UK, though NICE recommends sertraline as initial treatment. At present, five medications are licensed for GAD in the UK: escitalopram and paroxetine (both are SSRIs), duloxetine and venlafaxine (both are SNRIs), and pregabalin. Among these drugs, the same meta-analysis found duloxetine was most likely to produce a beneficial response, escitalopram most likely to establish symptom remission, and pregabalin most likely to be best tolerated. Relative to SSRIs or SNRIs, pregabalin might have an earlier onset of effect. It also reduces the sleep disturbance commonly seen in GAD, both directly and indirectly, via the reduction of anxiety. It is generally tolerated well (although dizziness and drowsiness are common during acute treatment), is eliminated unchanged in the urine and has few drug interactions, and has a low rate of discontinuation symptoms

Table 92.3 Summary of possible treatment options in anxiety disorders

	Generalized anxiety disorder	Panic disorder with/without agoraphobia	Specific phobia	Social anxiety disorder
First line				
Psychological	CBT	CBT	Exposure-based therapy	CBT
Pharmacological	SSRI	SSRI	SSRI	SSRI
Second line				
Psychological	Applied relaxation	Supportive psychotherapy	CBT	Combination (CBT + SSRI)
Pharmacological	SSRI, SNRI, pregabalin	SSRI, SNRI	SSRI	SSRI, SNRI, SSRI plus benzodiazepine
Third line				
Psychological	Uncertain	Combination (CBT + SSRI)	Uncertain	Uncertain
Pharmacological	Agomelatine, buspirone, quetiapine, TCA, benzodiazepine	Psychodynamic psychotherapy TCA, MAOI, benzodiazepine	Uncertain	MAOI, pregabalin, benzodiazepine

No randomized controlled trials of adult separation anxiety disorder are currently published (August 2017).

[5]. However, concern has been raised about the possible risks of dependence and abuse [6].

Dopamine-serotonin antagonists, particularly quetiapine, have been investigated in GAD, both as monotherapy and as adjuncts to antidepressants. A potential benefit is an earlier onset of action, but this must be balanced against potential adverse effects such as metabolic syndrome. Use of quetiapine is therefore mainly limited to a second-line role, but it might be appropriate to use quetiapine in primary care in this way as long as the clinician feels s/he has sufficient experience and competence. Agomelatine, which acts as an agonist at melatonin MT₁ and MT₂ receptors and as an antagonist at 5HT_{2C} receptors, is generally well tolerated and has no significant discontinuation symptoms and relatively few drug interactions, when compared with SSRIs and SNRIs. Agomelatine is also efficacious in GAD, both in acute treatment and in preventing relapse [7]. Due to its mechanism of action, it may be particularly beneficial in patients with marked sleep disturbance. Preclinical studies with the novel 'multimodal' antidepressant drug vortioxetine suggested potential anxiolytic effects, and it reduces anxiety symptoms in depressed patients; however, despite its efficacy in preventing relapse, randomized placebo-controlled trials of acute treatment of GAD have produced inconsistent findings [8]. Vilazodone has both SSRI and 5-HT_{1A} partial agonist properties and is effective in acute treatment of GAD [9]; it may have an advantage, compared with SSRI or SNRI treatment, in having a lower incidence of treatment-emergent sexual dysfunction.

There is uncertainty about how best to proceed after a non-response to first-line treatment. A pragmatic approach suggests employing a further monotherapy before proceeding to augmentation strategies. Other efficacious drugs (usually reserved for specialist psychiatric treatment) include benzodiazepines (alprazolam, diazepam), imipramine, and the 5-HT_{1A} partial agonist buspirone. Clinicians and patients have concerns about the use of benzodiazepines, mainly the long-term risk of dependence, though this risk has to be weighed against the potential relief an individual with chronic, severe, distressing, and disabling symptoms might derive from intermittent use or more prolonged treatment [10]. When attempting to relieve acute exacerbations of symptoms, a short-acting benzodiazepine (for example, lorazepam) may be preferable to a longer-acting alternative due to its more rapid onset of effect and a lower risk of sedation. A prescriber should evaluate the likelihood of developing problematic use before issuing a first or subsequent prescription [11] (**Box 92.1**); for example, individuals who abuse drugs and/or alcohol and those with chaotic lifestyles are more likely to develop long-term problems with benzodiazepines.

Many psychological treatments have been investigated in GAD, but CBT and applied relaxation have the strongest supporting evidence.

CBT offers an effective alternative to pharmacological treatments and can help around half of patients with GAD to achieve significant symptom reduction and to improve their level of functioning. Although other psychological approaches may produce some benefit, relapse rates over the longer term are probably lower with CBT [12]. However, CBT may be less efficacious in older adults than in adults of 'working age' [13]. Augmentation of escitalopram treatment with CBT is more effective in reducing worrying than escitalopram alone, but there is at present minimal evidence for an additional benefit when combining other

Box 92.1 Predictors of the risk of dependence upon benzodiazepines

- 1 Participation in self-help group for medication dependence
- 2 Younger age
- 3 Longer duration of use
- 4 Higher dose use
- 5 Lower level of education
- 6 Non-native cultural origin
- 7 Outpatient treatment for alcohol and/or drug dependence
- 8 Short duration of elimination half-life
- 9 Higher levels of depression and anxiety

pharmacological and psychological treatments, although this is often done in practice.

Panic disorder with or without agoraphobia

Accurate diagnosis depends on establishing the presence of recurrent unexpected panic attacks, with relative freedom from anxiety (at least initially) between these attacks, together with associated concern, worry, or change in behaviour. Coexisting depressive symptoms are common, and patients with comorbid depressive episodes are typically more impaired by symptoms, make greater use of health services, and have a worse prognosis. Panic disorder can occur with or without agoraphobia—anxiety in feared situations from which escape might prove difficult or embarrassing—and agoraphobia can either precede or follow the development of panic attacks.

Treatment is aimed at achieving complete recovery from panic attacks, resolution of anticipatory anxiety (fearful expectation of attacks), and abolition of agoraphobia [1]. Panic attacks can be shortened by rebreathing exhaled air, which corrects the abnormal blood chemistry that arises from rapid shallow breathing. In established panic disorder, psychological and pharmacological interventions are helpful. As with GAD, NICE guidance for panic disorder recommends a stepwise approach to patient management.

SSRIs are the preferred first-line drug treatments in primary care, as they cause less drowsiness and carry lower risks of tolerance and dependence than benzodiazepines. In secondary care, treatments include venlafaxine, the selective noradrenaline reuptake inhibitor reboxetine, and the tricyclic antidepressants (TCAs) imipramine and clomipramine. Certain SSRIs, venlafaxine, some TCAs, and the reversible monoamine oxidase inhibitor (MAOI) moclobemide have demonstrated long-term efficacy in clinical trials, though SSRIs tend to be better tolerated. Patients must follow a restricted diet while taking an MAOI, and these compounds are therefore reserved for second- or third-line treatment.

There are few studies to guide pharmacological management of treatment resistance, but several strategies may be beneficial. These include augmentation of fluoxetine with the beta-blocker pindolol, switching to an agent that acts via different receptors (for example, non-responders to citalopram could be switched to reboxetine, and vice versa), augmentation of a TCA with fluoxetine or augmentation of fluoxetine with a TCA, combination therapy with sodium valproate and clonazepam, or augmentation of clomipramine with lithium.

Psychological and pharmacological interventions have broadly similar efficacy and acceptability [14]. A network meta-analysis indicates that CBT is probably superior to other psychological treatments, though non-specific supportive psychotherapy also appears efficacious and psychodynamic psychotherapy may have fewer associated dropouts from treatment [15]. Routinely combining CBT with medication as a first-line approach in all patients is not recommended, but findings from a meta-analysis suggest that combining CBT with drug treatment can enhance the efficacy of CBT. CBT alone may be more cost-effective than either SSRI alone or SSRI when combined with CBT [16].

Specific (simple) phobia

Specific fears of particular objects, animals, or situations are very common, but only a minority of affected people present for treatment, this often being at the time of changes in domestic or career responsibilities. The impairment associated with specific phobia is usually limited, but the presence of comorbid specific phobia in other anxiety disorders or depression can increase their associated disability. The effectiveness and acceptability of psychological or pharmacological treatments for specific phobia are less well researched than in other anxiety disorders.

A meta-analysis of randomized controlled trials indicated that exposure-based therapies (particularly those involving *in vivo* exposure) are more effective than other psychological interventions—effectiveness being seen regardless of the nature of the phobia, and greater with multiple, rather than single, sessions [17]. Patients with ‘blood-injury phobia’ can develop hypotension and bradycardia during exposure sessions, so they may require additional muscular tension exercises to benefit fully from treatment. Most patients respond to a few treatment sessions based on exposure techniques, but SSRI treatment (escitalopram, paroxetine) is helpful when patients have not responded to exposure therapy. It is unclear if concomitant benzodiazepine use enhances or reduces the efficacy of exposure therapy. Efficacy may be increased marginally by d-cycloserine administration prior to a session, though not all evidence is consistent [18].

Social anxiety disorder (social phobia)

Social anxiety disorder is characterized by the intense, persistent fear of being scrutinized or evaluated negatively by others. Patients anticipate ridicule or humiliation and either avoid many social situations or endure them with great distress. Some experience panic attacks, but the condition can be distinguished from panic disorder, as in social phobia, the attacks occur expectedly in feared situations. Furthermore, in panic disorder, the presence of a friend typically provides some reassurance, but in social phobia, this makes little difference. Shyness is a core symptom of social phobia, though this should be distinguished from healthy individuals who are merely shy and typically experience little anxiety, functioning well at home and at work. A significant proportion of patients develop depression, and differentiating the disorders can sometimes be difficult, but in social phobia, the capacity to enjoy oneself remains and energy levels are not impaired significantly. Many patients use alcohol or other drugs in an attempt to quell anxiety symptoms prior to a social encounter.

Medications with proven efficacy in acute treatment include most SSRIs (escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline), venlafaxine, the MAOIs phenelzine and moclobemide,

some benzodiazepines (bromazepam, clonazepam), some anticonvulsants (gabapentin, pregabalin), and olanzapine. There is little evidence of a dose–response relationship in acute treatment. Response is more likely in patients whose symptoms have reduced in intensity within 2 weeks of starting treatment. Beta-blockers can reduce physical symptoms of anxiety in some discrete performance activities (for example, acting or singing), but they do not help in patients with generalized social phobia who fear and avoid multiple social situations. As with GAD, SSRI treatment is usually regarded as being first line, based on efficacy, tolerability, and safety [1].

CBT is the most established psychological treatment. A network meta-analysis of the comparative efficacy of pharmacological and psychological treatments indicated that SSRIs and venlafaxine are superior to pill placebo, and CBT superior to ‘psychological placebo’ (that is, non-specific psychological intervention) [19]. In one study, the combination of phenelzine and group CBT was more effective than either treatment given alone, on measures of both response and remission, but there is inconsistent evidence regarding whether the combination of CBT with medication is associated with greater improvement than with either treatment given alone [20].

SAD is typically a long-lasting condition, and successful response to acute treatment should be followed by at least 6 months of continuation treatment, in order to consolidate recovery and prevent an early relapse of symptoms. However, relapse prevention studies demonstrating the long-term efficacy of pharmacological treatments (escitalopram, paroxetine, sertraline, pregabalin) are limited. Patients who make only a limited initial response to CBT may benefit if further CBT is combined with medication, and those who respond only partially to pharmacological treatment may benefit if further drug treatment is combined with CBT. Combination of an SSRI (sertraline) with a benzodiazepine (clonazepam) has been found superior to continuing with sertraline alone or switching to venlafaxine [21].

Separation anxiety disorder

Differential diagnosis between separation anxiety disorder and panic disorder is difficult, but in patients with the former, the primary concern is fear of separation, rather than fear of a panic attack. Furthermore, patients with panic disorder are preoccupied with their personal health and safety, whereas individuals with separation anxiety disorder are concerned for the well-being of their attachment figures. Differential diagnosis between separation anxiety disorder and GAD can also be troublesome, as worrying that something bad might happen to loved ones is a feature common to the two conditions. Distinction largely rests on establishing that in GAD, the fear and worry of losing loved ones is just one of a wide range of worrisome themes, whereas in separation anxiety disorder, the central and often only concern is fear of, and worry about, losing a major attachment figure. Other important differential diagnoses include dependent personality disorder, emotionally unstable personality disorder, and morbid jealousy [22].

The efficacy of psychological or pharmacological treatment in adults with separation anxiety disorder has not been studied extensively, and treatment studies in children have often involved mixed diagnostic groups. The findings of randomized, placebo-controlled trials of pharmacological treatment in children with separation anxiety disorder provide no convincing evidence of benefit for any medication. However, the SSRIs fluvoxamine and sertraline have been found efficacious among the separation anxiety disorder subgroup of

patients within mixed diagnostic samples. Psychological treatment studies in children find some evidence of benefit with CBT, parent-child interaction training, and 'summer camp' programmes [23].

Room for improvement in the treatment of anxiety disorders

A wide range of options is available for the pharmacological and psychological treatment of patients with anxiety disorders. Current recommendations included within evidence-based guidelines and consensus statements are derived mainly from the findings of randomized, double-blind controlled trials, which suggested robust efficacy and generally good tolerability for many interventions, both in acute treatment and in preventing relapse. However, the patient groups that participate in randomized controlled trials may have a better prognosis than patients treated in 'real-world' clinical settings. In routine practice, response rates to initial treatment can be disappointing; many patients will experience unwanted effects during treatment; others will relapse despite adhering to treatment, and some will be affected by troublesome discontinuation symptoms. Furthermore, at present, it is not possible for doctors to predict the likelihood of a treatment response in an individual patient with great accuracy, and there are continuing uncertainties about optimal steps in the further management of patients after non-response to first-line treatment approaches.

For the time being, attempts to optimize clinical outcomes rest largely on making the best use of currently available treatments. However, there is much room for improvement in the pharmacological and psychological treatment of anxiety disorders. Improvements in clinical outcomes could result from the development and arrival of approaches with novel mechanisms of action, leading to greater efficacy and improved acceptability in all patient groups. Alternatively, novel treatments could lead to enhanced effectiveness and higher acceptability in certain specific patient subgroups, when combined with the use of reliable biomarkers for identifying which individuals are most likely to benefit.

Core dimensions of obsessive–compulsive disorder

Sophie C. Schneider, Eric A. Storch, and Wayne K. Goodman

Introduction

Obsessive–compulsive disorder (OCD) was once thought to be a relatively rare disorder; however, the lifetime population prevalence is now estimated at 2.3% [1]. Sustained research efforts have led to a better understanding of the aetiology, presentation, and treatment of OCD. However, debate continues regarding the conceptualization and classification of OCD in diagnostic systems. Further, there is increasing recognition that OCD is a clinically heterogeneous disorder, and thus treating OCD as a unitary disorder may obscure important aetiological and clinical variables. This has led to an interest in identifying subtypes and dimensions of OCD and examining dimension-specific associations between OCD and important constructs.

Classification of OCD

Historically, OCD was classified as an anxiety-related disorder due to similarities between OCD and anxiety disorders across core symptoms of fear and avoidance, cognitive styles, and response to pharmacological and psychological therapies [2]. However, a competing conceptualization of OCD is that it belongs to a separate group of disorders characterized by repetitive thoughts and behaviours, often referred to as the obsessive–compulsive spectrum [3]. Evidence supporting this approach has emerged from studies of genetic risk factors, comorbidity, familial transmission, neuroanatomical correlates, neuropsychological functioning, and treatment response [4, 5]. Despite initially proposing the creation of a shared anxiety and obsessive–compulsive spectrum [6], the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) [4] saw the creation of a separate ‘Obsessive–Compulsive and Related Disorders’ (OCD) chapter, placed after the ‘Anxiety Disorders’ chapter. The DSM-5 OCD chapter includes OCD, body dysmorphic disorder, hoarding disorder, trichotillomania (hair pulling disorder), excoriation (skin picking disorder), and other specified and unspecified OCDs. A similar OCD chapter is proposed for the forthcoming eleventh edition of the *International Classification*

of Diseases and Related Health Problems (ICD-11), which will also include hypochondriasis and olfactory reference disorder [5].

The creation of a separate OCD chapter is not without criticism, particularly regarding the close relationship between OCD and the anxiety disorders, the limited evidence for the association between some OCD disorders, and the distinctive presentation of excoriation and trichotillomania (for example, see [2] for a critique of the empirical validity of the DSM-5 OCD chapter). Further research on the classification of OCD is clearly needed, especially given that some of the OCD diagnoses are new or have been substantially changed, for example hoarding disorder and excoriation in DSM-5 and body dysmorphic disorder in ICD-11. Despite the ongoing debate about the classification of OCD, there is a strong consensus regarding the diagnostic criteria and clinical features of OCD.

Clinical features of OCD

Core symptoms

Obsessions are persistent and unwanted thoughts, images, or urges that evoke distress or negative affect such as anxiety, disgust, feelings of incompleteness, or unease [5, 7]. Individuals typically attempt to counteract obsessions, either by ignoring, resisting, or controlling them, avoiding things that may trigger the obsession, or by neutralizing their obsessions with a thought or action. Compulsions are repetitive behaviours or mental acts performed in response to an obsession, to achieve a feeling of completeness or rightness, or following very specific rules. Compulsions are unrealistic or excessive and function to relieve distress or negative affect or to prevent a feared outcome from occurring. Compulsions can include observable behaviours, such as rearranging items or excessive cleaning, or mental acts such as making mental lists, neutralizing unacceptable thoughts with ‘good’ thoughts, or praying in response to sexual thoughts [8]. Examples of common types of obsessions and compulsions are presented in [Table 93.1](#).

Although a diagnosis of OCD only requires the presence of obsessions or compulsions, they co-occur in 99% of cases of OCD [8]. To meet diagnostic criteria, obsessions or compulsions must be

Table 93.1 Examples of obsessive-compulsive disorder symptom dimensions

Symptom type	Obsession	Compulsion
Symmetry/ordering	Uncomfortable sensation that things do not 'feel right'; for example, household objects are misaligned	Touching, tapping, or rubbing things in special ways
Contamination/cleaning	Concern about developing cancer from environmental pollution	Repeated and excessive cleaning such as cleaning all household surfaces with bleach every day
Harm/aggression	I may be responsible for a murder	Checking that nothing bad happened, asking others if they are ok, checking the news for reports of murders
Sexual/religious	Unwanted images of violent sexual behaviour towards others	Praying over and over to prevent the sexual behaviour from occurring
Hoarding	Do not throw things away as they may be important in the future	Hoarding unusual items or excessive acquisition of objects like magazines
Miscellaneous	Intrusive non-sensical images, songs, or words	Getting stuck performing everyday tasks such as getting dressed, eating, and work tasks

Source: data from *Mol Psychiatr.*, 11(5), Rosario-Campos MC, Miguel EC, Quatrano S, *et al.*, The Dimensional Yale-Brown Obsessive-Compulsive Scale (DY-BOCS): an instrument for assessing obsessive-compulsive symptom dimensions, pp. 495–504, Copyright (2006), Springer Nature.

associated with significant distress or impairment and usually occur for at least 1 hour per day [4]. Obsessions and compulsions should be carefully assessed to differentiate them from symptoms of other mental disorders, for example from worries as found in generalized anxiety disorder, appearance preoccupation in body dysmorphic disorder, and ritualized eating in eating disorders.

Clinical correlates

Lifetime comorbidity is very common, reported by 90–92% of those with OCD [1, 9]. The most common types of comorbid disorders, as defined using the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* [10], were anxiety disorders (70–76%), mood disorders (61–63%), impulse-control disorders (36–56%), and tic disorders (28%). The most common individual disorders were major depressive disorder (41–56%), social phobia (31–44%), specific phobia (31–43%), separation anxiety disorder (28–37%), alcohol use disorders (8–39%), and generalized anxiety disorder (8–34%). Further details are given in Chapter 95.

OCD is associated with high levels of functional impairment in both community [1] and clinical populations [11]. Individuals with OCD reported poor social functioning, particularly relating to social and leisure activities and romantic relationships [12]. Their social functioning quality of life was poorer than those with schizophrenia, panic disorder, or major depressive disorder [11]. This may be due to the excessive time spent on obsessions or compulsions and the often secretive nature of their symptoms. Suicidality appears to be relatively common in OCD; thoughts that life was not worth living were reported by 60% of those with OCD, 38% reported suicidal thoughts, 22% had suicidal plans, and 11% had attempted suicide [13].

Family accommodation of OCD symptoms is also common, whereby parents or partners of the affected individual engage in OCD-related behaviours such as washing their hands excessively, changing family routines to avoid triggering or exacerbating OCD symptoms, taking on responsibilities for the individual such as a child's chores, or providing reassurance [14].

OCD is typically a chronic disorder, with a 5-year full remission rate of 17% and a partial remission rate of 22%, and a relapse rate of 59% [15]. Chronic OCD was associated with longer illness duration, higher baseline OCD severity, and greater burden of illness [15, 16].

Insight

Insight refers to the extent to which the individual recognizes that they are experiencing obsessions and compulsions, that these symptoms are excessive, and that their concerns are unrealistic [17]. Insight occurs on a spectrum—good or fair insight indicates that the individual recognizes that their OCD-related beliefs are untrue or that they may be false; poor insight indicates that the individual believes these are likely to be true, and absent insight or delusional beliefs indicate that the individual is convinced that their beliefs are true [4]. Although OCD with absent insight is often referred to as delusional OCD, it is not considered to be a psychotic disorder [4]. This is clinically important as those with delusional OCD should receive treatment recommended for OCD, rather than treatment indicated for psychotic disorders [18].

Absent or poor insight was reported in 9–22% of clinical samples and was associated with greater OCD severity and earlier OCD onset, a lower probability of achieving remission following treatment, and a need for a higher number of medication trials during treatment [8, 19, 20]. Poor insight can complicate the process of psychotherapy; thus, therapists should adapt the therapy content to the level of OCD insight, for example, including additional psychoeducation about insight, spending extra time on symptom identification, and adding additional sessions [17].

Subtypes of OCD

OCD is a highly heterogeneous disorder. The heterogeneity of OCD has led to concerns that treating OCD as a unitary disorder may obscure differential associations between OCD subtypes and aetiological factors, clinical features, and even treatment response [21]. This has led to efforts to identify meaningful subtypes of OCD based on specific clinical features.

Tic-related OCD

Tics are particularly common in those with OCD, with a history of tics reported by 30–55% of youth with OCD [22, 23] and by 24% of adults with OCD [8]. Simple tics involve rapid and recurrent movements or sounds with no clear purpose such as jerking limbs, blinking eyes, grunting, or squeaking [24]. In contrast, complex

tics involve repetitive behaviours that appear purposeful, such as touching and rubbing in certain ways, imitating people's mannerisms, or repeating phrases, and tics which are often elicited by specific stimuli. Tic-related OCD was characterized by a higher proportion of males, an earlier onset of OCD, and possibly with greater OCD severity and higher rates of some comorbid disorders [8, 22, 23, 25]. Tic-related OCD may be associated with lower overall efficacy of SSRIs and greater response to neuroleptic augmentation of SSRIs [25], but was not associated with differences in cognitive behavioural therapy (CBT) outcome [22, 23]. Due to the evidence that tics may be associated with distinctive clinical features, tic-related OCD was added as a specifier to DSM-5, and tic disorders will be cross-referenced with OCD in ICD-11 [4, 5].

Age of onset

The mean age of OCD onset was reported at 19–22 years [1, 26], though symptoms are often present for several years before full disorder onset. Age of onset has been proposed to delineate subtypes, with studies suggesting that early onset may be associated with male gender, greater OCD severity, more symptoms of attention-deficit/hyperactivity disorder, lower rates of employment, and a greater probability of living alone in adulthood [26–28]. Conversely, later disorder onset is relatively rare, and onset after the age of 40 was associated with female gender, greater frequency of precipitating factors and traumatic events, and lower odds of a positive family history of OCD [26, 29]. Unfortunately, interpretation of age of onset findings across studies is complicated due to the use of different criteria for onset. Further, some studies divide participants based on pre-determined developmental groups such as child, adolescent, or adult, while others use statistical methods to determine group membership. Further research is needed before robust subtypes of OCD based on age of onset can be identified; thus, age of onset was not included as a specifier in DSM-5 [25].

Symptom presentation

Many studies have attempted to classify participants based on the focus of their OCD symptoms, for example washing or checking. The most common measure used to assess OCD is the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS), which contains checklists of obsessions and compulsions grouped into similar symptom types, and items assessing the severity of obsessions and compulsions [30]. Factor analysis of the Y-BOCS typically identifies four or five factors, and a meta-analysis of 21 studies reported a four-factor solution: (1) symmetry, repeating, ordering, and counting; (2) cleaning and contamination; (3) forbidden thoughts, aggression, sexual, religious, and somatic; and (4) hoarding [31]. These factors were similar across child, adolescent, and adult samples [32] and were temporally stable [33].

Another common measure for assessing OCD dimensions is the Dimensional Yale-Brown Obsessive-Compulsive Scale (DY-BOCS), which identifies six dimensions: (1) symmetry, 'just right', counting, and arranging; (2) contamination and cleaning; (3) harm content, including aggression, injury, violence, and accidents; (4) moral, sexual, and religious content; (5) hoarding; and (6) miscellaneous, including somatic and superstition [21].

A review of studies that classified participants according to their primary OCD symptoms found differences across treatment response, neuroimaging findings, and neuropsychological deficits

[34]. However, 81% of those with OCD reported symptoms across multiple symptom groups [1], challenging the validity of assigning individuals into discreet symptom-specific groups. Instead, a multi-dimensional model of OCD symptoms has been proposed [35].

A multi-dimensional approach to OCD symptoms

In the multi-dimensional model of OCD, symptoms are conceptualized as forming several overlapping dimensions based on the content of these symptoms [35]. Although there are some differences in the factors identified in the Y-BOCS and DY-BOCS, the following factors are the most robustly identified.

Symmetry/ordering

Symmetry/ordering symptoms may be the most frequently reported OCD symptom type [9, 36]. They involve obsessions about things being symmetrical or 'just right', for example the alignment of objects or needing school work to be done perfectly. Compulsions can involve rewriting over and over, performing actions a special number of times, or touching or tapping in specific ways. A review of studies found that symmetry/ordering symptoms have been associated with perfectionism, 'not just right' sensations, magical thinking, and compulsive slowness [37]. There may also be associations between symmetry/ordering and anger, suicide, and traumatic life events.

Contamination/cleaning

Contamination/cleaning symptoms are often considered 'classic' symptoms of OCD. Contamination obsessions often involve concerns about contracting an illness or disease, sensations of being dirty or unclean, and fears of spreading contaminants to others. A wide range of contaminants can be feared such as germs, pollution, bodily fluids, and household/environmental chemicals. Individuals often go to great length to avoid dirty or contaminated objects, people, or situations and, when exposed to these, may compulsively and excessively clean themselves or contaminated objects. Contamination/cleaning symptoms may be closely associated with feelings of disgust, which can take longer to habituate than feelings of anxiety [37].

Forbidden thoughts

Symptoms related to forbidden thoughts are sometimes identified as a single dimension [31], but they are often divided into separate dimensions [4, 21] of harm/aggression and sexual/religious symptoms. Harm/aggression symptoms include obsessions about causing harm to self or others, or other violent or aggressive acts occurring. Associated compulsions can include checking that the feared outcome did not occur or mental rituals to neutralize or distract from the thoughts. Sexual/religious obsessions involve religious taboos and blasphemy, morality, and improper sexual thoughts, and associated compulsions can involve ritualized praying and religious behaviour, avoidance of situations that may trigger the obsessions, and checking that the feared outcome did not occur.

Forbidden thoughts may vary from other OCD dimensions in their personal significance; for example, obsessions about sexually assaulting someone may be associated with greater shame and negative self-perceptions, compared to obsessions that are morally neutral such as symmetry concerns [38]. The fear of harming others

may be associated with particularly severe social withdrawal, due to the feared outcomes of the obsessions [12]. Forbidden thought obsessions may also face a greater burden of stigma; individuals in the community are least likely to recognize forbidden thoughts as a symptom of OCD, compared to other symptom types, and community members report a greater level of fear and perceived dangerousness and a greater desire for social distance in those with forbidden thought symptoms, compared to other OCD symptoms [39].

Other symptoms

Hoarding symptoms were initially considered a subtype of OCD and thus are included in OCD measures. However, hoarding disorder has since been established as a separate diagnosis due to its distinct genetic risk factors, phenotype, comorbidity patterns, and poor response to OCD-focused treatment [2, 40]. As hoarding is discussed in depth in Chapter 99, it will not be a focus of this chapter. The Y-BOCS and DY-BOCS also contain miscellaneous symptoms such as appearance obsessions, intrusive thoughts about numbers, and excessive list-making. The miscellaneous group of symptoms are generally not considered to be a discreet OCD dimension due to the heterogeneity of the symptom content and thus are not analysed in most studies.

Evidence supporting the multi-dimensional model of OCD symptoms

The interest in identifying OCD symptom dimensions stemmed not only from a desire to better characterize the disorder, but also from the possibility that symptom dimensions may have differential associations with important aetiological and clinical factors. Evidence supporting the multi-dimensional model of OCD has been reported across a diverse range of research areas. A summary of key findings is presented, but note that the identified symptom dimensions vary somewhat across studies, depending on the measures and methodology used.

Genetics and family history

The familial transmission of OCD has long been recognized, with twin studies and family linkage studies indicating that OCD involves polygenic influences, likely on serotonergic, glutamatergic, and dopaminergic neural systems [41]. For a full discussion of the genetics of OCD, see Chapter 96. A small number of studies have explored dimension-specific familial and genetic associations. In sibling pairs with OCD, forbidden thought symptoms had the highest sibling concordance, whereas other symptoms were weakly or non-significantly associated [42]. Interestingly, sibling associations were strongest among female pairs, and weaker in male and cross-sex pairs. In OCD patients, those with a family history of OCD were more likely to report symptoms of contamination/cleaning and symmetry/ordering than those without a family history of OCD [43]. A population study of Brazilian children also reported familial transmission of OCD symptom dimensions, with the strongest familiarity found for contamination/cleaning symptoms [36]. Another family history study found specific familial transmission of contamination/cleaning symptoms, but not of other symptom types [44].

Studies of the genetic heritability of OCD dimensions indicate both common and dimension-specific genetic influences. In one family history study, all OCD symptom dimensions were heritable, but specific genetic associations were found between forbidden thoughts and both contamination/cleaning and doubting symptoms [45]. A large twin study indicated that around 50% of the variance in OCD symptoms was due to genetic factors, that 30–35% of the genetic effect in checking, obsessing, and ordering symptoms was due to specific genetic factors, but that washing symptoms showed no specific genetic factors [40]. Another twin study found evidence of differential associations between OCD symptom dimensions and the genetic overlap with OCD and anxiety disorders [46]. Specifically, sexual/religious and contamination/cleaning symptoms had a stronger genetic association with anxiety disorders than with OCDs; symmetry/ordering and harm/aggression symptoms had a stronger association with OCDs than anxiety disorders, and symmetry/ordering showed a high proportion of specific genetic factors. In most cases, common genetic factors were strongest when considering both anxiety disorders and OCDs in the models. Single gene studies have also reported dimension-specific associations; symmetry/ordering symptoms were associated with the DRD4 dopamine receptor gene [47], and washing symptoms with the HTR3E serotonin receptor gene [48].

Neuroanatomy and neuropsychology

Abnormalities in fronto-striatal functioning are robustly associated with OCD [41], and there appears to be dimension-specific associations with anatomical and functional differences in these brain regions [49]. In studies using whole-brain voxel-based morphometry, symmetry/ordering symptoms were associated with differences in the volume of the left lateral orbitofrontal cortex and insula, aggressive/checking symptoms with differences in insula volume, and washing symptoms with the volume of the premotor cortex [50]. Patterns of striatal functional connectivity also differ across the dimensions; aggressive symptoms were associated with decreased connectivity with the amygdala and increased connectivity with the ventromedial frontal cortex, whereas sexual/religious symptoms were associated with greater connectivity between the ventral caudate and the mid and antero-basal insular cortex [51]. Further, heightened amygdala activation to fearful faces was associated with increased severity of aggressive/checking and sexual/religious symptoms, suggesting that these types of symptoms may be particularly related to abnormal fear processes [52]. Theories of psychopathology are now increasingly informed by neuroscience (see Chapters 94 and 97).

There is also evidence of dimension-specific neuropsychological deficits. Contamination/washing symptoms were associated with deficits in visuo-spatial skills, working memory and attention, and impulsive response patterns; checking was associated with deficits in association learning, and symmetry with poorer verbal fluency; and forbidden thoughts with improved performance on attention and working memory and visuo-spatial scanning [53]. Symmetry/ordering symptoms have been associated with specific forms of neuropsychological impairment (for a review, see [54]); for example, in youth with OCD, symmetry/ordering symptoms are associated with greater deficits in non-verbal fluency, processing speed, and inhibition and switching [54].

Clinical features

A range of clinical features have been associated with OCD symptom dimensions. In those seeking treatment for OCD, forbidden thoughts were associated with higher overall OCD severity, both before and after receiving CBT [38]. OCD-related insight also varied by dimension; higher scores for contamination symptoms predicted poorer insight, whereas higher forbidden thoughts scores predicted better insight [19]. There are also differences in the association between OCD dimensions and broader obsessive-compulsive cognitive domains; symmetry/ordering was specifically associated with perfectionism and intolerance of uncertainty cognitions, forbidden thoughts with importance and control of thoughts cognitions, and doubt/checking with cognitions related to increased responsibility and threat estimation [55]. Contamination/cleaning symptoms were not significantly associated with the examined obsessive-compulsive cognitive domains, suggesting either a lack of specific cognitive associations or associations with cognitions not assessed by the study measure.

Suicidal ideation and behaviours have been independently associated with symmetry/ordering symptoms [56] and with sexual/religious symptoms [57]. Sexual/religious symptoms were also associated with poorer social functioning [12]. Another study found specific associations between quality of life and OCD symptom dimensions; contamination/cleaning symptoms were associated with impairment in leisure, social, and health-related quality of life, symmetry/ordering symptoms with social quality of life, and forbidden thought symptoms with health-related quality of life [58].

The onset and course of OCD may also vary across symptom dimensions. In one study, early disorder onset was associated with religious and symmetry obsessions and repeating compulsions [27]. Symmetry concerns had the earliest age of onset of the dimensions, and the presence of forbidden thoughts was associated with a more fluctuating course of illness and reduced chances of reporting a deteriorating course [59]. Contamination/cleaning symptoms were associated with a chronic OCD course [16]. Primary harm obsessions have been associated with higher odds of OCD remission over time [15].

Some studies have explored the association of OCD symptom dimensions with other demographic variables. For example, those with tic-related OCD report an earlier age of onset for cleaning symptoms than those without tics [59]. Symptom dimensions may also vary by gender; females report a greater frequency and severity of harm/aggression and contamination/cleaning symptoms, whereas males report a greater frequency and severity of sexual/religious symptoms [13]. Although symmetry/ordering frequency did not differ by gender, it was reported as more severe by females.

There is also evidence that symptom dimensions may be associated with different comorbidity profiles [9]. Sexual/religious symptoms were specifically associated with mood disorders, panic/agoraphobia, social phobia, separation anxiety disorder, non-paraphilic sexual disorder, somatoform disorders, body dysmorphic disorder, and tic disorders. Harm/aggression symptoms were associated with comorbid post-traumatic stress disorder, separation anxiety, impulse control disorders, and excoriation. Contamination/cleaning was associated with hypochondriasis. Interestingly, there were no specific comorbidity associations for symmetry/ordering symptoms. In a different study of siblings with OCD, forbidden

thoughts were associated with higher odds of comorbid major depressive and bipolar disorders, hypochondriasis, separation anxiety disorder, tic disorder, and body dysmorphic disorder; symmetry/ordering symptoms with higher odds of alcohol dependence, bulimia nervosa, and attention-deficit/hyperactivity disorder; and contamination/cleaning symptoms with separation anxiety disorder [42].

Overview of findings

Studies have replicated a multi-dimensional model of OCD symptoms across individuals from different developmental stages, cultural backgrounds, and recruitment settings. Further, there is support for dimension-specific associations in genetic, neural, and clinical features of OCD. However, future research should focus on further characterizing the nature of these dimensions to resolve discrepancies across studies. Further development of assessment measures and statistical techniques is also required to better assess these dimensions. Consistency in identified dimensions will allow clearer comparisons across studies and may help to clarify associations with meaningful clinical variables. Despite these limitations, there is evidence that OCD symptoms comprise several overlapping dimensions that have differential associations to important aetiological and clinical variables.

Summary

Important research advances have led to an improved understanding of the core features of OCD and to the reclassification of OCD in DSM-5 and ICD-11. A core focus of OCD research has been to better understand the heterogeneous presentation of the disorder, with the aim of identifying meaningful disorder subtypes. Studies attempting to classify participants using features like age of onset, tic status, or primary symptom types have largely been superseded by the multi-dimensional model of OCD symptoms. This notion that OCD symptoms can be understood as a number of overlapping symptom dimensions has received support across a wide range of studies. Further, there is evidence of dimension-specific associations across studies of family history and genetics, neuroanatomy and neuropsychological functioning, clinical features, and treatment response. The multi-dimensional model of OCD thus provides a framework for an improved understanding of OCD.

Basic mechanisms of, and treatment planning/targets for, obsessive–compulsive disorder

Eric Burguière and Luc Mallet

Introduction

As described in Chapter 93, obsessive–compulsive disorder (OCD) is a condition featuring obsessions (intrusive ideas) and compulsions (repetitive behaviours such as checking, washing, or iterated thought patterns) associated with high levels of anxiety, and conservative estimates suggest it may affect 2.9 million persons across the EU (that is, 0.7% prevalence) [1]. The most severe forms lead to high costs both for the individual and society as a whole [2]. While there are currently many validated pharmacological and psychotherapeutic treatments for OCD, 20–30% of patients do not respond to them [3]. This is particularly problematic, given that 10% of these patients show severe symptoms (for example, compulsions taking >4 hours/day), resulting in high social and financial burdens to both families and society in general.

In this chapter, we describe some promising approaches that have been developed in recent decades to better understand the functional and pathophysiological basis of OCD at various different levels, including:

- Improved understanding of functional impairments and behavioural dimensions that most affect patients (*macro-scale level*).
- Characterization of dysfunctional brain activities and their related neural circuits (*meso-scale level*).
- Identification of specific cell type and neuronal assemblages implicated in obsessive and/or compulsive disorders (*micro-scale level*).

Importantly, we refer to studies carried out both on humans and animal models, providing a wider range of tools to investigate the dysfunctional neural activity associated with this condition. In particular, we consider the extracellular recording of single neurons at different brain sites during specific behaviours and also the recent development of optogenetic approaches that allow the study of neural activity with a high degree of spatial, cellular, and temporal specificity. Despite the major challenges and limitations in conducting such a translational approach across species, we believe that

it offers the best means of unravelling the neural basis of psychiatric diseases [4, 5]. Our description of studies in human is complemented and extended in Chapter 97.

We do not aim exhaustively to review all the possible therapeutic strategies to treat OCD here but will illustrate the potential of a multi-level approach using powerful, recently developed tools to develop new treatments for OCD, using some relevant examples.

Expanding the toolbox to find relevant targets for OCD

Numerous studies on OCD patients over the past two decades have consistently identified abnormal patterns of activity in one neural circuit in particular—the cortico-basal ganglia (CBG) loop [6], which is known to serve both motor and cognitive functions. Anatomical and functional studies of the CBG provide further evidence of their role in the parallel processing of sensorimotor, associative, and limbic information arising from topographically and functionally distinct cortical areas [7]; sensorimotor, associative, and limbic information appears to be segregated along a dorsolateral to ventromedial axis within the CBG (Fig. 94.1).

These circuits are used to differing extents during the learning of a behaviour (either motor or cognitive). While the ventral loop—the ‘reward circuit’—is more important during initial behaviour acquisition, it is the dorsolateral loop that is crucial once learning becomes habitual [7, 8, 9]. Recent studies have supported the view that the dorsomedial and the dorsolateral striatum complement each other in the elaboration and consolidation of learnt behavioural sequences. This associative CBG loop is essential in linking contextual information with its appropriate motor response. The associative loops can therefore modulate the action of sensorimotor loops in the control of stereotyped actions [10, 11].

This organization within distinct functional loops has been characterized in the context of the pathophysiology of OCD through

Fig. 94.1 Schematic illustration of the convergence of projections from the cerebral cortex (CX), caudate nucleus (CD), and globus pallidus (GP) in the basal ganglia. Different colours represent the types of information processed through the CBG: limbic (light blue), associative (dark grey), and sensorimotor (light grey).

Adapted from *Proc Natl Acad Sci*, 104(25), Mallet L, Schüpbach M, N'Diaye K, *et al*, Stimulation of subterritories of the subthalamic nucleus reveals its role in the integration of the emotional and motor aspects of behaviour, pp. 10661–10666, Copyright (2007), with permission from National Academy of Sciences, U.S.A.

a number of studies on both human and animal models. In recent years, novel investigative techniques have emerged while more established methods have improved, allowing more detailed studies of dysfunctional brain circuits and the neural basis of OCD.

Animal models

Detailed experimental evidence on the role of the different CBG loops in OCD is scarce in human subjects, mostly due to ethical issues arising from the use of invasive procedures and the time and spatial specificity constraints inherent in non-invasive imaging techniques. For these reasons, and with the development of genetically engineered mutant mice, we have witnessed the emergence of numerous animal models relevant to OCD-like behaviours within the last decade [12]. These animal models allow detailed study of the specific mechanistic processes that could be altered in OCD treatments; the results of recent studies are promising and point to investigations of specific targets in human patients. Two recent studies have shown that in a mouse model expressing compulsive-like behaviour, compulsions could be drastically reduced by targeting the lateral orbitofrontal cortex (OFC) and the medial part of the striatum (that is, the caudate in humans) [13, 14]. The combination of animal models of obsessive-compulsive spectrum symptoms with new methods available to neuroscientists should allow to better investigate the links between the genes implicated in OCD-related disorders and the neurophysiological circuits affected and behavioural phenotypes [13, 15–17].

The main characteristics of validating mutant animals as models of OCD are functional (OCD-related behaviour), neurophysiologic (the neural circuits affected by the mutation), and genetic (OCD candidate genes). The most promising mouse models developed so far share common behavioural phenotypes characterized by excessive grooming, which can be interpreted as a proxy for compulsive behaviour in mice, that is, an analogue of abnormal ritualistic and stereotyped behaviours that are overexpressed despite their negative consequences (for example, deleterious skin lesions). From a neural

circuits point of view, there is striking evidence that a mutation in all these mouse models alters the normal functioning of the CBG circuits known to be implicated in OCD (Fig. 94.2).

The introduction of gene mutations causing symptoms related to OCD had anatomical consequences such as a decrease in striatal volume [15], but also more consistently pointed towards dysfunctional synaptic transmission, particularly in the striatum compartment (for example, equivalent to caudo-putamen areas in humans) receiving cortical inputs. These features have been shown following the deletion of genes coding for SAPAP3, Slitrk5, and EAAC1—proteins located post-synaptically in striatal neurons [13, 15, 18]. These mutations had electrophysiological consequences resulting in abnormally hyperactive striatal neurons, supporting the idea that elevated striatal activity is implicated in OCD pathophysiology, as suggested by some imaging studies in human patients [14, 16].

Imaging

Structural connectivity MRI

Diffusion-weighted imaging (DTI) is now a well-established technique to infer brain connectivity based on magnetic resonance imaging (MRI) of the random motion of water molecules in tissues [19] (see Chapter 12). Because this motion is firmly restricted by the sheets of myelin surrounding the axons, the diffusion pattern reveals the main direction of these axons locally. The integration of information on the local directionality of white matter fibres can then be used to infer the entire network of connections within the brain using the tractography techniques now popular.

The directional dependence of molecular diffusion in white matter ('anisotropy') can be used to reconstruct tracts through the brain *in vivo* by assuming that the main direction of diffusion in a voxel indicates the local orientation of white matter fibres [20, 21]. A number of DTI tractography algorithms have been proposed to reconstruct fibre tracts [20]. Tractography enables the investigation of both tract-specific white matter lesions and the changes in connection probability between distinct brain regions (Fig. 94.3).

DTI has been used recently to study the pathophysiology of OCD and possible deficits in neural circuit connectivity in particular. Most of the studies have confirmed the implication of the CBG and its related fibres such as the cingulate bundle, the corpus callosum, and the anterior limb of the internal capsule [22].

Thanks to the increasing resolution and refinement of analytical algorithms in the field of anatomical imaging, it has been possible to discover new connections of interest. For example, the subthalamic nucleus (STN) has only recently been the subject of structural connectivity studies using diffusion MRI. Very few empirical data have yet been collected on the role of this nucleus in OCD, although its direct connectivity to the cortical areas, known as the hyperdirect pathway, has been implicated in action selection and decision-making [23]. A detailed connectivity map of the cortico-STN pathway in OCD patients, compared to healthy subjects, would therefore be of great interest in assessing its involvement in this condition.

With the advent of high magnetic field systems (>3 T) capable of producing strong gradients, diffusion methods have been extended from human to small animal imaging. With such MRI systems, high resolution can be achieved (in the order of 100 microns) and very small structures in rodent brains can be visualized to study the

peripheral nervous system [24], as well as neurodegenerative diseases such as multiple sclerosis, Alzheimer's disease, and Parkinson's disease (PD) [25]. Recently, feasibility studies of DTI tractography have allowed the identification of neural networks in rodent brains in target regions relating to homologous limbic and associative regions [26] (Fig. 94.4).

With the high definition offered by recent MRI systems (up to 17 T), one could hope to detect potential structural differences in the CBG circuits between wildtype and animal models of OCD. One of the main advantages using anatomical connectivity in these models is that these data can be compared to the functional connectivities which can be finely characterized in animal models by using innovative investigative tools (for example, dense chronic single neurons recording and/or optogenetic neuromodulation).

Functional connectivity MRI

Once the anatomical features of a given circuit are established, the next challenge is to describe its functional aspects. Such characterization may be achieved by analysing the long-distance synchronization between structures connected by the circuit.

By using fMRI [for example, echo planar imaging (EPI)] to measure the slow changes in blood oxygenation level-dependent (BOLD) signal across distant brain regions, one can identify connected networks. This technique allows the detection of spontaneous patterns of functional connectivity MRI (fcMRI). In recent years, the fcMRI approach has identified large-scale brain networks interacting, while the subject is at rest, as well as while engaged in an active task. Across neurological and psychiatric disorders, abnormal patterns of fcMRI have been interpreted as correlates of altered brain-scale network functioning, so providing a potential marker for abnormalities in information processing. For example, recent studies of fcMRI in OCD have reported changes in functional coupling between the striatum and frontal regions, compared to healthy controls. Nakame *et al.* [27] found increased functional connectivity between the ventral striatum and the OFC and ventral medial prefrontal and dorsal lateral prefrontal cortices of subjects with OCD using this method. Similarly, Harrison and colleagues

[28, 29] consistently found that this augmented functional connectivity between the OFC and the ventral striatum was positively correlated with OCD severity. However, in the particular case of the associative-limbic hyperdirect pathway, the small volume of the STN (relatively to the typical voxel size used with functional imaging, for example 2 mm isotropic) poses special difficulties.

At the whole-brain scale, functional imaging of OCD points towards hyperactivity in the limbic and associative cortical regions [anterior cingulate cortex (ACC) and OFC] and related basal ganglia areas [30]. Additionally, studies from our groups and others identified abnormalities in the CBG circuits in OCD. Indeed, in fMRI studies of OCD patients, abnormal haemodynamic responses in the OFC and ACC may decrease as patients improve either through deep brain stimulation (DBS) therapies [31] or psychotherapy [32]. These data support the involvement of limbic/associative frontal-basal ganglia loops in OCD and suggest that their dysfunction might result in pathological doubt, obsessive anxiety, and compulsive behaviours.

Neural recording and neuromodulation

Electrophysiology and long-range synchronization

Unlike metabolic measures, electrophysiological recordings provide a unique source of information to assess long-distance synchronization at sub-millimetre scales with sub-millisecond resolution. Two main types of signal can be recorded—either using micro-electrodes (diameter <50 µm), which allows the identification of spike activity, and therefore single- or multi-neuron activities; or macro-electrodes (diameter >500 µm), which collect local field potentials (LFPs) that sum the relatively low-frequency (<150 Hz) electrical activity of millions of neurons and their afferences in the area surrounding the tip of the electrode. The micro-electrodes are typically used in animal studies, but they can also be used during DBS neurosurgery to confirm the targeting of the intended structure. In DBS-treated patients, LFPs may be directly recorded from the definitive stimulating electrodes, while their leads are still externalized prior to connection to the pulse generator.

To date, electrophysiological assessment of long-distance network connections has been little used in OCD patients. Most recently, simultaneous recording of the STN, LFPs, and cortical activity from scalp measurements [such as magneto- or electroencephalography (MEG/EEG)] has allowed the identification of long-distance coherence between the STN and motor cortical areas, in specific frequency bands (alpha and beta, 7–12 Hz and 13–35 Hz, respectively), suggestive of the involvement of the motor hyperdirect pathway [33, 34]. Interestingly, functional connectivity measures using electrophysiological recordings have been conducted on DBS-treated PD patients and shown increased values at higher frequencies when levodopa was concurrently administered to improve motor symptoms.

Characterizing the differences in neural activity between OCD patients and unaffected subjects would show how neural activity within elements of the CBG pathway is altered in DBS-implanted OCD patients and provide valuable data on the functional interactions between the various brain areas. By providing insight into how limbic cortical activity is co-ordinated with subcortical activity, such analyses would be crucial in understanding the pathophysiology of OCD and begin to dissect the mechanisms by which DBS functions in OCD patients. Finally, these data could lead to novel DBS technologies to target specific pathways to normalize the information transfer along the cortico-subcortical pathway that is disrupted in OCD.

Deep brain stimulation

DBS (see Chapter 19) represents a promising type of intervention for severe, resistant forms of OCD, based principally on the serendipitous observation that DBS of the basal ganglia can reduce OCD symptoms in those patients suffering from comorbid OCD [35, 36]. Independent studies have proposed multiple targets in the CBG for DBS in OCD, such as the anterior limb of the internal capsule and the STN [37–39] (Fig. 94.5), as an alternative to stereotactic lesional neurosurgery. But progress has been limited by the lack of understanding of the pathophysiology of OCD at both the neural

and behavioural levels and how DBS operates on these brain circuits and their functions. Two meta-analyses have suggested that OCD symptoms showed a mean improvement of 45% after 3–36 months of DBS, with 60% of patients being considered responders (>35% reduction in OCD severity) and found no significant differences between the brain structures targeted [40, 41]. Yet according to Kisely *et al.* [40], only one study meets all four of the quality criteria, namely the first randomized double-blind study performed on 16 OCD patients which showed that 3 months of DBS of the STN is sufficient to decrease OCD severity [38]. Only a few studies report long-term efficacy (>3 years) and sustained toleration of DBS in OCD patients. Stimulation of the nucleus accumbens, the ventral caudate/ventral striatum and the anterior limb of the internal capsule, and the bed nucleus of the stria terminalis have been associated with a median reduction of 46%, 36–64%, and 45% in OCD severity, respectively, 36–171 months after surgery [42–45, 45a].

Understanding the contribution of cortico-subcortical circuits to OCD pathophysiology and therapeutic interventions therefore represents a major challenge in improving the selection of candidate patients and the optimization of treatment strategies. As recognized by various authors [46], traditional nosography—even when combined with more recent techniques such as brain imaging, has made limited progress in this direction, and novel approaches combining hypothesis-driven experimental studies of endophenotypes, animal models, and neuromodulation may be essential to open the way to translational research for innovative treatments.

As an example, therapeutic mechanisms underlying the action of STN high-frequency stimulation (HFS) involve the hyperdirect pathway. This pathway provides direct cortical inputs to the STN. It was first described in the motor/premotor domain and was considered to act through motor selection [23]. Recent evidence shows a limbic element stemming from the OFC and ACC [47]. Current proposals regarding DBS treatment in humans now incorporate the hyperdirect pathway not only for motor disorders, but also for psychiatric conditions such as OCD [48, 49]. Indeed, the effective target for OCD was the associative-limbic part of the STN-HFS [38], which is the target of hyperdirect afferents from the limbic and associative prefrontal regions (ACC and OFC).

Interestingly, per-operative recordings have revealed that populations of neurons from the associative-limbic part of the STN exhibit electrophysiological correlates of OCD symptoms (for example, repetitive checking [50]). At the cellular level, burst and oscillatory patterns of activity from the associative-limbic part of the STN correlate with OCD symptomatology (across patients) and predict the post-operative long-term response of STN-HFS [51].

However, the nature of the benefit is not clear and difficult to investigate in patients, as the amount of physiological data simultaneously available at each node of the cortico-subcortical loops is limited. Moreover, the use of DBS is today empirically driven. The exact effects of this technique are not known, especially the physiological consequences of such stimulations on the CBG loop [52]. Finally, electrical currents may trigger antidromic effects in afferent neurons, most notably in limbic cortical areas, paralleling the effects shown in cases of Parkinsonism [53].

Optogenetics

The functional deconstruction of neuronal circuits can now be achieved in animal models using optogenetic techniques [54]. These

Fig. 94.5 (see Colour Plate section) Three-dimensional image of electrodes implanted in a DBS procedure. Depending on the stimulating electrode (5) configuration and stereotactic co-ordinates, several anatomical sites can be targeted. Two brain targets are represented in this example: the caudate nucleus (2) and the subthalamic nucleus (2). Other brain structures, such as the substantia nigra (3) and the red nucleus (4), can be used as anatomical landmarks. Adapted courtesy of Jerome Yelnik, INSERM/ICM.

have already been used in rodents to decipher neural codes of basic motor, cognitive, and emotional behaviours [14, 53, 55, 56]. These techniques allow the manipulation of neuronal activity using optical stimulation by expressing, through viral vectors, specific light-sensitive membrane proteins—called opsins—in neural cells. This approach is of great interest in the selective inhibition or excitation of nodes of given targeted circuits and can be used to assess physiological and functional causal links. Using a combination of genetic and stimulation-dependent effects, optogenetics allows a high level of temporal, spatial, and cell type specificity.

It can also be used to overcome certain issues encountered in previous classical approaches. For example, the observation of electrophysiological effects of DBS in OCD patients is challenging because of the electrical artefacts it induces. DBS effects also depend on cell type, active fibres, and nearby structures. These issues could be overcome by taking advantage of the optogenetic technology, which avoids electrical artefacts and allows the stimulation of specific cell types only.

Primary applications of optogenetics have been used to better analyse and understand discrete and specific normal or abnormal behaviours in rodents. To effectively validate and translate this novel knowledge to clinical applications, the next step is to scale up these optical experiments to animal models displaying greater anatomical and physiological similarities with human beings, especially in

complex behavioural abnormalities. In particular, rodents allow for a wide range of tools to be used in order to manipulate the cortex–basal ganglia circuits, yielding models of neurologic and psychiatric disorders.

Using optogenetics in rodents, some recent studies have suggested new targets that could be considered to be causally linked to OCD symptomatology. Optogenetic manipulation of specific brain circuits, such as the orbitofrontal–striatal pathway, could induce or decrease compulsive-like behaviours [14, 57]. Although these brain areas have previously been regularly identified as abnormally active in OCD patients, these studies were the first to show their manipulation could elicit/decrease compulsive-like behaviours. Thus, an optogenetic approach in animal models not only allows the testing of circuit-level hypotheses for OCD, but also challenges further the micro-circuitry within various brain areas. Indeed, genetic studies in human patients have already indicated that genes affecting the serotonergic, dopaminergic, and glutamatergic systems, and the interaction between them, may be affected in OCD and many potential therapeutic targets may arise from these biological systems [58]. Furthermore, Burguière *et al.* [14] focused on a new potential cellular subtype—the striatal interneurons—which may play an essential role in regulating the expression of striatal-dependent behaviours and could be implicated in OCD (Fig. 94.6).

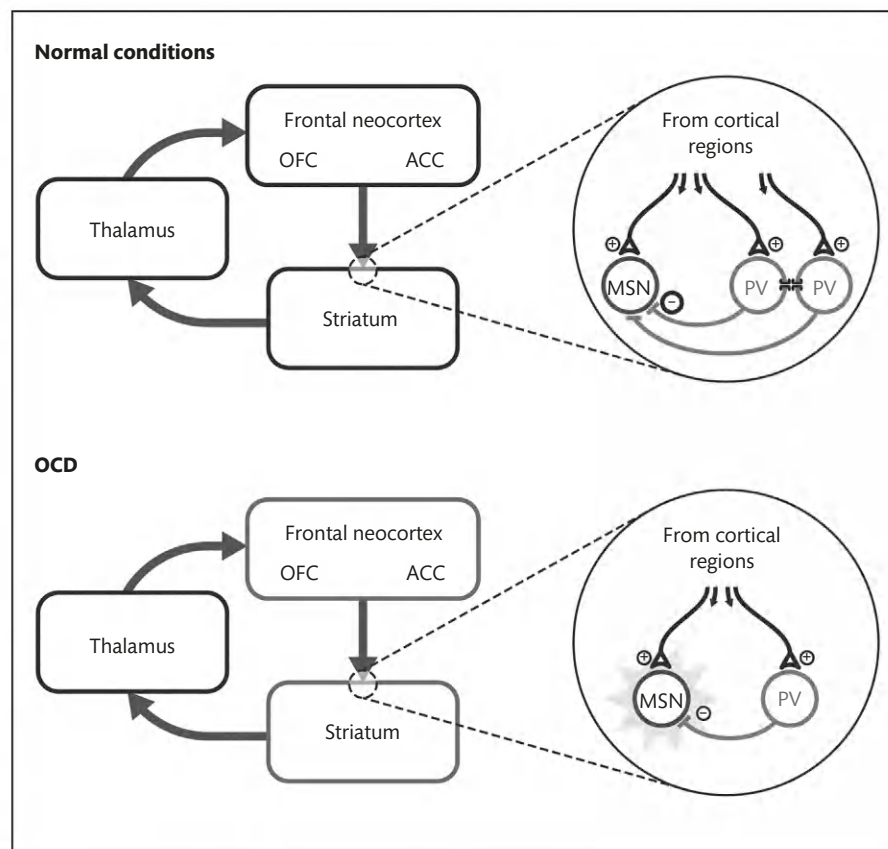

Fig. 94.6 Hypothetical model to illustrate striatal hyperactivity as a consequence of interneuronal network deficiency. Above: in normal conditions, an extensive inhibitory network in the striatum preserves a balance of excitation and inhibition driven by the cortex. Below: in the OCD condition, there is an imbalance towards excitation in the striatal region due to a lack of interneurons. As a result, there will be hyperactivation of the entire CBG loops. ACC, anterior cingulate cortex; MSN, medium spiny neurons; OFC, orbitofrontal cortex; PV, parvalbumin-positive interneurons.

Reproduced from *Curr Opin Neurobiol.*, 30, Burguière E, Monteiro P, Mallet L, *et al*, Striatal circuits, habits, and implications for obsessive-compulsive disorder, pp 59–65, Copyright (2015), with permission from Elsevier Ltd.

In fact, it has been shown that a powerful inhibitory network of parvalbumin (PV)-immunoreactive and cholinergic (Chat)-immunoreactive interneurons is crucial for the functional regulation of striatal networks [59]. Moreover, depending on whether either the sensorimotor or associative-limbic cortico-striatal pathways are affected by a lack of interneurons, the functional consequences can be drastically different. According to human imaging studies, it has been suggested that cortico-striatal sensorimotor pathways (including the dorsolateral part of the striatum equivalent to the putamen in humans) are more likely to be affected in Tourette's patients, while cortico-striatal associative-limbic pathways (including the medio-ventral part of the striatum or caudate nucleus in humans) are more likely to be affected in OCD patients, although some overlap can be observed in the pathophysiology of these behaviours [60–63].

Linking behavioural and neurophysiological endophenotypes of OCD to strengthen target validity

Experimental psychologists and clinicians have performed numerous studies on OCD patients to assess their performance in the main cognitive domains (memory, attention, verbal fluency, etc.) using classical behavioural test batteries. Even if some deficits have been observed, no clear magnitudes of effects for each cognitive domain have been observed using meta-analyses [64–66]. So in order to identify the relevant behavioural dimensions that might be affected by OCD, investigators must focus on more selective cognitive processes. To illustrate this approach, we will discuss three dimensions that could prove dysfunctional in OCD, as well as the underlying brain circuits that play a role in these processes and that often overlap with those identified in the pathology.

Uncertainty monitoring

Compulsive checking is a core symptom of OCD. It is characterized by the urge to verify repeatedly that an action, usually aimed at preventing a possible harm, has been properly completed [67]. The clinical phenomenology of compulsive checking illustrates two hypotheses regarding its psychopathological mechanisms—compulsive checking may proceed from a maladaptive goal-directed behaviour towards uncertainty reduction; or, in the context of habit-driven behaviours, it may result from a failure to control impulses to check. These two alternatives fit nicely into two lines of research on the behavioural functions of the basal ganglia in general, and the STN in particular.

A growing number of studies have expanded the role of the STN from purely motor functions to include higher-level processes such as emotion and decision-making [68, 69]. In PD patients (for whom STN-HFS treatment is most widespread), the STN has been associated with the regulation of behaviour in the face of conflicting stimuli [70], for example postponement when faced with two positively reinforced cues in reward-based motor tasks [70–72]. Conversely, lesion and stimulation studies in animals have also shown that various forms of STN intervention result in premature responses and increased attentional errors [73, 74]. Interestingly, the hyperdirect pathway, which connects the cortical frontal areas to the STN [23], as previously described, could constitute an anatomical route for such

decisional signals whereby behaviour is regulated according to the strength of the sensory evidence. Indeed, the hyperdirect pathway not only connects motor/premotor functions, but also the limbic/associative regions, such as the ACC to the anterior-medial STN, precisely the target of DBS in the context of OCD [47]. Considering the role of the ACC and other associative/limbic frontal cortices in action selection and decision-making, one could surmise that the STN receives higher-level decisional signals [69] to regulate a behaviour adaptively.

Recently, new behavioural paradigms have been developed to assess uncertainty monitoring in animals, revealing that, when given the opportunity, rats can adaptively 'opt out' and move on to the next, possibly easier, trial of the task [75, 76]. In such tasks, varying uncertainty about stimulus identity (hence decision difficulty) leads the animal to discard the trials where its response is most uncertain. Indeed, simultaneous electrophysiological recordings have shown that stimulus-related uncertainty is encoded in the spike rate of the OFC neurons. However, despite putative connectivity (via the hyperdirect pathways), it is still unknown whether these uncertainty monitoring signals reach the STN and participate in the regulation of goal-directed behaviour, either to opt out from a trial or to check back at the stimulus.

Paradoxically, empirical studies in humans have reported that repetitive checking, even in healthy subjects, instead of reducing stimulus-related uncertainty, actually decreases subjective confidence [77]. To investigate repetitive checking in the laboratory, we introduced a so-called 'verification task', based on a working memory paradigm in which, on each trial, participants could review the stimulus before proceeding to the feedback. This paradigm allowed us to provoke and assess compulsive checking in OCD patients [78, 79] and also to reproduce this pathological behaviour during the DBS surgery when the patient is awake and behaving [50]. We were therefore able to record the STN from populations of neurons, as OCD patients entered bouts of repetitive checking. The STN showed a significant increase in the population spike rate when the patient was about to perform another checking action, compared to when he/she was about to proceed to the next trial. These results suggest that uncertainty signals anticipating checking actions may be detected in STN neurons [50].

Behavioural inhibition

A different and contrasting line of research has focused on action control [80, 81], comprising behavioural inhibition and the cessation of ongoing motor programmes before they have reached overt expression. According to the classical model of the basal ganglia-thalamo-cortical loops, the major output nuclei of the basal ganglia (the STN and the internal globus pallidus) maintain sustained inhibition at the cortical level via the thalamic relay. To explore behavioural inhibition in humans, clinical [35], functional [68], and electrophysiological studies in DBS-treated PD patients have proved critical, linking successful behavioural inhibition to frequency-specific changes of oscillatory activity within the STN [71], as well as between the STN and prefrontal cortices [82]. As a consequence, a lesion or inactivation of the STN performed in rats leads to impulsive behaviour, characterized by failed inhibition of prepotent responses initiated in the striatum-pallidum circuits [83]. In this context, compulsive behaviour may reflect a functional deficit at the STN level, causing failure to inhibit prepotent

or habitual actions that are produced, irrespective of the behavioural context.

Indeed, neural representations of habitual sequences of actions triggered as encapsulated motor programmes, or 'chunks', have been observed in the striatal circuits of rodents [84–86]. Additionally, perturbation of the fronto-striatal circuitry could indeed modulate the execution of habitual actions and prevent compulsive behaviour, as has been shown using optogenetic manipulation in mice [14] and DBS in OCD patients [31]. Therefore, the fronto-striato-pallidal pathway may play an important role in the emergence of motor programmes and, if dysfunctional, provoke their overexpression, leading to compulsive behaviours. Complementary to the cortico-striatal pathway, the cortico-STN pathway (that is, the hyperdirect pathway) has been shown to stop habitual behaviours before they reach completion [82, 87]. In this context, compulsive behaviour may reflect a functional deficit which fails to inhibit prepotent or habitual actions that are produced, irrespective of the behavioural context.

Behavioural flexibility

OCD in humans is characterized by repetitive behaviour, performed through rigid rituals. This phenomenological observation has led to exploration of the idea that OCD patients have diminished behavioural flexibility (that is, the ability to change one's behaviour according to contextual cues). Behavioural flexibility may be challenged in experimental tasks such as reversal learning paradigms. In these tasks, the participant has to respond to either of two visual stimuli. In the deterministic version, one stimulus is positively rewarded while the other is not. Unbeknown to the participant, the reward contingencies are reversed after a certain number of trials, so that the previously neutral stimulus is now rewarded while the previously rewarded stimulus is not. In this deterministic version, healthy adult humans immediately detect the change in contingencies and start responding to the other stimulus. In addition, the task may be rendered more challenging using a probabilistic version of it [88]. Here, the reward is not systematically delivered after the subject has chosen the rewarding stimulus, providing uncertainty regarding the current state of the reward contingencies. Only after having collected enough evidence that the previously reinforced stimulus has changed, will the participant shift to the newly (but still varyingly) reinforced stimulus. Performance in reversal learning is scored according to the number of persistent errors committed when participants maintain their response towards previously reinforced stimuli in spite of a negative reward. At the brain level, behavioural flexibility tasks, and reversal learning in particular, appear to engage the OFC and ACC regions. In a 2006 study, Remijnse *et al.* [89] showed that OCD was associated with a reduced response in the orbitofrontal–striatal network during adaptive switching to the new stimulus reinforcement regime. Using a different type of behavioural flexibility task, Chamberlain *et al.* [90] has demonstrated that OCD patients, as well as their relatives, show diminished OFC responses to behavioural adaptation triggered by the task, pointing towards the existence of an OCD endophenotype. Interestingly, in PD, STN stimulation has a beneficial effect on mental flexibility and working memory [91] and on cognitive flexibility, as expressed by the inhibition of habitual responses tested in a random number generation task [92]. Unsurprisingly, similar behavioural tasks have long been used with mice using various response modalities (T-maze, lever

press, nose-poke), and animal studies have confirmed the role of OFC or OFC homologous regions in behavioural flexibility.

Conclusions

Within the last decade, a multi-dimensional approach has been proposed to better link clinical observations with the increasing amount of data obtained in biological psychiatry studies [93, 94].

In fact, the integrative view of complementary research fields, including neuroimaging, genetics, experimental psychology, computational psychiatry, and animal models, has led to a redefinition of OCD nosography and its heterogeneous expression. In the future, further insights may come from studies combining different fields, as illustrated by recent pioneering work with OCD patients which has combined computational and neurophysiological approaches [95] or experimental psychology with neuroimaging [96]. The identification of new targets using such complementary approaches could also be used to develop entirely novel animal models of psychiatric diseases. It would open the way to developing new ideas by manipulating brain circuits, for example using optogenetic manipulations that would reproduce relevant aspects of the OCD symptomatology.

To analyse and understand abnormal behavioural functions in OCD patients, a promising perspective comes from the recent field of computational psychiatry. It sets out to investigate the changes in elementary cognitive processes in dysfunctional patients, such as behavioural flexibility or uncertainty monitoring, as described previously. Using the computational approach, researchers try to infer the hidden variables and states associated with the computations the brain might use when performing a task. Indeed, mathematical models of how choices emerge from elementary computations can potentially bridge the gap between neural activities and the behavioural choices.

A more translational and comprehensive approach that integrates novel fields of fundamental and clinical research should therefore be used to unveil the neurobiology of OCD and possibly lead to the development of more effective treatments.

Obsessive–compulsive disorder

Lior Carmi, Naomi A. Fineberg, Oded Ben Arush, and Joseph Zohar

Introduction

Up to the early 1980s, obsessive–compulsive disorder (OCD) was considered a rare (less than 0.5%) treatment-refractory, chronic condition of psychological origin. Dynamic psychotherapy was widely used and yet had little benefit; this was also the case for pharmacological interventions [1].

The observation that clomipramine, a tricyclic drug for depression with a serotonergic profile, is effective in treating symptoms of OCD [2, 3] has increased clinical interest in this disorder, including its epidemiology; several researchers have since reported a prevalence of OCD of about 2% in the general population [4, 5]. However, changes to the diagnostic system, especially the addition of OCD-related disorders (OCRDs) to OCD (and creating the OCD cluster) [6], have dramatically increased the calculated prevalence of this cluster to close to 9%.

Diagnosis

The diagnosis of OCD according to DSM-5 criteria is based on the presence of either obsessions or compulsions, which cause marked distress, are time-consuming (more than an hour daily), or significantly interfere with a person's normal routine and social and occupational activities. Notably, in DSM-5, two specifiers were added: the degree of insight (ranging from good or fair to absent) and the presence (or absence) of tics.

According to DSM-5 [6], obsessions are repetitive, intrusive, and distressing thoughts, ideas, images, or urges that are often experienced as meaningless, inappropriate, and irrelevant, and persist despite efforts to suppress, resist, or ignore them. Compulsions are repetitive, stereotyped behaviours and/or mental acts that a person feels driven to perform as a standalone urge or as a perceived reaction to an obsession. Though such intrusive thoughts and ritualistic behaviours are also frequently reported in the general population [7–9], those seen in OCD are considered psychopathological as they are time-consuming and cause marked distress and significant functional impairment [10]. OCD can express itself in various ways. The

obsession component includes: dirt/germs, aggression/harm, religious/moral issues, and sexual obsessions. The compulsion component include: washing, checking, ordering, counting, reassurance seeking, and symmetry acts and various mental compulsions [11].

In accordance, a common expression of OCD is an obsession around dirt or 'germs', together with washing or avoiding presumed contaminated objects (door knobs, electrical switches, newspapers, peoples' hands, telephones, etc.). It contains 'hard-to-avoid' substances (for example, faeces, urine, dust, or germs), to the extent that individuals sometimes avoid leaving home. Another common expression of OCD involves pathological doubt, which is frequently accompanied by a compulsion to check. For example, the person may need to check whether the oven is turned off or the front and back doors are closed—the checking may involve many trips back home to recheck what was already checked. In OCD, the checking procedure, instead of resolving uncertainty, often contributes to even greater doubt, which leads to further checking. Other common expressions of OCD are related to the fear of causing harm, for example by being neglectful (for instance, an obsession of hurting someone while driving, leading to driving back towards the relevant spot repeatedly and checking no one was hurt).

The need for symmetry or precision, which may interfere with task completion and result in pathological slowness, is another presentation of OCD. For those patients, it can take hours to eat a meal or shave, in an attempt to do things 'just right'. Other common expressions include hoarding, involving the urge to accumulate and difficulty with discarding objects ('What if I will need it?') and religious obsessions (fear of blasphemy).

At times, patients complain of intrusive thoughts without noticeable compulsions. However, such patients are often found to be engaging in mental compulsions, for example mental checking or analysing (for instance, whether the intrusive thought exists).

Several studies [12–16] have used factor-analytic methods to systematically examine the structural characteristics of OCD symptoms, revealing four main obsessive–compulsive (OC) factors:

1. Aggressive/sexual/religious/somatic obsessions accompanied by checking compulsions.

2. Symmetry obsessions accompanied by ordering and arranging/counting/repeating compulsions.
3. Contamination obsession accompanied by cleaning compulsions.
4. Hoarding obsession accompanied by hoarding and collecting compulsions.

Other theories [17–20] have suggested that the heterogeneity of OCD may be better understood with two core dimensions: harm avoidance and sense of incompleteness. They suggested that OCD is characterized either ‘by anxious apprehension and exaggerated avoidance of potential harm’ (for example, washing, repugnant obsessions, harm-avoidant checking) or alternatively by attempts to reduce feeling of incompleteness (for example, symmetry, counting, repeating, slowness). Interestingly, these feelings of incompleteness were first described in 1903 [21] as a central phenomenological feature of OCD, according to which OCD patients are tormented by the feeling that their actions are incompletely achieved or do not produce the expected satisfaction. Their inability to achieve ‘closure’ concerning actions/perceptions leads to what later was labelled as the ‘not just right experience’ (NJRE) [22, 23].

However, it should be noted that recent studies [24] documented that obsession may not always precede compulsion, as the traditional acronym OCD suggests. Alternatively, the pathological loop may start with the actual urge to perform the compulsion (not as a purposeful, goal-driven act, but as a habit), while the obsessional component develops later as a secondary phenomenon. The acronym OCD may be used to describe this course of illness.

Indeed, obsessions and compulsions are not necessarily rationally related; hence, a patient might perform a compulsion of clapping hands in a specific way, in order to prevent an obsession of being contaminated with germs.

Most patients present with multiple obsessions and compulsions. The symptoms may shift over time; for example, a patient who had washing rituals during childhood may present with checking rituals as an adult [19, 20].

As OCD symptoms are usually embedded within the updated culture and technology, it often assimilates with the frequent usage of the Internet and smartphones in daily life. Harnessing this technology into compulsive behaviours (for example, compulsive checking of emails/posts, taking photos as another presentation of list makings, electronic hoarding, etc.) might not always be diagnosed, since it often camouflages as proper Internet use.

Diagnosis and differential diagnosis

As OCD has diverse expressions, the diagnosis, as well as differential diagnosis, requires careful and thorough evaluation.

The NICE guidelines include five simple questions that might help identify OCD (Box 95.1) [25]. These questions are recommended whenever a mental status examination is carried out; since patients tend to hide their symptoms (due to the ego-dystonic nature of OCD), asking direct, specific questions is often the only way to diagnose OCD.

Another clue may be past or current tics (including vocal tics) and a family history of OCD or OC spectrum disorders (OCSs) which include: hoarding disorder; body dysmorphic disorder (BDD); and body-focused repetitive behaviours such as trichotillomania (hair pulling), onychophagia (nail biting), and excoriation (skin picking). Personal distress and functional impairment, which are required for

Box 95.1 Quick screen for obsessive-compulsive disorder

- Do you wash or clean a lot?
- Do you check things a lot?
- Is there any thought that keeps bothering you that you would like to get rid of but can't?
- Do your daily activities take a long time to finish?
- Are you concerned about orderliness or symmetry?
- Do these problems trouble you?

diagnosis, differentiate OCD from ordinary or mildly excessive worries, thoughts, and habits.

Psychiatric diagnoses that show a presentation similar to that of OCD include schizophrenia, depressive disorder, post-traumatic stress disorder (PTSD), social anxiety, eating disorder, and phobias. The importance of an accurate diagnosis is due to the uniqueness that underlines the treatment, as well as the course, prognosis, and therapeutic goals for these disorders. Severe, bizarre, and incapacitating OCD symptoms, especially when accompanied with a lack of insight (delusions), are often misdiagnosed as schizophrenia. By introducing the lack of insight specifier and by restricting the diagnosis of schizophrenia to only those with primary symptoms, DSM-5 might help to reduce such misdiagnoses.

At times, OCD symptoms may appear as a phobia. While the classic phobic objects are avoidable (for example, tunnels, dogs, elevators) and the anxiety is reduced in the absence of the stimulus, the ‘phobic’ stimulus in OCD are often unavoidable (for example, germs, dirt, radioactive waves, etc.).

Major depressive disorder (MDD) is frequently associated with ruminations that are mood-congruent and, unlike OCD, usually involve beliefs of personal failure related to past events. Although MDD is common in OCD, in the majority of cases, the OCD had started first and depression developed later as a secondary response to the substantial difficulties resulting from OCD.

Epidemiology

Prevalence

OCD is a global phenomenon, with substantial similarity across cultures in symptom clusters, gender distribution, age of onset, and comorbidities [26]. However, regional and historical variations in symptom expression exist, and cultural factors may shape the content layer of obsessions and compulsions (for example, contamination by syphilis in the past and by AIDS nowadays; repetition of prayers by religious individuals vs personal mantras in secular persons).

Using the restricted DSM-IV definition (that is, not including OCD-related disorders), the lifetime prevalence of OCD in the general population was calculated at 2–3% in a number of seminal studies [4, 27]. Those percentages have been confirmed across cultures [5] and support the biological basis of OCD. Although the cultural, economic, and social factors play a role in the presentation of

OCD (that is, the content of obsessions and the shape of the compulsions), yet its prevalence is equally distributed across the globe.

More recent large-scale cross-sectional surveys of US and European citizens using diagnostic instruments compatible with DSM-IV produced a more conservative estimate of a 1.6% [28, 29] and 0.8% [30, 31] lifetime prevalence, respectively. In contrast, a detailed longitudinal prospective study of community respondents in the Swiss Canton of Zurich, [32], that additionally looked for subthreshold forms of OCD, reported a prevalence rate of 3.5% for OCD (males: 1.7%; females: 5.3%), 9.7% for obsessive-compulsive syndrome (males: 1.7%; females: 5.3%), and 11.2% for obsessive-compulsive symptoms (males: 13.7%; females: 8.8%). Thus, in this study, taking into account the whole spectrum of obsessive-compulsive symptomatology, over 10% of the population were affected.

In DSM-5, OCD was separated from the anxiety disorders and categorized within a new diagnostic category ('Obsessive-compulsive and related disorder'), which includes, in addition to OCD, disorders such as: hoarding disorder; BDD; and body-focused repetitive behaviours such as trichotillomania (hair pulling), onychophagia (nail biting), and excoriation (skin picking). Considering this spectrum-oriented view of OCRDs, the cumulative prevalence of OCRDs is much higher than that of OCD alone. Summing up the prevalence of the individual OCRDs (Table 95.1) and factoring in the comorbidity rates, the overall prevalence of OCRDs as a group could be as high as 9.5%.

Gender

OCD is overrepresented in females (around 1.5:1) [32], and gender differences in the pattern of symptom dimensions have been reported. For example, females are more likely to have contamination obsessions and symptoms in the cleaning dimension and males are more likely to have symptoms in forbidden thoughts and religious and symmetry rituals [41]. Males are more prone to be associated with significant interference in life; for example, two-thirds remain single vs only one-third of women. Moreover, almost half of male patients continued to live with their original families or in assisted homes, compared with only 20% of women. These rates might be due to the relatively earlier onset of the pathology in males [41] or the different course of OCD in males vs females.

Course of OCD

The onset of OCD is often spontaneous; however, in some cases, OCD symptoms follow a stressful or traumatic event (for example, pregnancy, labour, accident, etc.) [42, 43]. Due to the secretive

nature of the disorder, there is often a delay (of up to several years [44]) before patients are adequately diagnosed. However, the delay may shorten with increased public awareness to the disorder, for example through articles, books, and movies, and if specific questions regarding OCD are included in the mental status examination (Box 95.1).

The course is usually chronic; yet some patients experience a fluctuating course [45]. In a 40-year longitudinal study (1953–1993), during which no effective and long-lasting therapies were available, the duration of illness was chronic for most patients, with half still experiencing clinically relevant symptoms and another third sub-clinical symptoms at 40 years' follow-up [46]. Among those followed up for half a century since onset, 37% still had OCD. Although, in the study, most patients showed some improvement along the years, complete recovery occurred in only about one-fifth of patients. A study prospectively examined 113 OCD patients (all of whom had a history of at least one other comorbid anxiety disorder) and found that the probability of OCD remission was 0.16 at year 1 and reached 0.42 by year 15 [47]. For those who remitted, the probability of recurrence of OCD remained low, approximating 0.25 from year 5 onwards. Those who were married and those without comorbid MDD were more likely to enter remission. A relatively high rate of remission at a specialist paediatric OCD clinic was also found in a 2010 study [48] where approximately 60% of 142 young people with OCD assessed at baseline did not have a full clinical syndrome of OCD after up to 9 years. However, approximately 50% of participants were still receiving treatment and about 50% expressed a need for further treatment. In the same study, the main predictor for persistent OCD was the duration of illness at assessment. Indeed, a meta-analysis of 22 studies ($n = 521$) of child/adolescent-onset OCD found that earlier age at onset and increased duration predicted persistence of illness [49].

Environmental factors like family accommodation or compliance with OCD symptoms are also important variables. Those kinds of family interactions, while understandable, can be destructive. For example, answering reassurance questions or participating in avoidance behaviours (for example, 'I will open the door for you so you will not need to wash,' 'I will turn the stove off so you will not need to check,' etc.) stands as a significant barrier to recovery.

Age at onset of OCD

The mean age at onset of OCD has traditionally been reported to be late adolescence [50–52], with a range of 10–22 years [32]. However, recent studies report an even earlier mean age at onset of around 15 years [53], with onset after 30 years being uncommon

Table 95.1 Summary of prevalence of OCRD

Disorder	Prevalence	Comorbidity with OCD	Net prevalence (prevalence - comorbidity)
Body dysmorphic disorder	1.9–2.2% [33]	30–35% [34]	1.4%
Hoarding disorder	2–5% [35]	8–35% [36]	2.4%
Trichotillomania (hair pulling disorder, HPD)	0.6–2% [37]	13% [38]	1%
Excoriation (skin picking disorder)	1.4–5.4% [39]	16% [40]	3%

Net prevalence equals prevalence (mean) minus comorbidity (mean).

Comorbidity equals comorbidity (mean) times prevalence (mean).

Sum of OCRD = 1.6% (OCD) + 1.4% (pure BDD) + 2.4% (pure hoarding) + 1% (pure trichotillomania) + 3% (pure skin picking disorder) = 9.4% (OCD).

[54]. Females are overrepresented in late-onset OCD (around 1.5:1), while in the earlier onset of illness grouping, males are more representative [55]. Nearly 25% of males have an onset before the age of 10 years [56].

In a 40-year longitudinal study [46], early-onset OCD was associated with poorer outcome, especially in men. More recent studies have reported a negative correlation between age at onset and duration of illness [53]. Additionally, an association between early onset and greater symptom severity [57], male gender [58], genetic loading [59], [60], severity of compulsions [61], poor insight [62], co-occurring tic disorders [63], hair pulling [64], multiple anxiety disorders [61], and OC personality disorders [65] has been identified.

Late-onset OCD may include cases of OCD that have been developed after exposure to traumatic events (post-traumatic OCD) [66]. Females may develop OCD in pregnancy or after parturition or miscarriage [42].

OCD and suicidal risk

Historically, OCD was considered a psychiatric disorder with relatively low rates of suicidal ideation (which was attributed to its compulsive domain). However, recent studies have challenged this perception and concluded that the risk of attempted and completed suicide among individuals with OCD is substantial [67]. Some authors suggested that suicide risk is more strongly predicted by psychiatric comorbidity, for example rates of comorbid depression and anxiety, rather than OCD itself [10, 11]. However, even when controlling for comorbidity, the risk of suicidality remains significant among OCD sufferers [68], and rates of suicidal ideation ranging between 20% and 46% have been reported [11–15]. Sixty-five per cent of one OCD sample had endorsed at least one of the questions about suicidal phenomena as positive. Of these, 32% had made suicidal plans and 19.4% had attempted suicide [16]. Nevertheless, it is important to note that suicidal thoughts may sometimes be a symptom of OCD (for example, 'I might commit suicide,' 'what is the preferable way to commit suicide'), and not a genuine suicidal ideation.

OCD and insight

Classically, OCD is defined as an ego-dystonic disorder, that is, a disorder in which the patient realizes that the obsessions and/or compulsions are irrational or excessive.

However, keeping in mind the diversity of the disorder, DSM-IV included the subtype of 'poor insight'.

DSM-5 extended the diagnostic boundaries of OCD by allowing to include absent insight or delusions in OCD [6]. Even if the clinician spotted a clear-cut delusion, that is, the individual is completely convinced that the OCD beliefs are true, a diagnosis of OCD may be appropriate. The diagnosis should, however, be based on careful history-taking; in OCD, the disorder usually starts as ego-dystonic and slowly moves on the continuum of insight to delusional symptomatology. Moreover, in the case of OCD diagnosis, other compulsive components (now or in the past) are present and help to differentiate OCD from delusional disorders.

Comorbidity

If another Axis I disorder is present, the diagnosis of OCD requires that the content of the obsessions or compulsions is not restricted to that disorder (for example, a preoccupation with food or weight in eating disorders, or guilt feelings in the presence of a major depressive episode). Similarly, OCD should not be diagnosed if it is due to the direct effects of a substance (for example, a drug abuse or a medication) or a general medical condition.

In a national survey of adults in the United States [44], OCD was associated with substantial comorbidity, not only with anxiety (75.8%) and mood disorders (63.3%), but also with impulse control (55.9%) and substance use disorders (38.6%).

Anxiety disorders

In a lifetime comorbidity community study [69], 73% of OCD patients experienced an anxiety disorder (specifically: GAD 50%, social phobia 40%, agoraphobia 30%, simple phobia 20%, and panic disorder 17%). However, a recent international study reported a more conservative prevalence of comorbidity, with 14% of patients experiencing social anxiety, 13% experiencing GAD, and 12% experiencing panic disorder with or without agoraphobia [26].

Obsessive-compulsive spectrum disorders

An early study by Du Toit and colleagues [70] showed that 57.6% of their OCD sample currently met the criteria for at least one putative OCSD and that 67.1% had a lifetime history of at least one comorbid OCSD. In that study, the OCSDs with the highest prevalence were compulsive self-injury (22.4%), compulsive buying (10.6%), and intermittent explosive disorder (10.6%). More recently, a cluster analysis of OCSDs in a sample of 210 OCD patients identified three separate clusters that were named: (1) 'reward deficiency' [including hair pulling disorder (trichotillomania or HPD), pathological gambling, hypersexual disorder, and Tourette's disorder (TD)]; (2) 'impulsivity' (including compulsive shopping, kleptomania, eating disorders, self-injury, and intermittent explosive disorder); and (3) 'somatic' [including body dysmorphic disorder (BDD) and hypochondriasis] [9]. Along these lines, a report from the International College of Obsessive-Compulsive Spectrum Disorders (ICOCS) showed that rates of comorbid OCSDs were high, particularly given the relatively low base rate of such disorders in the general population [26]. This is consistent with earlier work [4], which has emphasized the high prevalence of tic disorders, as well as of OCSD, in OCD.

Depression and bipolar disorder

The lifetime prevalence for a major depressive episode in individuals with OCD ranges from 40% to 80% [44]. However, depression is usually secondary (that is, the OCD started first). Depression in children and adults with OCD has been related to variables, including an early age at onset, more severe obsessive-compulsive symptoms, lower levels of perceived competence, and family history of recurrent MDD [71]. This comorbidity is often associated with greater illness severity [72] and reduced quality of life [73].

Few studies have identified a greater likelihood of bipolar (especially bipolar-II) disorder comorbidity in OCD, as compared to its prevalence in the general population [44].

Addiction

Up to the 1980s, OCD was regarded as a disorder of 'overcontrol' and the consensus was that substance use would be incompatible with OCD [74]. This notion has been dramatically changed with later studies [75–78], which found a strong association between OCD and substance abuse/dependence (including alcohol). Earlier age at OCD onset was associated with an increased risk of alcohol use disorders, but only comorbid bipolar disorder was associated with an increased risk of drug use disorders, suggesting that patients with early-onset OCD or comorbid BPD may be especially vulnerable to substance abuse disorder [79].

Schizophrenia

Up to 30% of patients with chronic schizophrenia experience OC symptoms, and about 12% of them may be qualified for the diagnosis of OCD [80].

As in OCD in general, the OCD symptoms in these patients do not necessarily surface, unless specific questions are asked. Moreover, compulsive behaviour may be interpreted as 'stereotypic behaviours'. Patients with schizophrenia can distinguish (if properly questioned) ego-dystonic OC symptoms (perceived as coming from within) from schizophrenic ego-syntonic delusions (perceived as introduced from the outside). Follow-up studies demonstrated that a 'schizo-obsessive' diagnosis has stability over the years and is characterized by poor prognosis, especially if appropriate (that is, symptomatic, rather than syndromatic) treatment is not administered [81].

The poor prognosis of patients with schizophrenia and OCD, along with preliminary data regarding their response to a specific combination of treatments [specific drugs for psychosis (for example, amisulpride, ziprasidone, aripiprazole) in combination with serotonin reuptake inhibitors (SRIs)], has led several researchers to suggest that a 'schizo-obsessive' category may be of value [82].

Post-traumatic stress disorder

PTSD–OCD comorbidity and post-traumatic obsessions have been reported [83, 84]. In one study, 41% out-of-combat PTSD patients were diagnosed with OCD, while an additional 6% had subthreshold OC symptoms [66]. No difference was found between PTSD and PTSD–OCD participant characteristics (including demographics, trauma-related factors, and other psychiatric comorbidity). The surprisingly high number of OCD found in this study suggests that PTSD–OCD (post-traumatic OCD) might be underdiagnosed and signifies the importance of direct assessment of OCD in patients with PTSD.

Tic disorder

The high comorbidity with tic disorders raises interesting pathophysiological and therapeutic implications. The rate of tic disorders approaches 40% in juvenile OCD [85, 86], and the prevalence of Tourette's syndrome is increased among the relatives of OCD patients [87]. Due to its high prevalence, tic disorder was introduced as a specifier in DSM-5. Namely, each time that OCD is diagnosed, a specific and extra question needs to be included in order to identify tics. The importance of the specific attention to tics is related to different pharmacological intervention; augmentation (of serotonergic medications) with very small doses of a D2 receptor antagonist (for example, Haldol) or a D2/5-HT2 receptor antagonist (for example,

risperidone) or a partial agonist (for example, aripiprazole) in those cases was repeatedly found to be clinically effective [88].

Prognosis

OCD is traditionally considered to be a relatively chronic disorder [46, 89, 90]. However, some studies reported a more favourable prognosis and outcome [48, 89]. In a prospective, community-based study that followed up respondents for up to 30 years [32], almost two-thirds of individuals with OCD entered a sustained period of remission. The median duration for OCD was 16 years, suggesting a better prognosis for remission for less severe illness. Individuals with a longer duration of illness (more than 14 years) and a greater number of OC-burdened years (more than 5 years) and those seeking professional help (probably due to a more severe condition) experienced significantly delayed remission. In addition, these factors, together with comorbid anxiety and—to a lesser extent—affective disorders, were associated with significantly reduced remission rates.

With adequate treatment [which includes ERP, family guidance, encouragement to return to full activity, and therapeutically appropriate (that is, medium to high) doses of SRI], a significant percentage of patients show considerable to full improvement in their symptoms [91]. Prognosis in children is even better, with up to 80% achieving partial or full remission in a 3-year prospective study [92]. Good prognosis is associated with compliance to treatment of both the family and the patient, good social and occupational adjustment, and less avoidance [45]. The obsessional content does not seem to be related to the prognosis, except for hoarding, which is usually considered to have a less favourable outcome.

Conclusions

OCD is a chronic condition, considered by the World Health Organization as one of the ten most disabling disorders. Two main changes took place in DSM-5 in relation to OCD: the creation of the 'Obsessive-compulsive and related disorders' cluster and the addition of two specifiers to the diagnosis procedure—the degree of insight [ranging from good or fair to absent (delusional)] and the presence (or absence) of tics. OCD is a worldwide disorder, with substantial similarity across cultures in symptom clusters, gender distribution, age of onset, and comorbidities. Mood disorders and other OCRDs are among the most common comorbidities in OCD. While the life prevalence of OCD is about 2% of the population, the life prevalence of OCRD is about 9%.

The mean age at onset of OCD is late adolescence, with a range of 10–22 years. Females are overrepresented in late-onset OCD, while in the earlier onset of illness grouping, males are more representative. Early onset and long duration of illness have been reported to be associated with poor prognosis. OCD is associated with substantial comorbidities, among which anxiety, mood disorders, and other OCRDs stand with the highest prevalence.

As OCD symptoms are usually embedded within the related culture, Internet-related compulsion is becoming more and more frequent. Taking into account its diverse expressions and its ego-dystonic manner/presentation (which make it difficult for patients

to come forward with their symptoms), the diagnosis, as well as differential diagnosis, requires careful and thorough evaluation.

Genetics of obsessive–compulsive disorder

Gerald Nestadt and Jack Samuels

Introduction

Clinicians have long observed that many of their patients with obsessive–compulsive disorder (OCD) have relatives with the disorder, and they have suspected that hereditary transmission underlies this familial aggregation. In an early report in 1936, of 50 cases of ‘obsessional neurosis’, Lewis reported that 37% of the parents and 21% of the siblings of these cases had pronounced obsessional traits; moreover, he noted two pairs of identical twins who were concordant for obsessive–compulsive features [1]. Additional clinical case series of OCD patients and their twins and other relatives have provided presumptive evidence of the inheritance of OCD. Based on these early studies, Slater concluded in 1964 that ‘of all neurotic syndromes, the evidence relating to genetic predisposition is best in the case of obsessional neurosis’ [2].

Since then, abundant evidence has been provided from genetic epidemiological (twin and family) studies to support a genetic contribution to OCD [3]. In contrast, apart from relatively rare instances of OCD associated with brain trauma, ischaemia, tumours, perinatal factors, or β -haemolytic streptococcal infections [4–6], there is limited evidence for a major contribution of environmental factors to most cases of OCD. Therefore, the discovery of specific genes and the functional relevance of proteins encoded by them hold promise for elucidating the molecular pathogenesis of OCD and for developing rational, mechanism-based approaches to its treatment.

Molecular genetic studies of OCD and other neuropsychiatric conditions have advanced rapidly and sequentially over the past 20 years, due to developments in genotyping technology and computational genetics. Initially, efforts were focused on specific candidate genes hypothesized to be functionally related to the disorder in question. Then, genetic linkage studies predominated; as more genetic markers were identified throughout the genome, genotyping became more rapid and less costly, and statistical genetic methods developed. During this scientific phase, the thought was that relatively few genes, that is, those with a ‘major effect’, make a major contribution to the risk of OCD. Subsequently, with recognition that neuropsychiatric conditions are genetically complex, the ‘common disorder–common gene’ hypothesis became predominant, which posited relatively frequent genetic variants, each with a small effect on the risk of disease, ushering in an era of genome-wide association studies (GWAS). As sample sizes increased to the tens of thousands,

relevant findings emerged for several of the complex neuropsychiatric disorders; for example, with a sample of 37,000 cases, 108 genetic polymorphisms were found to be significantly associated with schizophrenia [7]. Nevertheless, these variants, although numerous, appeared to explain only a small proportion of the heritability of these diseases. With decreasing cost and speed of genotyping, and increasing sophistication of computational genetic methods, whole-genome and exon-wide sequencing studies of OCD are now in progress.

Genetic epidemiological studies

Family studies

At least 15 family studies of OCD have been conducted, and their findings support the familial aggregation of OCD. These include the most recent family studies, which used clear diagnostic criteria, direct assessment of family members, and inclusion of families of case as well as non-OCD control probands (that is, the index case or the first person identified in the family). For example, Black and colleagues found that the risk of ‘broadly defined OCD’ (that is, OCD plus subsyndromal obsessive–compulsive symptoms) was substantially greater in the parents of OCD probands (that is, index cases or the first person identified in the family) than parents of controls (16% vs 3%) [8]. Pauls and colleagues found a higher risk of OCD in first-degree relatives of OCD probands than controls (10% vs 2%) [9]. The Johns Hopkins Family Study also found a similarly higher prevalence of OCD in first-degree relatives of case than control probands (12% vs 2% [10], as did Grabe and colleagues in a European family study (10% vs 1%) [11]. Several studies have found even greater differences in the prevalence of OCD in the relatives of case vs control paediatric probands—for example, 23% vs 3% in the study by Hanna and colleagues [12]—suggesting that early-onset OCD may differentiate a strongly inherited subtype of the disorder. In addition, several family studies have found that additional disorders were more prevalent in relatives of OCD than control probands, including generalized anxiety disorder, body dysmorphic disorder, trichotillomania, pathologic skin picking, tic disorders, and obsessive–compulsive personality disorder, suggesting that these may be part of the spectrum of conditions aetiologically related to OCD in these families [13–15].

A statistical approach—complex segregation analysis—has been used to determine if the transmission of OCD in families is consistent with a Mendelian mode of inheritance. The five published studies support a Mendelian model, with transmission of a gene, or genes, of major effect. Three of the studies found that the data were most consistent with a dominant transmission model; however, the data could not reject alternative models such as codominant or recessive [16–18].

Twin studies

Although evidence of familial aggregation is a necessary condition for a genetic contribution to OCD, it is not sufficient, since it does not rule out aggregation due to common exposures of family members to possible environmental factors related to the disease. Therefore, twin studies have been used to contrast concordance of OCD in monozygotic (identical) twins and dizygotic (fraternal) twins, under the assumptions that: (1) monozygotic twins are genetically identical; (2) dizygotic twins share only 50% of their genes, on average; and (3) both types of twins share similar environments. Thus, greater concordance of OCD symptoms in identical than non-identical twins provides further support for a genetic influence. Using the Maudsley Twin Registry, concordance of ‘obsessive symptoms or features’ was found in 13 of 15 (87%) monozygotic twin pairs, but only seven of 15 (47%) of dizygotic twin pairs [19].

Moreover, twin studies have been used to estimate the ‘heritability’ of OCD, that is, the proportion of variation in dimensional obsessive-compulsive symptom scores that is explained by genetic effects, rather than by environmental influences. For example, in 4564 4-year-old twin pairs rated by their parents, the estimated heritability of obsessive-compulsive behaviours was 65%, with the remaining 35% of the variance attributed to unshared environmental influences [20]. Similarly, in 4246 child twin pairs, the estimated heritability of parent-rated obsessive-compulsive symptoms was 45–61%, with unique environmental influences of 42–55% [21].

Thus, twin studies provide further support for a substantial genetic contribution to OCD. However, unshared environmental factors also appear to contribute to OCD and interaction between genetic and environmental factors may be important. Adoption studies comparing twins raised together and apart would provide further evidence of the importance of genetic and environmental factors in OCD, although no such studies have been reported to date.

Molecular genetic studies

Linkage studies

The aim of genetic linkage studies in OCD is to identify chromosomal regions that contain genes for the disorder, by statistically testing whether specific genetic marker alleles cosegregate (that is, ‘travel together’) with OCD in families. Whereas parametric approaches analyse genetic recombination events and need to assume the mode of inheritance, non-parametric approaches evaluate the extent of sharing of marker alleles between affected relatives and do not require assumption about the mode of inheritance. If a linkage peak is identified, ‘fine mapping’ is often conducted by including additional markers to further narrow the linkage region, and family-based association analyses may be conducted to evaluate associations between specific single-nucleotide polymorphisms (SNPs) within these regions and OCD.

Hanna and colleagues were the first to report a linkage scan in OCD, which studied 56 individuals in seven families with a paediatric proband. Using parametric linkage analysis and assuming a dominant transmission model, they identified a linkage peak in the 9p24 region on chromosome 9. This region harbours the glutamate transporter gene *SLC1A1*, which is involved in neurotransmission and is a potential candidate gene for OCD [22]. This finding was replicated by Willour and colleagues in a linkage analysis in 50 OCD pedigrees, using the same 13 genetic markers in the region used by the Hanna group, and pedigree-based association analyses identified two markers associated with OCD in this region [23]. These linkage findings stimulated further studies of *SLC1A1* as a candidate gene for OCD, as described in the next section.

A genome-wide linkage study was conducted in 219 families with multiple relatives affected with OCD, mostly affected sibling pairs, as part of the OCD Collaborative Genetics Study. Using non-parametric linkage analysis, the strongest suggestive linkage signal was found on chromosome 3, in the 3q27–28 region; other suggestive linkage signals were found in regions on chromosomes 1, 6, 7, and 15 [24]. Further analyses provided evidence for different linkage patterns in these families, depending on specific phenotypic characteristics of probands or families. For example, after stratifying families by proband gender, Wang and colleagues found suggestive linkage to the chromosome 11p15 region in families with male probands, and the linkage signal became substantially stronger after fine mapping in this region [25]. In another analysis, families were stratified into those with two or more individuals with compulsive hoarding behaviour and those with one or fewer hoarding relatives. In the hoarding-loaded families, there was significant linkage on the chromosome 14q23–32 region [26].

Findings from linkage studies have provided evidence linking specific chromosomal regions to OCD and suggest that genetic linkage may be stronger for specific phenotypic subtypes of the disorder. However, other than the findings for the hoarding phenotype, all of the regions identified so far have not met the threshold for ‘statistically significant’ linkage. The linkage finding in the 9p24 region was particularly intriguing, given that this region harbours a functional candidate gene for OCD. However, the 9p24 region spans over 7 million base pairs and contains dozens of potential OCD candidate genes; moreover, this region was not identified in the largest genome-wide linkage scan, which found several other regions more strongly linked to OCD. It may be that a greater number of families are required to detect and replicate statistically significant linkage findings. Furthermore, as has emerged from genetic studies of other psychiatric disorders, including schizophrenia and bipolar disorder, OCD may have a complex pattern of inheritance, with multiple genes each exerting a small effect, and genes of ‘major effect’ may be rare in OCD and may occur in only relatively few families.

Candidate gene studies

Genes have been identified as potential candidate genes for OCD, based on their location within linkage peaks and/or knowledge of the pathophysiology and pharmacology of the disorder. The neuronal glutamate transporter gene *SLC1A1* was hypothesized as a primary candidate gene for OCD, based on its location within a linkage peak, as described; the protein it encodes—a neuronal transporter; and its high expression in the cerebral cortex, striatum, and thalamus, which are regions connected in functional circuits are implicated in

OCD. Several research groups have reported associations between OCD and SNPs in this gene, while another found an association with SNPs about 9 kilobases ‘upstream’ of the gene. Moreover, the findings were specific to families with male probands or to males affected with OCD [27]. These replicated association findings implicating the *SLC1A1* gene in OCD are intriguing, and further investigations of this and possibly other interacting glutamatergic genes are warranted.

Given the therapeutic effect of serotonin reuptake inhibitors (SRIs) in the treatment of OCD, the serotonergic system also has been a major focus of candidate gene studies. Polymorphisms in the promoter region of the serotonin transporter gene (*5HTTLPR*), 5-hydroxytryptamine (serotonin) receptor 1D (*5HT1-D*), and 5-hydroxytryptamine (serotonin) receptor 1D (*5HT2C*) have been reported associated with OCD. Of these the serotonin transporter polymorphism (*5HTTLPR*), located on chromosome 17, has received the most attention. Findings from these association analyses have unfortunately been conflicting. It is interesting that the short (s) allele of this polymorphism is consistently reported associated with anxiety, depression, and neuroticism, whereas it is the long (l) allele often reported to be associated with OCD, although other studies have implicated the S-allele, rather than the L-allele, in OCD. Nevertheless, meta-analyses of polymorphisms in the *5HTTLPR* and *5HT2* genes support an association with OCD [28].

Several studies have found an association between OCD and alleles of the dopamine receptor 4 (*DRD4*) gene on chromosome 11. In some studies, the association was specific to a phenotypic subtype, for example tics or early onset of OCD. Other studies, however, have been negative, as have studies of other dopaminergic genes, including *DRD2*, *DRD3*, and the dopamine transporter *SLC6A3*. Association studies of other genes have been reported, including the catechol-*O*-methyltransferase (*COMT*) gene, the monoamine oxidase A (*MAO*) gene, the brain-derived neurotrophic factor (*BDNF*) gene, and the oligodendrocyte lineage transcription factor 2 (*OLIG2*) gene. Some of the positive findings have been gender-specific. In general, however, the positive findings have not been consistently replicated [28].

Thus, although there have been many reports of a positive association between functional candidate genes and OCD, the lack of consistent replication ‘in the majority of OCD psychiatric genetic association studies may seem discouraging,’ as noted by Hemmings and Stein [29]. At least part of the inconsistency may be due to differences between study samples, including clinical and underlying genetic heterogeneity, as well as methodology differences, including sample size and statistical power. Taylor conducted a comprehensive meta-analysis of 230 polymorphisms that had been investigated in 113 genetic association studies of OCD. The analysis found that OCD was significantly associated with serotonin-related (*5HTTLPR* and *HTR2A*) and, in males only, catecholamine-related (*COMT* and *MAOA*) genes; an additional 18 polymorphisms had significant odds ratios. The findings support a polygenic model of OCD, in which multiple genes each have a small, incremental effect on the risk for development of OCD [28].

Genome-wide association studies

GWAS of OCD involve scanning hundreds of thousands, or even millions, of SNPs across the genome to detect relatively common genetic variants associated with the disorder. The studies have

compared the variants in individuals with and without OCD or have focused the analysis on ‘trios’, affected individuals and their parents, whether affected or unaffected.

Three GWAS of OCD have been reported to date. The International OCD Foundation Genetics Collaborative (IOCDF-GC) analysed almost 1500 OCD cases, 5600 controls, and 400 trios with nearly 500,000 SNPs. In the case-control analysis, the two most significantly associated SNPs were located within the *DLGAP1* gene, although no association had ‘genome-wide significance’ after correcting for the large number of comparisons. In the analysis of trios, but not in the combined case-control-trio analysis, an SNP near the *BTBD3* gene was found to be significantly associated with OCD [30].

The OCD Collaborative Genetic Association Study (OCGAS) analysed over 1000 families and 500,000 SNPs. Although no association was found with genome-wide significance, the most significant finding was for an SNP on chromosome 9, near the protein tyrosine phosphate receptor D (*PTPRD*) gene. Several additional candidate genes emerged from these two studies, including Fas apoptotic inhibitory molecule 2 (*FAIM2*), glutamate ionotropic receptor NMDA type subunit 2B (*GRIN 2B*), and the cadherin genes *CDH9* and *CDH10*. Several of these genes appear to be involved in glutamatergic neurotransmission [31].

The third GWAS analysed almost 7000 individuals and 31,000,000 SNPs as part of the Netherland National Twin Registry, using a quantitative measure of obsessive-compulsive symptoms. A genome-wide significant finding was found for an SNP in the myocyte enhancer factor 2B neighbour (*MEF2BNB*) gene in region 19p13 on chromosome 19. Additional gene-based testing found four significantly associated genes in the same region—*MEF2BNB*, *MEF2B* and *MEF2BNB-MEF2B*, and *RFXANK* [32].

Several analytic approaches have recently been developed to estimate heritability based on genotype information collected in GWAS, that is, SNP-based heritability. Using the genome-wide complex trait analysis (GCTA) approach, the estimated heritability of quantitative obsessive-compulsive symptoms was 34%, based on the Netherlands twin genotypes. In another study, the estimated heritability of OCD was 37%, based on OCGAS genotypes. Also it was found that common alleles contribute more to the heritability of OCD than did rarer alleles and that certain chromosomes contribute more than others to OCD risk [33].

The experience with other disorders, particularly neuropsychiatric conditions, with complex patterns of inheritance, indicates that sample sizes for GWAS need to be an order of magnitude larger than those in the three studies reported here. This is because the magnitude of the association (odds ratio) between common genetic variants and these disorders is in the range of 1.0–1.4. GWAS in schizophrenia, for example, required samples in the tens of thousands before significant associations were detected. Meta-analyses of samples from several studies are currently being conducted, in order to increase the power to detect significant associations in OCD.

In search of rare variants

Among the genetic complexity of OCD is genetic heterogeneity, that is, the pattern of genetic variation may be different in different cases of OCD. Although GWAS search for the more common genetic variants, the search continues for less common variants associated with the disorder, which may have a ‘major effect’ and provide insight into the pathophysiology of the disorder. Three types of these

variants have been reported in OCD: chromosomal rearrangements, copy number variants (CNVs), and rare variants identified by 'deep sequencing' of the genome.

There are few reports of chromosomal rearrangements in OCD, and most are in cases with co-occurring Tourette's syndrome (TS). Bertelsen and colleagues reported a 21-year-old male patient with TS, OCD, and attention-deficit/hyperactivity disorder. The patient inherited a chromosome 3 to 9 translocation t(3;9) (q25.1;q34.3) from his mother, who had a complex motor tic. Sequencing revealed that the translocation breakpoints truncated the olfactomedin 1 (*OLFM1*) gene, which plays a role in neuronal development and is a likely candidate gene for other neuropsychiatric disorders [34]. Devor and Magee reported a balanced chromosomal translocation t(1;8) (q21.1; q22.1) in siblings multiply affected with TS, OCD, complex motor tics, and attention-deficit disorder [35].

McGrath and colleagues reported the only GWAS of large (>500 kilobases), rare (1%) CNVs in OCD. They found that the proportion of individuals with deletions in known pathogenic neurodevelopmental loci was four times greater in patients with OCD than in controls. Deletions in the 16p13.11 region, which contributed disproportionately in the OCD cases, have been implicated in other neuropsychiatric conditions [36]. Since this was a case-control study, it could not distinguish between inherited and *de novo* variants, which would require a study of families. (A *de novo* variant is a new mutation that occurs for the first time in a family member, arising from a germ cell mutation in one of the parents or in the fertilized egg during embryogenesis.) *De novo* mutations in sporadic cases provide more certainty with respect to the causal nature of the variant, and such studies are in progress in OCD.

'Deep sequencing' involves sequencing a genomic region multiple times, allowing detection of rare variants, including *de novo* variants. To date, only one study has been reported for OCD. Cappi and colleagues sequenced all genome-coding regions in 20 sporadic OCD cases and their unaffected parents in order to identify rare *de novo* single-nucleotide variants. The study found a higher than expected rate of *de novo* non-synonymous variants (that is, those that alter the amino acid sequence of a protein) in OCD cases. Analysis of the protein-protein interaction network suggested an enrichment of genes involved in immunological and central nervous system functioning and development [37]. Other genetic deep sequencing studies are in progress. As with CNVs, both inherited and *de novo* variants can be studied. It is clear that much larger sample sizes will be necessary to test the significance of rare causal variants. The identification of rare genetic variants through sequencing studies may be aetiologically relevant for smaller subgroups of cases, which may exhibit different treatment response profiles.

Alternate phenotypes

An important consideration in investigating the genetic aetiology of OCD is the definition of the phenotype. Thus far, we have focused on the disorder OCD as the phenotype of interest in genetic studies. However, OCD is quite clinically heterogenous, with different cases exhibiting different constellations of symptoms, which could result from different underlying genetic or environmental aetiologies. In addition, OCD might share the same genetic basis with co-occurring disorders. Moreover, there may be subclinical dimensions

that are more proximal than the OCD diagnosis to the ultimate genetic causes of the disorder. The challenge is to identify more genetically homogenous clinical subtypes, genetically related disorders, and genetically relevant subclinical dimensions that maximize the elucidation of the underlying genetic aetiology.

Clinical subtypes

In the preceding sections, we discussed several clinical features that may be useful for subtyping in genetic studies of OCD. For example, several family studies have reported that the relative odds of OCD in relatives are substantially greater in families of paediatric probands or of adult probands with onset in childhood or adolescence [9, 10, 12]. Several candidate gene studies have found stronger associations for one gender than the other; for example, some studies found an association with the *COMT* gene in women, but not men, while others found an association in men, but not women [38, 39]. Association studies of the *SLC1A1* gene have found a stronger association in men, but not women [27]. The OCGS study found significant linkage of OCD to a region of chromosome 14 in families with two or more hoarding relatives, but not in other families [26]. These and other potential phenotypes might be the focus of future genome-wide and newer-generation association studies. However, clinical subtyping increases the cost of studies, given the larger number of affected OCD cases with specific subtypes that must be identified and the increased time required for clinical examinations.

Cross-disorder phenotypes

Several psychiatric disorders have been proposed to be related to OCD. This is an example of pleiotropy, that is, that the same genetic background can be expressed as clinically different disorders. The evidence for these relationships has typically been based upon the co-occurrence of these disorders with OCD, as well as by phenomenological similarities or treatment response profiles. A stronger case for a genetic relationship between OCD and these disorders is provided for by family studies, in which the relatives of OCD cases have greater prevalences of these other psychiatric conditions than do the relatives of controls. As discussed, several family studies have found that generalized anxiety disorder, body dysmorphic disorder, trichotillomania, pathologic skin picking, and obsessive-compulsive personality disorder and additional disorders were more prevalent in relatives of OCD than control probands [13–15].

There has been much interest in the genetic relationship between OCD and TS and other tic disorders. Tic disorders and OCD frequently co-occur, and family studies have found that the prevalence of OCD is significantly higher in TS than control relatives, whether or not the TS-affected proband had OCD, supporting the hypothesis that the disorders share genetic risk factors [40]. More recent analyses of SNPs collected in GWAS found a genetic correlation between OCD and TS of 0.41, comparable to heritability estimates based on twin and family studies [33]. However, Yu and colleagues found that although genetically related, the two disorders had distinct genetic components and OCD with co-occurring tic disorders may be genetically different from OCD alone [41].

Endophenotypes

Like many other psychiatric disorders, OCD appears to be aetiologically complex, with suspected involvement of multiple genes, epigenetic factors, and environmental influences, which has complicated

the search for specific genes and gene networks that may ultimately underlie the disorder. An endophenotype, or 'intermediate phenotype', is a biological marker that lies intermediate in the aetiological pathway between genes and the clinical phenotype, that is, the signs and symptoms of the disorder. A psychiatric endophenotype may be biochemical, neuroanatomical, neurophysiological, neuropsychological, or behavioural. A useful candidate endophenotype is associated with the disorder, is heritable, cosegregates with the disorder within families, and occurs in non-affected, as well as affected, family members with greater frequency than in controls. It is a 'trait' marker underlying the disorder and independent of symptoms [42].

A large number of studies have found differences between OCD cases and non-cases in a variety of neurocognitive domains, including response inhibition, planning, decision-making, working memory, and visuo-spatial abilities [43]. Several of these domains involve functioning of orbitofrontal-striatal-thalamic networks in the brain, which imaging studies have implicated in OCD. In one of the first studies, Menzies and colleagues measured performance on a response inhibition task (Stop-Signal task) in 31 OCD patients, 31 of their first-degree relatives, and 31 non-OCD controls and their first-degree relatives. They found that OCD patients and their relatives had significantly longer reaction times than the controls, indicating reduced ability to inhibit their response. Using magnetic resonance imaging (MRI), they also found that the impairment in response inhibition was significantly associated with reduced grey matter in the orbitofrontal cortex in right inferior brain regions and increased grey matter in the cingulate, parietal, and striatal regions. Moreover, there were significant familial effects for reaction times and brain volumes in these regions [44]. Several later studies, using a variety of neurocognitive paradigms, as well as structural and functional imaging approaches, have supported deficits in inhibitory control, as well as structure, function, and connectivity in corticostriatal-thalamic-cortical circuits, as candidate endophenotypes for OCD [45].

Another neurocognitive domain of recent focus is performance monitoring. Many studies have found that OCD cases show a negative deflection of the event-related potential following making an error on a flanker task. Recently, error-related hyperactivity of the anterior cingulate cortex has been found in OCD cases and their relatives, compared to controls [46, 47]. More recently, higher-level executive functions have been investigated as candidate endophenotypes for OCD. For example, Zhang and colleagues found that OCD cases and their unaffected first-degree relatives had deficits in decision-making under ambiguous conditions, as well as in planning [48].

Although these findings are promising, additional family studies with greater numbers of cases and relatives are needed to determine the heritability and segregation patterns of candidate endophenotypes in OCD families. Those candidates and families with the strongest presumptive evidence for genetic transmission would then be useful for genetic association and sequencing studies to elucidate specific genetic aetiologies.

Pharmacogenetics

A substantial proportion (40–60%) of OCD patients show poor response to SRIs, and others have significant adverse side effects that

make treatment intolerable. Genetic variation appears to be an important contributor to antidepressant response in major depression, but less is known about the genetic contribution to pharmacologic treatment response to SRIs in OCD. Some studies have reported associations between treatment response and SNPs in genes known to be involved in serotonergic, dopaminergic, or glutamatergic neurotransmission (for example, *HTR1B*, *5-HT2A*, *HTR2A*, *BDNF*, *SLC1A1*, *SLC6A4*, *COMT*). However, findings mostly have been based on small samples, have small effect sizes, and have not been replicated, and further studies are needed [49, 50].

Recently, results from a GWAS of SRI treatment response in nearly 1600 OCD-affected individuals in over 1000 families were reported. The most strongly associated SNP is located near the *DISP1* gene, and two other moderately associated SNPs are near the *PCDH10* gene; both genes are known to be involved in cell–cell adhesion. An additional 35 SNPs with signals of potential significance were in several genes expressed in the brain and implicated in neuronal development, psychiatric disorders, or drug effects, including *GRIN2B*, *GPC6*, *NTM*, *PARK2*, *PLCB1*, and *PKC* [51].

There has been important work on genes coding for liver enzymes involved in drug metabolism, specifically among the polymorphic cytochrome P450 enzymes. There is substantial genetic variation in the *CYP2D6* and *CYP2C19* enzymes, for instance. This can affect the metabolism of selective SRIs and lead to a range of treatment response in OCD patients with different genetic alleles [52]. Different medications, even those within the same class, could therefore have different effects, from reduced efficacy to increased liability to toxicity. The clinical utility of testing for these alleles remains controversial, but the implications need to be borne in mind by practitioners.

Genetic studies in animals

Canine compulsive behaviours

Ethologists have described stereotypical behaviours in non-human mammals that appear to be excessive, maladaptive variants of normal behaviours involved in grooming, predation, eating and suckling, or locomotion. Among the best studied are canine compulsive behaviours, including acral lick dermatitis, tail chasing, flank sucking, and pacing and circling. A GWAS of 92 Doberman pinschers with compulsive flank and/or blanket and sucking behaviours and 68 control dogs found a significant genome-wide association in chromosome 7, with an SNP in the *CDH2* gene, which codes for cadherin, a neuronal adhesion protein. Dogs having both blanket and sucking behaviours had the greatest frequency of the risk allele (60%), compared to 43% in dogs with only one behaviour and 22% in unaffected dogs [53]. Using a more powerful genotype-calling algorithm, 13 new OCD-associated regions were found, in addition to the *CDH2* locus; these regions included genes involved in catenin-binding and regulation of dendrite morphogenesis. Sequencing these regions found variants specific to dogs with OCD and were significantly more common in dog breeds at high risk for OCD; four genes in these regions are involved in synaptic function: neuronal cadherin (*CDH2*), catenin alpha2 (*CTNNA2*), ataxin-1 (*ATXN1*), and plasma glutamate carboxypeptidase (*PGPC*). Several of these genes appear to be functionally connected to several of the SNPs most strongly associated with OCD in a recent genome-wide OCD study in humans [30] and involved in glutamatergic signalling pathways [54].

Recently, variants in the *CDH2* gene have been reported to be associated with OCD in humans [55].

Knockout mice models

A mouse model of compulsive grooming behaviour has been developed by genetic deletion of the *SAPAP3* gene, which codes for a scaffolding protein at excitatory synapses and is highly expressed in the striatum. Knockout mice express increased anxiety and compulsive grooming behaviour, leading to facial skin lesions and hair loss, and have reduced activity in cortico-striatal synapses, which comprise the majority of glutamatergic synapses in the striatum. When viruses containing the gene were injected into the striatum of these mice, excessive grooming behaviour, lesion severity, and anxious behaviour were reduced and cortico-striatal synaptic transmission increased [56]. In humans, a strong association between SNPs in the *SAPAP3* gene and grooming behaviours in OCD families has subsequently been reported [57], and mutations in SNPs in the *SAPAP3* gene have been found to be more frequent in individuals with OCD/trichotillomania than controls [58]. Mice with deletions of other genes involved in cortico-striatal functioning, including *SLITRK5*, *HOX-B8*, and *SLC1A1*, have been studied as possible models of compulsive grooming behaviours and OCD [59].

Conclusions and future directions

Evidence from epidemiological and molecular genetic studies strongly supports genetic susceptibility to OCD. The working hypothesis is that OCD, like several other neuropsychiatric disorders, has a complex pattern of inheritance that involves: many common genetic variants, each of which is expected to have a relatively small overall impact (effect size) on the risk of disease; rare genetic variants, each with potentially greater impact; and environmental factors, for which there are few, if any, supportable candidates thus far. However, to date, except for a few candidate genetic variants, such as *SLC1A1*, *DLGAP1*, and *PTPRD*, there is no established variant with unequivocal evidence for association with OCD. Many of the approaches outlined in this chapter, such as GWAS and whole-exome/genome sequencing, are in progress and are likely to be productive as sample sizes increase.

It should be borne in mind that identifying associated genetic variants is only the initial step in elucidating the pathogenic process underlying OCD. Understanding the functional basis of these findings will rely on additional experimental approaches, several of which are currently available and others being developed, for integrating the information obtained from multiple domains, including gene sequence, gene expression, gene regulation, and gene-gene and protein-protein interaction networks [60]. Genetic expression studies in brain tissues from relevant brain regions and application of induced pluripotent stem cell (iPSC) technology will help identify relevant variants and elucidate their functional relevance. Epigenetic studies will be important for elucidating how modification of gene expression, apart from variation in the gene sequence, contributes to the risk of OCD. The Encyclopedia of DNA Elements (ENCODE) programme of the US National Institutes of Health, the goal of which is to identify all functional elements in the human genome, is one example of a programme that will facilitate this progress [61].

It is likely that this progress will result in a redefinition of the phenotype of OCD and related conditions. We anticipate a phenotype that will differentiate clinical subtypes within the existing diagnostic categories, will expand across current diagnostic boundaries, and ultimately will be based on genetic criteria. We also envision a future in which understanding of the molecular pathophysiology will catalyse the development of rational treatments and preventive measures for OCD.

Imaging of obsessive–compulsive disorder

Rebbia Shahab and Emily R. Stern

Introduction

For the past several decades, neuroimaging techniques, such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET), have been used to investigate neurocircuit functioning in OCD. While earlier studies examining neural responses to symptom provocation have identified altered brain activity in OCD and are clearly relevant for the disorder, they do not address whether basic cognitive–affective mechanisms are impaired in the absence of direct symptom exacerbation. In this article, we discuss findings from cognitive neuroscientific studies probing basic cognitive–affective constructs that may underlie the complex phenomenology of OCD, including conflict and error monitoring, response inhibition, task switching and reversal, decision-making, and reward processing. Although several cognitive neuroscientific studies that are not discussed here have used task paradigms that tap into theoretically driven core mechanisms of OCD (including impaired fear extinction [1] or altered habit formation [2, 3]), we focus the main part of this review on those topics where at least four studies compared adults with OCD with a healthy control group. We conclude by discussing findings in the context of OCD heterogeneity and reviewing the small literature comparing functional neuroimaging findings between OCD subtypes. Our review is complementary to the description of brain circuits in Chapter 94.

Conflict and error monitoring

Much research into the cognitive neuroscience of OCD has taken place in the field of conflict monitoring and error detection. This approach is based on the proposal that obsessions are caused by an overactive conflict or error signal continually telling the patient that ‘something is wrong’ despite evidence to the contrary [4]. In this view, compulsions are behaviours that attempt to reduce this heightened conflict signal or to correct perceived errors. Cognitive conflict is typically studied in tasks where there is a mismatch between what a subject would automatically do (that is, a prepotent response) and what is required in the task. The classic example of a conflict monitoring paradigm is the Stroop task where subjects must make a response according to the font colour of a word, where the word itself is the name of a colour that is different from the font colour (that

is, the word ‘blue’ written in red font). In this case, the prepotent response is to read the name of the word, yet the task requires a response according to the colour of the word, which creates conflict that significantly increases response times, compared to trials where the colour and word name are the same [5]. Conflict monitoring in healthy controls fairly consistently implicates the dorsal medial frontal cortical (MFC) regions including the dorsal anterior cingulate cortex (dACC) and the supplementary motor area (SMA) and pre-SMA [6–9], yet results from the many neuroimaging studies investigating this process in OCD do not present a coherent picture. While some investigations have indeed found hyperactivity of the dorsal MFC regions during conflict in OCD [10, 11], other studies have identified reduced activity in this region [6–9, 12, 13] or no differences between patients and controls [14–16]. Many studies have reported differences between patients and controls during conflict monitoring in several other brain regions outside the dorsal MFC, including the parietal cortex [17, 18], inferior frontal gyrus/insula [19], ventral/rostral regions of the MFC [11, 20, 21], lateral [13, 17] and medial [18] temporal cortex, and striatum including the caudate nucleus and putamen [12, 13]. However, these results are often contradictory, with some studies finding activations to be greater in OCD than controls and other studies reporting the opposite effect.

Errors reflect a specific instance of conflict where the intended or correct response does not match the actual response made by the subject. Similar to conflict monitoring, errors elicit activation in the dorsal MFC regions, including the dACC and SMA. In addition, errors tend to elicit an emotional reaction related to frustration, disappointment, or fear of punishment and typically activate a broad range of brain regions, including the bilateral anterior insula, the rostral ACC (rACC), and the ventromedial prefrontal cortex (vmPFC), the dorsolateral prefrontal cortex (DLPFC), and the orbitofrontal cortex (OFC) [22]. The anterior insula, rACC/vmPFC, and OFC have been associated with valuation and emotion [23–26]; as such, activation of these brain regions to errors may reflect the neural processing of the emotional/motivational significance of mistakes [27]. Unlike the conflict processing literature, data somewhat consistently point to an enhanced error detection mechanism in OCD. The error-related negativity (ERN), a negative event-related potential (ERP) that peaks approximately 100 ms after an error and is thought to be generated in the dorsal MFC, is consistently larger in OCD than controls (for a review, see [28]). In fMRI studies, OCD

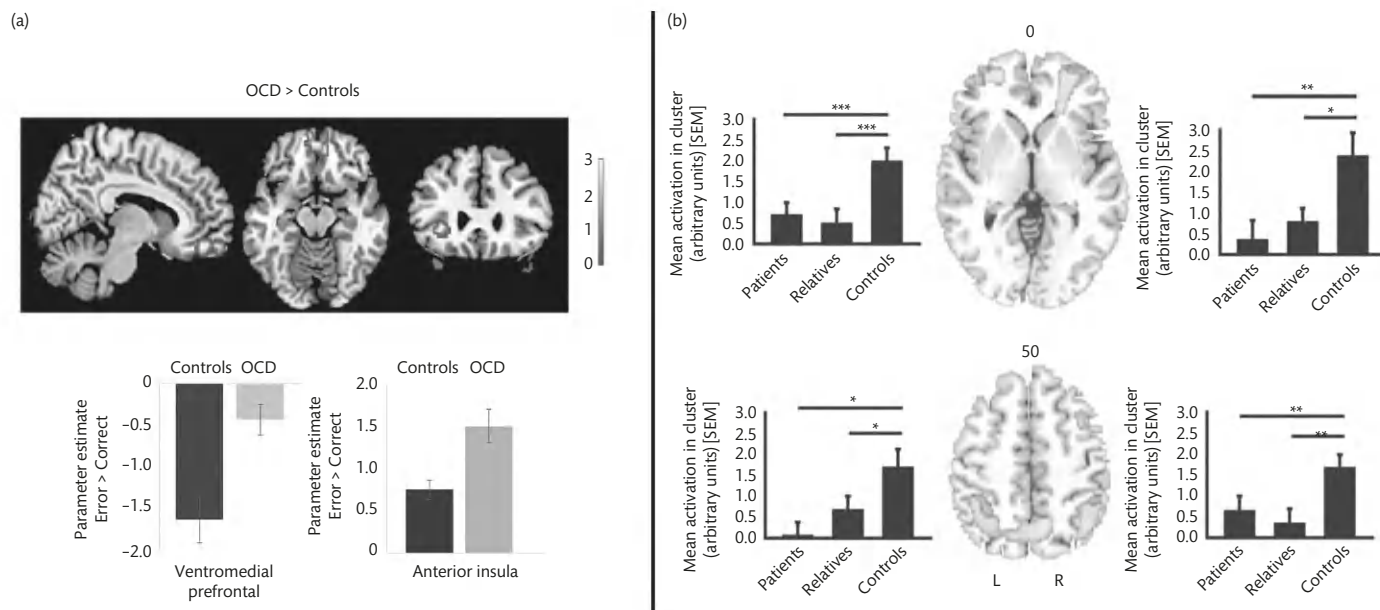

Fig. 97.1 (see Colour Plate section) (a) Results from [15] showing greater error-related activity in the ventromedial prefrontal cortex and anterior insula in OCD patients, compared to controls.

(b) Results from [54] showing regions activated for (successful) reversal (areas in yellow), overlaid with orbitofrontal and parietal areas showing reduced activity during reversal, for both OCD patients and their unaffected relatives, compared to controls (areas in blue).

Reproduced from *Science*, 321(5887), Chamberlain SR, Menzies L, Hampshire A, *et al.*, Orbitofrontal Dysfunction in Patients with Obsessive-Compulsive Disorder and Their Unaffected Relatives, pp. 421–2, Copyright (2008), with permission from American Association for the Advancement of Science.

patients have shown an increased neural response to errors in dACC [10, 29], rACC [29], and lateral frontal cortex, including the OFC and DLPFC [14, 29]. Fitzgerald *et al.* [12] found hyperactivity in the vmPFC in a small group of patients with OCD, a finding that was replicated in a larger study [15], which also identified hyperactivity of the anterior insula (Fig. 97.1a). Despite some variation among the studies, overall these data suggest that OCD patients respond more strongly to errors than healthy individuals, particularly in ventral frontal regions potentially involved in processing the value or emotional importance of the error. However, it is important to note that these studies examine OCD patients' responses to actual errors (and conflict), whereas the phenotype of the disorder is more consistent with the detection of errors (or conflict) where there are none (or at least where their presence is uncertain). Thus, while hyperactive error responses in OCD may reflect an important characteristic of the disorder related to sensitivity to mistakes, these studies do not directly probe the neural mechanisms associated with the feeling that something is wrong, even in the absence of overt errors. ERP studies that have attempted to address this issue by examining the 'correct related negativity' (CRN)—a small negative deflection that is the analogue to the ERN on correct trials—have been somewhat inconsistent as to whether OCD patients show an enhanced CRN [28].

Response inhibition/motor output suppression

It has been suggested that compulsions in OCD may result from an inability to engage mechanisms of response inhibition [30]. Response inhibition is commonly studied using a go/no-go task (or

a variant thereof such as the stop-signal task) where subjects make button-press responses to frequent stimuli ('go' trials) and are required to inhibit responses to infrequently presented stimuli ('no-go' trials). Even though this task inevitably involves conflict monitoring between the frequent 'go' and infrequent 'no-go' trials, these paradigms additionally involve a specific motor suppression component not present in conflict studies. Accordingly, while 'no-go' trials are associated with activation of some of the same regions as for conflict monitoring, including the dACC and SMA/pre-SMA [31–34], they also elicit activation in subcortical structures, including the thalamus and basal ganglia, as well as predominantly right hemisphere lateral frontal and inferior parietal regions [31–35]. In a meta-analysis, the right inferior frontal gyrus (IFG) has been most consistently associated with 'no-go' trials [32], which has been supported by lesion and brain stimulation studies showing impaired response inhibition after inactivation of this region [36, 37].

Studies comparing OCD patients and controls have found reduced activity in the SMA, ACC, right IFG, inferior parietal cortex, striatum, and thalamus in OCD patients during correct no-go trials (that is, successful response inhibition) [17, 38–41], which would suggest reduced recruitment of the response suppression network, even during inhibition success. However, OCD hyperactivity in the caudate nucleus and thalamus [29, 41], as well as the medial and lateral frontal regions, insula, premotor cortex, middle temporal cortex, posterior cingulate cortex, and cerebellum [17, 38–41], has also been reported for successful inhibition, which has been interpreted as compensatory activation [17]. Given the variability of findings, it is not clear whether abnormal hypoactivity or hyperactivity of a response inhibition network is a core feature of OCD. These

equivocal results may stem partially from the focus on neural differences during successful inhibitions (as opposed to inhibition failures, which would be most relevant for the disorder). Further research linking brain function to behaviour will be needed to address this issue.

Task switching and reversal

Another approach to investigating the basic mechanisms of OCD has focused on how patients switch attention between two or more different tasks, stimuli, or rewards. Rather than hypothesizing an overactive conflict or error signal or a failure to suppress motor output, these studies hypothesize that OCD patients exhibit an inflexibility that prevents them from shifting attention away from stimuli or features that are no longer relevant to the task at hand. For an in-depth discussion of behavioural measures of cognitive inflexibility in OCD, the reader is referred to a review article by Gruner and Pittenger [42].

Many studies of switching have investigated neural activity associated with shifting attention between features or dimensions of stimuli ('cognitive' switching tasks). Not surprisingly, in a meta-analysis examining brain regions involved in cognitive switching and motor suppression, overlap between these processes were found in the dACC/SMA, IFG, DLPFC, and inferior parietal cortex [32]. However, fronto-parietal activations were more widespread and bilateral for cognitive switching [32, 35], appearing very similar to a frontal-parietal network (FPN) often described as being involved in executive functions and task control [43, 44]. Studies looking at brain activity in OCD during cognitive switching have found reduced activation in patients, compared to controls, in FPN as well as in the OFC, caudate nucleus, temporal cortex, and medial parietal regions [17, 45, 46]. Two studies reported widespread reductions across the cortex and basal ganglia [45, 46], whereas two reported hypoactivations localized to only a few regions of the frontal and parietal cortices [17]. In addition to hypoactivation of the anterior prefrontal cortex extending into the lateral OFC, a recent study also found *hyperactivation* of the dACC and putamen and post-central gyrus activity during task switching in OCD [47].

Another type of switching that has been of interest in OCD involves reversing stimulus-reward contingencies (sometimes referred to as 'affective' switching). In reversal tasks, the reward and punishment value of two stimuli switch, so that the currently rewarded stimulus is punished and the previously punished stimulus is rewarded. There is some evidence to suggest that reversal of reward-punishment contingencies relies primarily on the OFC, rather than the lateral prefrontal regions involved in cognitive switching [35, 48–50]. Studies of reversal in OCD have examined neural activation on trials where subjects made a reversal error that lead to a successful switch, compared with errors that did not lead to a successful switch (thereby isolating activity associated with the moment subjects learn that a switch is required) [51–53], or during the correct choice after a successful reversal [54]. For these comparisons, OCD patients exhibit reduced activation in the OFC, but similar to results from cognitive switching studies, reductions have also been found throughout the FPN, including the DLPFC, bilateral insula, lateral parietal cortex, and putamen [51–54]. In one study, unaffected relatives of OCD also showed reduced activity in

the lateral OFC, DLPFC, and lateral parietal cortex during reversal [54] (Fig. 97.1b), suggesting that impaired frontal recruitment during reversal may be an endophenotype of the disorder. With a slightly different approach using a fear conditioning reversal task, OCD patients showed reduced medial orbitofrontal activity, when compared with controls, when viewing a stimulus that was previously associated with shock but was now safe [55].

Overall, these data generally support the notion that OCD patients show hypoactivation in a variety of cortical regions, both during task switching and when reversing reward-punishment contingencies. Despite the dissociation of lateral and orbital frontal involvement in these processes, dysfunctional brain activity in OCD does not appear to be localized to one of these systems. Reduced recruitment of both the DLPFC and OFC has been found when patients switch cognitive set, as well as when they reverse reward contingencies. Similar to the concerns discussed for the other approaches, interpretation of results from switching studies is complicated by the fact that neural differences between OCD patients and controls are examined during successful switches (either at the time of the correct switch response or at the time of the error right before a correct switch), rather than for unsuccessful switches. Future work focusing on brain activity during switch failures would further elucidate the neural mechanisms of cognitive inflexibility in OCD.

Decision-making

OCD has been characterized as a disorder associated with impaired decision-making [56, 57]. Clinically, OCD often manifests as risk aversion and intolerance of uncertainty [58, 59], and experimentally, OCD patients show reduced risk-taking [60] (but see [61]) and excessive information gathering in the face of uncertainty [62–65]. In healthy individuals, risk and uncertainty are associated with activation of the FPN [66, 67], with effects most consistently found in the anterior insula and dorsal MFC [67–72]. In a study where OCD patients played an interactive game where they could make risky or safe choices and anticipate outcomes of their choices, patients made fewer risky choices than controls and showed greater amygdala activation when anticipating outcomes of their risky choices [60]. By contrast, a recent study found that OCD patients did not show any differences from controls in risky decision-making both behaviourally and in the brain, although patients did show a stronger correlation between individual level of risk aversion and activation of the insula, DLPFC, and precentral/post-central gyri when making risky choices [61]. In an examination of uncertainty and checking, Rotge *et al.* [73] found that OCD patients showed reduced mid-OFC activity, compared to controls, for decisions that lead to subsequent checking behaviour. In another task investigating uncertainty, patients were required to make decisions based on evidence that was either uncertain (that is, the likelihoods for two different outcomes being similar) or certain (for example, the likelihood for one outcome being 100% and for the other being 0%) [74]. In this study, OCD patients reported more subjective uncertainty than controls, and showed increased activation of the amygdala, parahippocampus and hippocampus, temporal cortex, ventral anterior insula, lateral OFC, and vmPFC, when making decisions based on 'certain' (that is, unequivocal) evidence but showed no differences for decisions based on uncertain evidence. Interestingly, in the studies of Admon

[60] and Stern [74], hyperactivations in OCD were found in brain regions not typically linked to risk and uncertainty in healthy populations such as the amygdala, parahippocampus and hippocampus, lateral temporal cortex, and vmPFC [69]. One could speculate that recruitment of these additional limbic and paralimbic regions when processing risk and uncertainty may reflect greater emotional involvement during decision-making in OCD or an excessive internal focus associated with 'default mode network' activity [75]. This hypothesis is consistent with the finding that OCD patients hyperactivate the vmPFC and lateral temporal cortex (both areas of default mode network [75]), when making decisions about moral dilemmas [76]. Overall, these data suggest that OCD patients do engage different brain regions than controls when making decisions, although differences between paradigms and the relatively few studies investigating these behaviours in OCD suggest the need for additional study.

Reward processing

It has been suggested that the difficulty exhibited by OCD patients in terminating inappropriate responses is related to a reduced signal of goal attainment or satiety [77]. Within this framework, OCD patients continue to engage in compulsive behaviours, such as checking, washing, or repeating/ordering, because the normal 'reward' signal associated with successfully completing these tasks is not attained. In healthy individuals, rewards elicit activation in a network of brain regions, including the ventral striatum, thalamus, putamen, hippocampus, anterior insula, MFC, and parietal cortex [78]. Prior studies in OCD have found reduced activation in patients in some of these regions during reward feedback or anticipation, including the vmPFC in a reversal paradigm [52, 53] and the putamen in a spatial reward learning task [79]. However, using a version of the monetary incentive delay (MID) task [80], Jung *et al.* [81] reported increased activity in cortical and subcortical regions, including the putamen and dorsal MFC, to monetary reward in OCD patients, with no regions showing reduced activity, compared to controls. In another study also using a version of the MID, OCD patients showed reduced dorsal MFC activation, compared to controls, during reward feedback, as well as reduced activation in the ventral striatum when anticipating an upcoming trial that could potentially provide reward [82]. This latter finding contrasts with three other studies showing no difference in striatal activation between OCD patients and controls during anticipation of trials where reward was possible [81, 83, 84]. Overall, it is not yet clear whether dysfunctional brain responses to reward contribute to OCD, although impaired recruitment of the striatum during reward processing has not been consistently implicated in the disorder. Future work may benefit from examining reward processing from the standpoint of goal attainment or task completion, which may be particularly relevant for the symptoms of the disorder.

Neural correlates of OCD subtypes

As can be seen, results from fMRI studies are variable, with many revealing abnormalities of widespread fronto-parietal and fronto-striatal networks and others identifying more circumscribed

differences between patients and controls. Given the heterogeneity of the disorder, it is possible that the discrepant findings may be attributed to differing neural mechanisms mediating the various symptoms of OCD. There are several ways that OCD can be segregated into symptom clusters, including by distinguishing patients with sensory phenomena from those without [85] or by focusing on severity of harm avoidance symptoms in OCD [86]. While these approaches are critical to the future understanding of how dimensional (and fundamentally trans-diagnostic) symptoms manifest in the brain not only in OCD, but also in other psychiatric disorders (that is, sensory phenomena are prevalent not only in OCD but also in tic disorders; harm avoidance is a feature not only of OCD, but also of other anxiety disorders), the majority of work to date on OCD heterogeneity has focused on investigating subtypes that have been identified through factor analyses of Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) responses [87–89]. Although there are slight variations, typically these studies identify 3–5 dissociable factors of contamination/washing, aggressive/checking, symmetry/ordering, sexual/religious, and hoarding symptoms. This section will review the literature on fMRI studies that examine the neural substrates of these different symptom subtypes.

Contamination/washing

OCD patients with contamination/washing symptoms are heavily concerned about cleanliness and disease. Washing compulsions have been associated with activation in several prefrontal regions, such as the OFC, ACC, and DLPFC, as well as the insula, during a symptom provocation [90] and continuous performance task [91]. Greater insular activation has also been associated with washers' sensitivity to disgusting stimuli in general, including pictures and facial expressions of disgust [92, 93]. A recent study [94] found increased functional connectivity between the insula and the ventral striatum also during the provocation of contamination symptoms. The findings of insula hyperactivation are particularly interesting because the insula is one of the primary regions involved in processing disgusting stimuli [90, 95, 96], potentially due to its role in interoception [97]. Of importance, one study looking at the neural substrates of washing symptoms in a medication and comorbidity-free sample of OCD patients found *decreased* activation in the anterior prefrontal cortex, DLPFC, OFC, ACC, insula, parietal cortex, and caudate [98]. Although the same brain regions were implicated, the activity was in the opposite direction of that in previous studies on washers. Although these results suggest that some of the prior findings of hyperactivation could be related to confounding factors, the consistency of the insula hyperactivation finding in washers and the link between disgust processing and insula activity suggest a primary role for the insula in this OCD subtype.

Aggressive/checking, sexual/religious, and symmetry/ordering

The aggressive/checking, sexual/religious, and symmetry/ordering subtypes of OCD have not been widely studied, and the results paint an incomplete picture about the neural substrates of these subtypes. In a symptom provocation study, patients with checking

compulsions showed greater activation than healthy controls in various brainstem nuclei, globus pallidus, and right thalamus, as well as in the dACC, precentral gyrus, and superior frontal gyrus [90]. In a study looking at blood flow during a continuous performance task using PET [91], there was a positive correlation between severity of aggressive/checking and sexual/religious symptoms and blood flow in bilateral striatum, including areas of the caudate nucleus, putamen, and pallidum. Many of these regions are associated with sensorimotor functions that could possibly mediate some of the motor components of checking behaviour. Greater severity of aggressive obsessions has been correlated with increased resting-state functional connectivity between the ventral caudate and the vmPFC and decreased connectivity between the ventral caudate and the amygdala [99], and amygdala activity has also been correlated with the severity of both aggressive/checking and sexual/religious symptoms in OCD patients when viewing fearful faces [100]. Given the amygdala's role in fear processing [101], these data suggest that these subtypes may be associated with altered amygdala-based fear reactivity related to concerns about causing harm and having what are deemed to be morally unacceptable thoughts related to sexual or religious themes. Interestingly, patients with more severe sexual/religious obsessions also demonstrated relatively greater connectivity between the ventral caudate and the insula [99]. The involvement of the insula in the sexual/religious subtype could reflect a type of 'moral disgust' (which also activates the insula [102]) that is characteristic of patients with these types of obsessions. Few studies have reported relationships between brain function and symmetry/ordering symptoms, although the PET study using the continuous performance task described above did find that the severity of symmetry/ordering symptoms was negatively correlated with right caudate nucleus activity [91].

Hoarding

Hoarding is characterized by excessive collecting, or being unable to discard, items, even though they might not have objective value. Hoarders have emotional attachment to their possessions and face great difficulty in deciding what to keep or throw out. Although there is debate on whether hoarding is a subtype of OCD or is better characterized as its own distinct disorder [103], several studies have investigated hoarding symptoms within the context of OCD. One PET study found diminished glucose metabolism in the posterior cingulate cortex (PCC), occipital cortex, and ACC in hoarders, compared to non-hoarders or a control group [104]. Relatedly, anxiety evoked during the viewing of hoarding-relevant pictures was associated with reduced activity in the dACC, parieto-occipital regions, basal ganglia, and temporal cortex in a group of OCD patients including both hoarders and non-hoarders [105]. However, other work has shown that hoarding severity in OCD patients correlates positively with activation and connectivity in the vmPFC and OFC, as well as in the precentral and post-central gyri, which may point to a sensorimotor component of the hoarding phenotype [90, 99, 105]. The vmPFC has been implicated in compulsive hoarding in animal and brain lesion studies [106–108] and is also considered to be crucial for decision-making [109], suggesting that hyperactivation in this region may underlie the difficulty in making decisions regarding which objects to collect and discard.

Conclusions

The summary provides a selective review of neuroimaging correlates of psychological processes that could potentially underlie the complex symptom presentation of patients with OCD. The most consistent findings were hyperactivation in response to errors and hypoactivation during switching tasks, with both effects occurring predominantly in the prefrontal cortex, but with findings also noted in other areas, including the striatum, parietal cortex, and temporal cortex. Given the complexity of the brain in general, and OCD in particular, no one task paradigm is likely to fully explain the disorder, and it is clear that the task chosen is absolutely critical for interpreting findings. Indeed, other approaches investigating fear extinction [1], habit formation [2, 3, 110], emotional face and picture processing [93, 100, 111–115], planning [116, 117], and working memory [118–122] have identified neural alterations in OCD that may also contribute to the phenomenology of the disorder. Some of the variability in findings may be related to the heterogeneity of symptoms in OCD, with some studies identifying distinctions in limbic and sensorimotor regions based on subtype. Taken together, the many paradigms used in cognitive neuroscientific research provide powerful probes that have already shed some light on the underlying mechanisms of OCD. Future work would benefit from combining the strengths from these many approaches by further interrogating core processes and symptom dimensions in OCD in order to design novel treatments targeting symptom-specific neural markers.

Introduction

The earliest reports of the potential efficacy in obsessive–compulsive disorder (OCD) of pharmacotherapy with the tricyclic drug clomipramine and of behavioural forms of psychotherapy, initiated in the 1960s and 1970s and subsequently validated in a series of seminal studies in the 1980s, produced a dramatic change in the psychiatric management of this serious and previously treatment-refractory disorder. Since that time, treatments for OCD have been subject to considerable scientific scrutiny and treatment ‘standards’ have been developed and refined in succeeding evidence-based treatment guidelines [1, 2].

The disorder usually arises in childhood or early adulthood, follows a chronic course (though episodic forms do occur), and is associated with substantial psychiatric comorbidity, frequently in the form of anxiety disorders, affective disorders, and other obsessive–compulsive and related disorders. Whereas substantial improvement can be achieved in many patients following standard treatment with serotonin reuptake inhibitors (SRIs) [selective serotonin reuptake inhibitors (SSRIs), clomipramine] and cognitive behavioural therapy (CBT), for approximately 50%, the response is incomplete and new treatment paradigms are sought. Several other conventional drug treatments for depression and anxiety have been investigated and found not to be effective in OCD, though evidence has accrued that dopamine receptor antagonists may be effective for individuals with SRI-resistant OCD when prescribed as an adjunct to the SRI. In this context, a developing role for somatic treatments has also emerged, with implications for clinical service development [1].

In this chapter, we review the management and treatment of OCD, including rational options for those failing to respond to standard treatments, based, as far as possible, on randomized controlled trial (RCT) data. Where relevant, we have cited review papers of good quality to maximize efficiency.

Defining treatment response, remission, and relapse

The introduction of methods for the standardized assessment of OCD has contributed substantially to the evidence-based treatment of the disorder. Of the several available scales, the 10-item Yale-Brown Obsessive Compulsive Scale (Y-BOCS) [3] emerged as the most widely accepted instrument for rating the magnitude of symptomatic change, based on reliability, acceptability, and sensitivity to change. Pallanti *et al.* [4] were some of the first to advocate the use of standardized operational ‘responder’ criteria across OCD treatment trials. They proposed that a meaningful clinical response could be conservatively represented by an improvement of 25–35% in the baseline Y-BOCS, or a score of ‘much’ or ‘very much improved’ on the Clinical Global Impression of Improvement (CGI-I) Scale [5], whereas ‘remission’ necessitated a total Y-BOCS score of less than 16 (out of a total score of 40). Relapse, on the other hand, was defined as a worsening by 25% of the remission Y-BOCS score. Other suggested relapse criteria include a worsening by $\geq 50\%$ of post-baseline Y-BOCS scores, a 5-point worsening of the total Y-BOCS score, a total Y-BOCS score of ≥ 19 , and CGI-I scores of ‘much’ or ‘very much worse’ [6].

A disadvantage of so much variability in these criteria is that very different claims about efficacy and relapse may ensue. Hollander *et al.* [7] attempted to validate the previously empirical responder and relapse criteria using trial data. When the treatment response was defined as at least 25% improvement in the Y-BOCS score relative to baseline, the data showed both a statistically significant and a clinically relevant differentiation in social and occupational functioning and health-related quality of life (HR-QoL) measures between responders and non-responders. This suggests that a 25% improvement in the baseline Y-BOCS does represent a *clinically relevant* change equivalent to a minimal partial response. Similarly, the analysis validated a definition of relapse represented by a 5-point worsening of the remission Y-BOCS [7].

Evidence-based psychological therapies for OCD

Exposure and response prevention

Prior to the mid 1960s, there were no known effective treatments for OCD. Therefore, the development of new effective psychological treatments based on the principles of exposure to the feared object or situation, combined with compulsive ritual prevention, has had a huge and lasting impact. Victor Meyer, a psychologist working at St Luke's Woodside Hospital and the Middlesex Hospital Medical School, developed a treatment for children and adults with OCD, based on earlier experimental work with animals. This treatment involved exposing the patient to situations which would normally provoke compulsive rituals and then actively preventing them from performing these rituals [8]. As OCD had previously been considered an intractable condition with no effective treatment, this was a remarkable breakthrough. Isaac Marks, a psychiatrist working with the psychologists Stanley Rachman and Ray Hodgson, took this pioneering work further by developing a treatment based on exposure but in which the patient themselves took responsibility for preventing their compulsive rituals. This treatment proved to be effective, to have results which persisted over at least 2 years, and had fewer ethical issues than previous treatments when nurses and other health care workers had actively prevented patients from performing rituals [9].

Over the years, exposure treatment has been modified so that what is practised today is prolonged graded *exposure* in real life to the feared situation, combined with self-imposed *response prevention* (ERP). In order to perform this treatment, the patient needs to be educated about OCD and how the temporary reduction in anxiety produced by performance of compulsive rituals actually serves to strengthen the association between obsessive thought and compulsive ritual, thus worsening the condition.

Compulsive rituals and other behaviours, such as repeated reassurance seeking, reduce anxiety; because high anxiety is unpleasant, this reduction acts like a reward. Thus, repeated performance of compulsions strengthens the link between obsessions and compulsions, which frequently results in increasing the amount of time spent in rituals. In order to overcome the OCD, the patient needs to face up to the feared situation without performing the compulsions. Initially, the urge to perform the ritual will rise, but if the compulsions are successfully resisted, the urge will reduce and habituation will occur.

It can be too stressful for a patient to initially face their most threatening situation. For this reason, the patient and therapist will usually construct a *hierarchy* of fear-provoking situations for exposure, ranging from those that would invoke minor fear if faced without anxiety-reducing compulsions to those that would produce panic. The patient also needs to expose themselves to the fear-provoking situation *for long enough* to enable their anxiety to habituate. Due to the complexity of compulsive rituals and the fact that patients often give themselves reassurance mentally, it will generally take up to 2 hours until the anxiety of OCD has fully subsided. This is known as 'within-session habituation'.

There are several full descriptions of the treatment given elsewhere [9]. In summary, the therapist and the patient agree a task expected to induce moderate anxiety if performed without

compulsive rituals and the patient is asked to perform this task. This exposure may be performed by the patient on their own or together with a therapist or a family member or friend working with the patient. Once it has been successfully performed, then the task should be repeated in the same way approximately three times a day. This repetition of the ERP is usually referred to as 'ERP Homework'. As the task is repeated without compulsive rituals, each successive performance will generally become easier and the anxiety will last for a shorter time. This reduction in anxiety on successive repetitions is known as 'between-session habituation'. Once this task has been successfully performed, the patient tackles more difficult items on the hierarchy.

Standing the test of time, ERP treatment has been proven to be a successful treatment for patients with OCD. The theory behind it is relatively simple to apply, and it has been used effectively in a variety of self-help methods, including using computerized manuals [10]. Following on from the initial studies, evidence of the robust improvements produced with ERP has accumulated [11]. Recent studies have often assessed ERP in OCD together with other interventions, including psychopharmacological treatments [12, 13].

It is important to remember that one of the most common reasons for ERP not being successful is that it is not prescribed or performed in a regular, prolonged, predictable manner. For the best results, ERP should be practised three times a day and for sufficient time to allow the anxiety to reduce consistently by at least 50%. ERP can be applied most usefully in the patient's home where the symptoms are usually maximal [13].

Cognitive behavioural therapies in OCD

In recent years, there has been increasing usage of cognitive and behavioural methods to treat OCD. There are, of course, a variety of different forms of cognitive therapy which work on a variety of different principles. Rational emotive therapy was developed by Albert Ellis in the 1960s for depressive and anxiety disorders and is a confrontative type of therapy where beliefs are actively challenged by the therapist [14]. A rationale for using rational emotive therapy to treat OCD rests on the observation that OCD patients do not sufficiently challenge their beliefs before acting on them by performing compulsions.

Early developers of ERP theorized that OCD patients would experience a reduction in symptoms if they felt less responsible for any feared disastrous or harmful outcome resulting from their failure to perform compulsions. In the UK, a cognitive form of treatment, based on the theory that an over-inflated sense of responsibility is key to the symptomatology of OCD, leading to increased performance of compulsions, increased sense of threat, and depressed mood, thereby establishing a vicious cycle of excessive responsibility and guilt, was developed [15].

However, it was observed by others that ideas about danger were more highly correlated with compulsive activity than were ideas of responsibility, self-efficacy, perfectionism, or anticipated anxiety. Danger ideation reduction therapy (DIRT) is another form of psychotherapy that provides information about harm in a systematized way, combined with rational emotive therapy [16]. DIRT was initially developed for OCD patients with contamination fears and washing rituals. More recently, it has been trialled with patients with compulsive-checking rituals [17].

ERP or CBT?

Despite both the superficial attractiveness of the cognitive method of treatment, compared with ERP, and numerous studies designed to demonstrate its efficacy, there is little evidence to suggest that adding cognitive therapy to ERP offers any distinct advantage [18–20]. One of the problems with adding cognitive therapy to ERP is that it requires more training and supervision of the therapist and may thus be less cost-efficient. Some studies have found that cognitive methods can be as effective as ERP, but few have shown any clear advantage. This is true of rational emotive behaviour therapy [21]. Indeed a recent study demonstrated that in patients who initially failed to respond to ERP, there was no value in following this with a course of cognitive therapy in an attempt to improve outcome. These workers advocated using a serotonin reuptake-inhibiting drug (SRI) and demonstrated that this was a more effective second-line treatment [22].

Studies examining specific cognitive interventions aimed at an over-inflated sense of responsibility, similarly, have generally failed to demonstrate an advantage over ERP. Studies comparing ERP and cognitive therapy found that both had equal efficacy [23] or failed to demonstrate any improved efficacy of CBT, compared to ERP, on core OCD symptoms (although Cottraux *et al.* did find that depressive symptoms may improve more with CBT) [24]. A study examining group treatment for OCD found that ERP produced significantly better results than did CBT [25].

A major problem with most studies involving CBT or ERP is that the numbers of participants are small. Many studies also include pharmacological treatment. Inevitably, this leads to a higher chance of type 2 error and difficulty demonstrating statistical differences between treatments. It is for this reason that meta-analyses may be the most useful.

An early study [26] examining the use of ERP in severe, chronic, refractory OCD suggested that whereas ERP should be the treatment of choice, CBT may be useful for specific difficulties. A recent meta-analysis of available studies similarly concluded that ‘The available research indicates that ERP is the first line evidence based psychotherapeutic treatment for OCD and that concurrent administration of cognitive therapy that targets specific symptom-related difficulties characteristic of OCD may improve tolerance of distress, symptom-related dysfunctional beliefs, adherence to treatment, and reduce drop out’ [27].

Evidence-based pharmacotherapies for OCD

Clomipramine

Adults

Evidence from a series of small historical studies dating back to the 1960s [28] identified clomipramine as the first potentially effective treatment for OCD. Subsequent RCTs of clomipramine in adult OCD patient samples demonstrated efficacy in the presence of low mood or comorbid depression. A seminal placebo-referenced RCT in patients with *no coexisting depression* showed a significant advantage for clomipramine using relatively low, fixed daily dosages of 75 mg [29]. Two large multi-centre, double-blind RCTs, comprising a total of 520 patients, conclusively demonstrated significant

placebo-referenced superiority for clomipramine in non-depressed adults with OCD, using flexible daily dosages of up to 300 mg [30].

Further OCD RCTs comparing clomipramine ‘head to head’ with other tricyclic drugs, including imipramine, amitriptyline, nortriptyline, and desipramine [28], confirmed the superiority of clomipramine. Clomipramine has greater SRI activity than the other compounds, and this property was considered relevant in its anti-OCD effect.

Children and adolescents

Similar results were obtained in clomipramine studies of children and adolescents with OCD [28]. Not only was clomipramine found to be superior to desipramine, but a significant proportion of patients who had received clomipramine as their first active treatment also showed evidence of relapse when switched to desipramine, highlighting the efficacy of clomipramine, compared to desipramine.

Summary

These results suggest that clomipramine is an effective treatment for OCD, irrespective of the presence of comorbid depression across the young adult age range. However, there is a want of studies in the elderly population, who may be more susceptible to the adverse effects of tricyclic drugs. Moreover, the robustly successful results from these studies apply largely to patients with stable, severe, and untreated OCD. There were not many treatment-refractory cases included within the study groups.

Selective serotonin reuptake inhibitors

Following the success of clomipramine, the SSRIs fluvoxamine, fluoxetine, sertraline, paroxetine, citalopram, and escitalopram were tested in large adult OCD samples, in a series of well-powered multi-centre placebo-referenced RCTs, and consistently found to be efficacious [31, 32]. Similarly, evidence for the efficacy of the SSRIs fluvoxamine, sertraline, fluoxetine, and paroxetine subsequently accrued from RCTs of children and adolescents with OCD [33]. Each SSRI is reviewed in the next sections. The decision to use SSRIs in children and adolescents with OCD has to be weighed against the possible risk of behavioural disinhibition, including suicidal ideation, as a recognized concomitant of SSRI treatment in young people.

Fluvoxamine

Adults

The finding from a number of small randomized placebo-controlled trials that fluvoxamine appeared efficacious in adults with OCD was substantiated in multi-centre placebo-controlled studies [34]. An earlier improvement was seen for obsessions vs compulsions, and significant improvement on the total Y-BOCS was evident by 6 weeks. Efficacy for fluvoxamine (100–300 mg) delivered in controlled-release form was also demonstrated [35].

Children and adolescents

Fluvoxamine was also efficacious and well tolerated in a multi-centre study of 120 young patients (8–17 years) with OCD [36]. Insomnia, asthenia, and behavioural disinhibition were reported as possible adverse events. It has been suggested that paediatric OCD patients with comorbid impulsive or tic disorders may be at increased

risk of developing behavioural disinhibition after initiation of SRI treatment.

Sertraline

Adults

Positive placebo-referenced RCTs, as well as a multi-centre 12-week RCT involving 324 OCD patients [37], demonstrated that sertraline, flexibly prescribed in daily dosages of 50–200 mg/day, was effective in adults with OCD.

Children and adolescents

Evidence from large multi-centre RCTs, demonstrated a significant advantage for sertraline (≥ 200 mg/day), delivered as monotherapy or in combination with CBT, compared to placebo [38]. Prospective evaluation did not reveal clinically meaningful drug-related changes in vital signs, ECG indices, or cardiovascular adverse events in any of the study subjects.

Fluoxetine

Adults

The first placebo-referenced fixed-dose RCT of an SSRI in OCD, which allowed the direct comparison of different daily dosages, demonstrated placebo-referenced superiority for fluoxetine with a marginally statistically greater improvement for patients receiving the highest fluoxetine dosage (60 mg daily) and a significantly higher responder rate in patients receiving fluoxetine 40 mg or 60 mg daily, implying the existence of a dose–response relationship [39]. In a larger 13-week multi-centre RCT of 355 OCD patients [40], all fixed daily doses of fluoxetine (20 mg, 40 mg, 60 mg) were efficacious, compared to placebo, with a non-significant trend towards greater efficacy evident for the 60 mg daily dosage. Fluoxetine was adequately tolerated, even at the higher dosages. Another study [41] found fluoxetine to be superior to phenelzine, which did not differentiate from placebo.

Children and adolescents

The first controlled study in young OCD patients found fixed daily dosages of 80 mg fluoxetine demonstrated efficacy over placebo, with reports of discontinuation on account of suicidal ideation (resolved when fluoxetine was discontinued) and adverse events, particularly dose-related behavioural activation [42]. Thus, it was advocated that treatment should be initiated at low dosages in childhood OCD. More recent evidence confirmed fluoxetine to be significantly superior to placebo in terms of efficacy and just as well tolerated in terms of adverse event-related discontinuation. Moreover, after the first 6 weeks, the fluoxetine dose could be increased to 80 mg/day [43]. At week 16, those taking fluoxetine demonstrated a significant improvement in Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS) scores, and no patients discontinued due to adverse events. Taken together, these results suggest satisfactory efficacy and tolerability for fluoxetine in childhood OCD, imply that the treatment effect may take several weeks to develop, and draw attention to behavioural disinhibition and suicidal ideation as possible dose-related adverse effects.

Paroxetine

Adults

Paroxetine (20–60 mg/day) was superior to placebo and of comparable efficacy with the active comparator clomipramine (50–250 mg/

day) in a multi-national 12-week RCT of 406 adults with OCD [44]. Of note, paroxetine showed significantly better tolerability than clomipramine. In addition, a 12-week placebo-referenced fixed-dose RCT in 348 adult OCD patients [45] also found efficacy for paroxetine, compared to placebo, at fixed daily dosages of 40 or 60 mg/day, but no demonstrable efficacy over placebo at fixed dosages of 20 mg/day.

Children and adolescents

A multi-centre 10-week RCT in 207 children and adolescents [46] found paroxetine (10–50 mg/day) to be superior to placebo. Adverse events with paroxetine were of mild to moderate intensity, and the authors concluded it was generally well tolerated.

Citalopram

Adults

A 12-week multi-centre placebo-referenced fixed-dose RCT of 401 adults with OCD found that citalopram (20, 40, and 60 mg) was significantly superior to placebo [47]. Whereas no significant difference between the individual doses of citalopram was seen on the primary outcome, a dose vs time-to-response relationship favoured the 60 mg dose. Citalopram was well tolerated and associated with improved psychosocial functioning.

Escitalopram

Adults

A multi-centre fixed-dose RCT in 466 adults with OCD compared escitalopram (10 or 20 mg) and paroxetine (40 mg) with placebo [48] over 24 weeks. Escitalopram and paroxetine were each superior to placebo from 6 weeks onwards. Those in the escitalopram 10 mg/day group also exhibited improvement, compared to placebo, on the Y-BOCS, though this effect took more than 12 weeks to become significant. The higher (20 mg/day) escitalopram dose produced additional advantages (vs escitalopram 10 mg/day) on secondary efficacy measures, including remission.

Meta-analysis of placebo-referenced SRI studies

A meta-analysis provides an objective and quantifiable measure of effect size. However, by grouping together findings from disparate studies, the analysis is relatively removed from the originating data. Several meta-analyses in adults and in children and adolescents have supported placebo-referenced efficacy for SSRIs and clomipramine in OCD [32]. The meta-analysis by Soomro *et al.* [49], which included 17 adult OCD studies (3097 study participants), demonstrated that in treatment trials, SSRIs were almost twice as likely as placebo to produce a clinical response. Another recent random effects meta-analysis of SRI trials involving 789 young people with OCD [50] found a moderate effect size for treatment efficacy ($g = 0.50$), treatment response [relative risk (RR) = 1.80], and symptom/diagnostic remission (RR = 2.06).

Which SRI is the most effective?

There is a shortage of studies directly comparing available treatments for OCD. A few head-to-head comparator studies of adequate statistical power indicated equivalent efficacy for SSRIs and clomipramine, but superior tolerability for SSRIs [28]. The UK National Institute for Health and Care Excellence (NICE) meta-analysed all the available

evidence [51]. They concluded there was little difference between clomipramine and SSRIs, in terms of efficacy and adverse events. However, patients were more likely to discontinue treatment prematurely due to adverse events with clomipramine, compared to SSRIs. NICE therefore recommended SSRIs as the preferred first-line treatment for OCD, with clomipramine reserved for patients for whom SSRI treatment is ineffective or unacceptable [51].

Although SSRIs differ in pharmacokinetics, selectivity, and potency of effect on the serotonin transporter and other neurotransmitter receptor-binding properties, there is insufficient evidence to recommend one SSRI over another. Most recently, Skapinakis *et al.* [32] performed a *network meta-analysis* that combined direct and indirect evidence to rank treatments. The analysis demonstrated efficacy for SSRIs as a whole, compared to placebo; individual SSRIs produced similar effect sizes, and there was no evidence to suggest superiority of any individual compound. Clomipramine appeared to have a larger effect size, compared to placebo, than did the SSRIs, but this difference was not statistically significant.

Optimizing SRI dosage

Cumulative evidence suggests OCD responds preferably to a higher daily dosage of SRI, compared to depression or other anxiety disorders. Fluoxetine, sertraline, paroxetine, citalopram, and escitalopram were explored in fixed-dose studies (see Selective serotonin reuptake inhibitors, p. 1013). Of these SSRIs, a positive dose-response relationship was demonstrated for paroxetine (dose range 40–60 mg), fluoxetine (dose range 20–80 mg) [40], and escitalopram (dose range 10–20 mg) [48]. Neither clomipramine nor fluvoxamine have been subjected to multiple fixed-dose comparisons. However, a relatively low, fixed daily dose of 75 mg clomipramine was found to be effective vs placebo [29].

Another meta-analysis incorporating nine studies [52] demonstrated that the highest licensed doses of SSRI were more efficacious than low or mid-range doses. However, this advantage had to be balanced against poorer tolerability at higher dose levels. The British Association for Psychopharmacology treatment guideline [2, 53] suggested starting with the lowest efficacious daily dosage of SSRIs, which may subsequently be increased in the face of insufficient response. However, slow up-titration could be problematic for severely ill patients, for whom a speedy response is needed. The APA guidelines [54] recommend up-titration of SSRIs to the maximum FDA-approved doses within 4–6 weeks and waiting for another 6 weeks to evaluate effectiveness.

Onset of SRI efficacy

The SRI response in OCD is comparatively slow and gradual. Thus, although some well-powered studies were able to demonstrate placebo-referenced efficacy for SRIs within 2 weeks of starting treatment, in most RCTs, the onset of efficacy was delayed by several weeks. In the meta-analysis by Soomro *et al.* [49], SSRIs as a group produced a placebo-referenced statistical difference in Y-BOCS after between 6 and 13 weeks of treatment.

Is the efficacy of SRIs sustained long term?

The limited long-term follow-up data investigating SSRI treatment responders from acute-phase OCD studies suggest that treatment-related gains are maintained without tolerance developing. For example, in a large 24-week multi-centre study by Stein *et al.* [48],

responders continued to accrue over this extended period. Other follow-up studies suggested SSRIs remain efficacious and well tolerated for at least 2 years [31].

SRI and relapse prevention

It is of interest that in a recent study of a community-based sample of adults with OCD, approximately 50% achieved sustained remission by the age of 50 years, suggesting natural remission occurs commonly [55]. This contrasts with OCD as seen in the clinic, which usually follows a chronic and relapsing course. Full remission is infrequent, even in expert treatment centres.

Irrespective of treatment duration, discontinuation of pharmacotherapy is frequently, but not always, associated with relapse [31]. A number of relatively short-term studies have investigated the effect of stopping clomipramine. In the majority of cases, symptoms re-emerged within a few weeks, whereas improvement to a level near to that prior to discontinuation was achieved by reinstating clomipramine [6].

The effect of discontinuing SSRI has been subject to more robust, controlled investigation. A meta-analysis of randomized placebo-referenced RCTs of stable treatment responders demonstrated that continuing treatment with SSRIs as a class reduced relapse [6]. Interestingly, individual studies testing sertraline [56] and fluoxetine [57], which may have been underpowered, did not fully differentiate between continuation treatment or switching to placebo, although patients remaining on the highest (60 mg/day) fluoxetine doses showed significantly lower relapse rates than those given placebo [57].

Together, the results suggest that SSRIs are effective at preventing relapse. A pooled analysis by Hollander *et al.* [7] demonstrated the magnitude of the negative effect of relapse on quality of life and psychosocial functioning, emphasizing the importance of early intervention and relapse prevention, through the continuation of pharmacotherapy, as rational goals for those who have responded to an SSRI or clomipramine. Regular clinic appointments have been shown to enhance treatment adherence [58]. The APA treatment guidelines [54] recommend continuation of pharmacotherapy for a minimum of 1–2 years in treatment-responsive individuals and emphasize the importance of planning long-term treatment from the outset.

Treatment options for patients who do not respond

The clinical management of treatment-resistant OCD has not been thoroughly investigated, although studies indicating promising treatment strategies are starting to appear. The majority of such studies have investigated SRI non-responders, and there remains a want of data relating to psychotherapy resistance. Studies have also chosen different entry criteria; some included only extremely refractory cases who had failed to respond to successive sustained treatments with more than one SRI, whereas others included those who had made a partial response to treatment with a single drug.

Defining treatment resistance

Although most individuals with OCD respond well to first-line treatment with SRIs or ERP, for most, the treatment response is not

complete. In around 40% of cases, residual symptoms remain in spite of prolonged treatment [59]. There remains controversy as to the length of an adequate treatment trial before judging its success. As OCD responds in a slow, gradual way, expert guidelines suggest waiting at least 12 weeks using optimized SRI dosages [54]. For practical purposes, patients experiencing <25% reduction of their baseline Y-BOCS score, after completing 12 weeks of SRI treatment, of which at least 6 weeks should be at the maximal tolerated dose, may be considered to have failed to respond [54].

Extending trial of original SRIs

The APA [54] recommended continuing with an SSRI for 8–12 weeks, of which 6 should be at the maximum tolerated dose, before considering a change in treatment. However, this may result in patients enduring ineffective treatment for longer than necessary. A few studies attempted to identify likely treatment non-responders within a shorter time frame, based upon their early treatment response. For example, symptomatic improvement on SRIs at 4 weeks strongly predicted subsequent clinical response at 12 weeks [60]. This finding emphasizes the importance of looking for early treatment-related improvement and hints that changing SRIs could be considered earlier than 12 weeks into the course of treatment. However, data from another study of fluoxetine non-responders [61] suggested delayed benefit accrues with extended fluoxetine treatment. Importantly, the patients in this study were not necessarily fully SSRI-resistant at baseline. However, it may still be appropriate to persist for >12 weeks with a given SRI in patients showing at least some signs of improvement, particularly if the treatment is well tolerated.

Increasing SRI dosage

The maximum recommended dose (250 mg/day) of clomipramine should not usually be exceeded, due to the increased risk of dose-related serious adverse events, including cardiotoxicity or seizures. In contrast, some evidence suggests SSRIs may show better efficacy and are well tolerated by OCD patients at doses exceeding the licensed maximum. A double-blind study [62] randomized 66 OCD patients who had failed to respond to standard doses to receive sertraline 200 mg/day or 250–400 mg/day. Improvement (on Y-BOCS and CGI) was significantly greater for the high dose group. Both groups displayed similar levels of adverse events, suggesting sertraline is comparatively more effective and well tolerated at doses of >200 mg/day. Similarly, open-label studies that tested a ‘higher than usual’ dose of escitalopram (20–50 mg/day) [63] showed a significantly greater improvement in Y-BOCS scores and response rate than doses of 20 mg/day. Interestingly, the difference disappeared when baseline depression and anxiety scores were analysed as covariates, suggesting that OCD patients with comorbid depression or anxiety may specifically benefit from a higher SSRI dosage.

The APA OCD guideline [54] provides a list of upper doses of SSRIs that are occasionally prescribed for those who have failed to respond to conventional doses or are recognized to be ‘fast metabolizers’. As long as the patient is not experiencing undue adverse effects, the guideline [54] recommends ‘occasionally prescribed’ doses of up to 120 mg/day of fluoxetine, 450 mg/day of fluvoxamine, 100 mg/day of paroxetine, and 400 mg/day of sertraline. Such doses seem most warranted when the patient experienced a partial response to a lower dose and is tolerating the medication well. However, such

an approach is not without risk. In the case of citalopram and escitalopram, dose-dependent effects are recognized to extend the ECG QT interval. Therefore, caution is required if the maximum dose is exceeded. The elderly or those with a cardiac history may be at particular risk. However, a recent study did not show an elevated cardiac risk on higher doses of citalopram [64]. If exceeding the licensed daily dosage, it is advisable to monitor for adverse effects on cardiac conduction (for example, by ECG). The elderly may also be susceptible to SSRI-induced electrolyte disturbances and bleeding tendencies, and for those on anticoagulant therapy, the international normalized ratio (INR) may require more stringent monitoring.

Switching SRI/SSRI to SNRI

Assuming good adherence, if response to the first SRI is inadequate after 8–12 weeks on the maximum dose or is poorly tolerated, switching to another SRI or from SSRI to clomipramine is acceptable, though limited trial data support this option. The chances of responding to a second SRI were estimated at 40%, and to a third SRI at even less [59]. Some evidence supports switching SRIs in the case of non-response and suggests that paroxetine (SSRI) is more efficacious than venlafaxine (SNRI) for non-responders to a previous SRI trial [65].

Adjunctive dopamine antagonist (antipsychotic)

Adjunctive dopamine antagonists have arguably produced the strongest evidence of effectiveness in SRI-resistant OCD. Even so, the evidence is largely derived from small RCTs and uncontrolled case series (reviewed in [59]). There have been no dose-finding studies of dopamine antagonists in OCD. Moreover, there are limited data to inform the optimal duration of adjunctive treatment, the effect on relapse prevention, and the need for metabolic monitoring for this patient group. Apart from encouraging preliminary results for aripiprazole in young people (see Aripiprazole, p. 1017), the current limited evidence does not support the use of dopamine antagonists as monotherapy in OCD.

Early studies with dopamine antagonists

A case series by McDougle *et al.* [66] reported benefit from adding open-label pimozide in patients unresponsive to fluvoxamine. Those with comorbid chronic tic or schizotypal disorder responded best. A subsequent double-blind placebo-controlled study [67] demonstrated significant improvements when haloperidol was added to fluvoxamine. Better response was reported for patients with comorbid tic. However, dose-dependent extra-pyramidal side effects, such as akathisia, occurred to the extent that in some studies [66], up to half the patients required co-administration of β -blockers and/or anticholinergics. Therefore, these agents are usually reserved as third-line treatment after a trial of a dopamine antagonist drug with serotonergic actions. It is recommended to start treatment at low dosages and increase cautiously, subject to tolerability (for example, 0.25–0.5 mg haloperidol, titrated slowly to 2–4 mg) [67].

Newer dopamine antagonist drugs

Risperidone

Several small RCTs have demonstrated efficacy for adjunctive risperidone (0.5–4 mg/day) in SSRI-resistant OCD [68]. However, a RCT [69] that treated 100 SSRI partial or non-responders found no benefit for adjunctive risperidone (up to 4 mg) over placebo. These

data suggest that the benefits of adding risperidone may be limited to patients with clear evidence of SSRI resistance.

Paliperidone

A small 8-week double-blind, placebo-referenced RCT of adjunctive paliperidone (9-OH-risperidone) (≤ 9 mg/day) in 34 cases of SSRI-resistant OCD did not produce statistically significant improvement [70]. Better powered studies are needed to unequivocally demonstrate efficacy.

Olanzapine

There has been one positive and another negative placebo-referenced RCT, which may have failed because the study population was not truly SSRI-resistant prior to entering the trial (reviewed in [31, 59]).

Quetiapine

Studies investigating adjunctive quetiapine (≤ 400 mg daily) in treatment-resistant OCD have also yielded mixed results (reviewed in [31, 59]). In one double-blind, placebo-controlled study, adjunctive quetiapine was efficacious. However, another smaller RCT in more highly treatment-resistant cases found that although quetiapine (mean 215 mg/day) was numerically superior to placebo, the results did not reach statistical significance. In two further RCTs, no significant difference between adjunctive quetiapine and placebo emerged. Another study found that quetiapine successfully augmented the effect of citalopram in 76 cases of non-resistant OCD, suggesting its effects may not be limited to resistant patients.

Aripiprazole

Two small, double-blind, placebo-controlled trials of adjunctive aripiprazole (15 mg/day, 10 mg/day) found evidence of efficacy in adults with SRI-resistant OCD [(reviewed in [31, 59]). Adjunctive aripiprazole has also been subjected to a preliminary open-label study in young people with SRI-resistant OCD, with promising results. An open-label study that investigated aripiprazole *monotherapy* (2–7.5 mg/day) in 16 children with SSRI and CBT-resistant OCD also reported positive findings [71]. These results suggest promise for aripiprazole in treatment-resistant OCD across the lifespan and support further exploration of the effect of antipsychotic monotherapy in OCD.

Meta-analysis of adding dopamine antagonist/partial agonist drugs

While studies on the aforementioned drugs have demonstrated effectiveness as augmentation agents in OCD, the overall effect size is modest and only around one-third of patients are noted to respond. In a pooled analysis [72] of data from placebo-controlled quetiapine trials, the best results were seen when quetiapine was used in combination with clomipramine, fluoxetine, or fluvoxamine and when the SRI dose was lower, suggesting quetiapine may be of most benefit in patients unable to take maximal doses of SRIs.

A subsequent meta-analysis [73], which combined results from 14 randomized, placebo-controlled studies (incorporating 491 patients), showed that significantly more participants responded to augmentation with dopamine antagonists/partial agonists 'as a group' than placebo. Furthermore, aripiprazole, haloperidol, and risperidone significantly outperformed placebo control. Another recent meta-analysis [74] that was limited to newer drugs for psychosis

and included 14 studies and 493 patients produced a similar result. Dopamine antagonists as a class were efficacious, as were aripiprazole and risperidone, but there was insufficient evidence to suggest that quetiapine or olanzapine were superior to placebo.

A mixed-model meta-regression analysis of 13 RCTs [75] correlated the efficacy of each antagonist with its neurotransmitter receptor-binding affinities. A significant positive correlation was found between dopamine receptor (D2R, D3R) affinity and clinical efficacy (standardized mean difference in Y-BOCS score), suggesting the drugs may exert their clinical effects in OCD through this mechanism.

Intravenous administration of SRIs

The intravenous (IV) administration of SRIs is highly dependent on the configuration of health systems and has limited practicality outside inpatient settings. In a study of 54 oral clomipramine-refractory OCD patients randomized to IV clomipramine (25 mg/day, increasing to 250 mg/day) or IV placebo [76], significant advantages were seen for clomipramine on some efficacy measures, but not on the Y-BOCS. IV clomipramine was not associated with serious adverse events. In a more recent open-label study [77] of 30 multiply SRI-resistant *inpatients* administered with IV clomipramine for 1 week, followed by oral clomipramine dosed up to 225 mg/day, 76.7% were responders and 60% were still responders at 24 weeks. No relevant persistent adverse effects were reported. The results suggest IV clomipramine could be of at least short-term benefit for severe OCD cases that have not adequately responded to several therapies, but the long-term advantages need further exploration.

Another open-label study of IV citalopram in SSRI-resistant adults, which was well tolerated even at high doses (up to 80 mg daily) [78], produced satisfactory response rates. All 21 IV citalopram responders showed significant further improvement on continuation treatment with oral citalopram, suggesting that IV citalopram may be a useful method of accelerating the response for OCD patients and for predicting response to oral citalopram.

Combining SSRIs and clomipramine

This combination should be used with caution, as pharmacokinetic interactions on hepatic P450 cytochrome isoenzymes may occur, resulting in elevated clomipramine plasma levels and potential toxicity. One study found that the combination of fluvoxamine and clomipramine was efficacious and generally well tolerated, although high plasma levels of clomipramine associated with a higher frequency of clinically relevant adverse effects were seen [79]. Therefore, ECG, EEG, and clomipramine plasma level monitoring was recommended for co-medicated patients. Compared to other SSRIs, citalopram and escitalopram are potentially less likely to interact with clomipramine. Promising results from a small open-label trial of citalopram (40 mg daily) in combination with clomipramine (150 mg daily) contrast with the results from two more recent small studies with methodological weaknesses, which found no benefit from combining clomipramine with an SSRI and highlighted the potential for adverse effects associated with this combination [61, 80]. One patient on adjunctive clomipramine had to withdraw because of serotonergic syndrome. Another three developed ECG QTc prolongation and were withdrawn. Taken together, the results suggest limited benefits for such combinations,

and if they are contemplated, ECG and plasma level monitoring are advisable.

Novel pharmacological agents

The following compounds are under investigation for OCD and have shown some evidence of efficacy, but as so far they lack convincing validation in controlled studies, they cannot at present be judged to be effective.

The glutamatergic compound memantine has appeared helpful as an adjunct to an SSRI in a few open-label trials and two small randomized, placebo-controlled trials [31, 81]. Preliminary results from open-label studies suggesting efficacy for riluzole, another glutamate-modulating agent [31], have so far not been substantiated. In a placebo-controlled trial of riluzole in children with refractory OCD, no significant difference was noted on any of the primary or secondary outcome measures [82].

The glutamatergic hypothesis of OCD has been further explored through investigation of IV ketamine. Ketamine must be used cautiously, as it is associated with urinary tract damage. A placebo-referenced cross-over RCT in eight resistant patients produced a clinical response in 50% of those receiving ketamine [83]. However, in another 3-day open-label ketamine trial in ten subjects with refractory OCD and depression, there were no responders and, although depressive symptoms improved, the improvement in Y-BOCS scores amounted to <12% [84].

The 5-HT₃ receptor antagonist ondansetron, administered in combination with fluoxetine, demonstrated a superior effect over adjunctive placebo in a randomized controlled pilot study in treatment-resistant OCD [85]. However, an as yet unpublished multi-centre trial did not demonstrate an improvement in OCD symptoms vs placebo.

Mirtazapine as monotherapy was found to significantly improve outcomes in a placebo-controlled discontinuation study of 15 open-label mirtazapine responders [86].

Clonazepam, as an adjunct to an SRI, may produce symptomatic benefit, possibly through improving associated anxiety. It is less suitable in those with a previous history of benzodiazepine or other substance abuse or dependence [87].

Anti-epileptic mood stabilizers may, in combination with an SSRI, have a role in the treatment of OCD, but the supporting evidence is not strong and further placebo-controlled trials are necessary. Positive results were obtained in a small RCT of lamotrigine and another of topiramate in which the therapeutic effect was seen on reducing compulsions only (reviewed in [31]). A second RCT of adjunctive topiramate in 38 resistant patients failed to demonstrate efficacy [88]. Adjunctive pregabalin has been investigated in an open-label case series only, with signs of possible efficacy, as has gabapentin [89].

A randomized, placebo-controlled trial of single-dose D-amphetamine produced short-lived benefits, while another RCT directly comparing D-amphetamine and caffeine noted that both compounds were associated with rapid improvement of obsessive compulsive symptoms within a week, hinting that stimulants, such as D-amphetamine, could play a role in treating OCD, possibly in the context of comorbid attention-deficit/hyperactivity disorder (ADHD) [90].

Combined CBT and pharmacotherapy

Although many specialist centres offer combined treatment, there remains uncertainty over the degree to which combining CBT with SSRIs improves outcomes, compared to monotherapy. Some studies suggested that combining CBT with pharmacotherapy produced better results than CBT monotherapy [59]. Other studies found that patients who responded only partially to an SRI fared better if CBT with ERP was added [12, 91]. Thus, a trial of combined CBT plus an SSRI would seem appropriate for those patients failing to respond adequately to SSRI monotherapy.

The APA Practice Guidelines [54] suggest using either an SRI or CBT as first-line treatment. According to a cost-effectiveness analysis, the UK NICE guidelines [51] recommend combining CBT with an SRI only in more severe or treatment-resistant OCD cases.

The network meta-analysis by Skapinasis *et al.* [32] highlighted that although there are limited data regarding the efficacy of combination treatment, many trials of psychological therapies can be considered as variations of combination trials, as most allowed study participants to remain on stable doses of drugs. They concluded that the combination of SRIs with psychotherapy is likely to be more beneficial for patients with severe OCD than monotherapy. Further research is necessary to substantiate this claim.

Somatic treatments in OCD

Failure to respond to the aforementioned treatments, including combination treatment with intensive inpatient and/or home-based or clinic-based therapist-assisted CBT, may indicate refractoriness to treatment. At this stage, if the symptoms remain severe and incapacitating, it may be necessary to liaise with specialist services offering somatic treatments such as neurostimulation or neurosurgery.

Non-invasive neurostimulation

Repetitive transcranial magnetic stimulation

Repetitive transcranial magnetic stimulation (rTMS) modulates neuronal activity by inducing a magnetic field pulse. rTMS directed at the prefrontal subcortical circuits is hypothesized to be beneficial in OCD [92]. However, there is presently insufficient evidence to recommend the use of rTMS as treatment, and it remains an experimental procedure. A meta-analysis [93] of ten RCTs involving 282 subjects found a moderate effect size (0.59) and the response rates were 35% and 13% for patients receiving active and sham rTMS, respectively. The most promising target areas for stimulation included the orbitofrontal cortex (OFC) and the pre-supplementary motor area (SMA). rTMS is generally safe. However, rarely, high-frequency rTMS may induce seizures. Other reported adverse effects include localized pain, paraesthesiae, hearing change, thyroid-stimulating hormone and blood lactate level changes, and hypomania; however, these problems are usually transient [92].

Transcranial direct current stimulation

Research on the use of transcranial direct current stimulation (tDCS) for treating OCD is still in its infancy. There are no currently published RCTs of tDCS in OCD, but results from a small number of uncontrolled tDCS treatment trials targeting either the SMA

or the OFC, in which tDCS was well tolerated in all cases, appear promising [94].

Transcranial alternating current stimulation

A recent case series showed the successful application of transcranial alternating current stimulation (tACS) in seven SSRI- and psychotherapy-resistant OCD patients [95]. Again, further sham-controlled double-blind studies are warranted if transition of this therapy from the laboratory to the clinic is to be considered.

Deep brain stimulation

Deep brain stimulation (DBS) involves the neurosurgical implantation of electrodes that interrupt electrical impulses linking specific locations in the brain. This approach permits focal, relatively low-risk, and relatively reversible modulation of brain circuitry. It is hypothesized that DBS brings about therapeutic effects in OCD by modulating the cortico-striatal neurocircuitry proposed to mediate OCD [96]. At present, DBS remains a highly experimental treatment for extremely severe enduring illness, with evidence largely based on case series. Studies are small with, at best, partially controlled designs. Although the procedure is reported to be 'relatively safe', with limited side effects [96], the 3-year outcomes of bilateral stimulation of ventral capsule/ventral striatum in ten adult OCD patients included surgical adverse effects, such as asymptomatic haemorrhage, seizure, and superficial infection, as well as psychiatric adverse effects, including worsening of depression and OCD when DBS was interrupted [97]. Other acute adverse effects included transient hypomania, sadness, anxiety, euphoria, and giddiness.

A meta-analysis by Alonso *et al.* [98], which included 116 OCD patients from 31 studies, calculated the global reduction in Y-BOCS score as 45.1% and the global number of responders as 60.0%. Older age of onset of OCD and the presence of sexual or religious obsessions or compulsions were associated with a better response. Worsening of anxiety was the most commonly reported adverse event, occurring in 21.6% of patients. However, the authors state that all side effects were generally mild and transient and that the treatment appeared to be tolerable for most patients.

Ablative neurosurgery

Modern ablative neurosurgical procedures are stereotactically guided, resulting in small and accurately placed lesions. This is most commonly achieved using thermal stimuli, although there is ongoing research into the use of radiosurgical techniques such as the gamma knife.

Anterior cingulotomy, involving lesions placed in the dorsal anterior cingulate cortex, and anterior capsulotomy, involving lesions placed within the inferior fronto-thalamic connections within the anterior limb of the internal capsule, are the most common procedures [99]. Both are hypothesized to modulate functioning within the cortico-striatal-thalamic circuitry. The available evidence suggests that neurosurgery produces significant therapeutic benefits to 30–60% of patients with otherwise highly refractory OCD. Serious adverse effects are uncommon but have been reported with both procedures (for example, intracranial haemorrhage, recurrent seizures). Anterior cingulotomy appears to offer a superior safety profile to that of anterior capsulotomy. The quality of evidence supporting each procedure is reflective of neurosurgery as a whole. A single RCT of gamma capsulotomy has been performed in 16 highly refractory patients [100]. There was a

non-significant benefit on the Y-BOCS for the actively lesioned group. The most serious adverse event was a single asymptomatic radiation-induced cyst. Surgical intervention is reserved for patients with severe, incapacitating OCD who have failed an exhaustive array of expertly delivered medication trials and intensive evidence-based CBT.

Hoarding disorder

Lorena Fernández de la Cruz and David Mataix-Cols

Introduction

Hoarding disorder (HD) is a mental disorder that was newly included in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) [1]. More recently, it was also included in the eleventh revision of the *International Classification of Diseases* (ICD-11) [2]. Individuals meeting the diagnostic criteria for HD experience persistent difficulty discarding or parting with possessions due to a perceived need to save the items and distress associated with discarding them. This results in the accumulation of possessions that congest and clutter active living areas and substantially compromise their intended use, causing clinically significant distress, interfering in daily life, and sometimes posing a risk to self and others. General medical conditions and other mental disorders that are known to result in excessive accumulation of objects must be ruled out before the diagnosis of HD can be made.

Hoarding as a characterological trait has its origins in the psychoanalytical descriptions of the ‘anal’ character [3]. The ‘inability to discard worn-out or worthless objects even when they have no sentimental value’ became a core diagnostic criterion for obsessive-compulsive personality disorder (OCPD) only with the publication of DSM-III-R [4]. In 1994, DSM-IV [5] introduced the idea that ‘extreme’ hoarding might, in fact, warrant a diagnosis of obsessive-compulsive disorder (OCD), leading to the widespread conceptualization of hoarding as a symptom dimension of OCD. However, research accumulated over the last two decades has found that most individuals who display hoarding behaviour do not endorse other symptoms of OCD and has further delineated the differences between the two constructs. This culminated in the inclusion of the new disorder in DSM-5, separate from OCD [3].

In DSM-5, HD is included under the broad umbrella of obsessive-compulsive and related disorders, which—in addition to OCD—also includes body dysmorphic disorder, hair pulling disorder (trichotillomania), and excoriation (skin picking) disorder. The reasons for including HD in this chapter are primarily historical, given the previous conceptualization of problematic hoarding as being a criterion of OCPD and/or a symptom of OCD. While there are similarities between HD and other obsessive-compulsive and related disorders [6], it is also apparent that HD shares features with other emotional, impulse control, and neurodevelopmental disorders such as attention-deficit/hyperactivity disorder (ADHD) [7].

During the process leading to DSM-5, the OCD and Related Disorders Sub-Workgroup also proposed the removal of the hoarding criterion of OCPD, a recommendation that was initially endorsed by the DSM-5 Personality Disorders Workgroup [8], but eventually not followed. Thus, in DSM-5, OCPD retains the ‘inability to discard objects’ criterion, but it encourages clinicians to consider the possibility of HD, rather than OCD, when the hoarding is ‘extreme’.

Clinical features and diagnosis

The DSM-5 diagnostic criteria for HD [1] are based on an earlier operational definition of ‘compulsive’ hoarding [9]. The landmark feature of HD is a persistent difficulty with discarding or parting with possessions (Criterion A). The most commonly saved items include newspapers, old clothing, bags, books, and paperwork, but virtually any item can be saved. The nature of items is not limited to worthless possessions, because many individuals collect and save valuable things too. These discarding difficulties are generally motivated by the perceived utility or aesthetic value of the items, a strong sentimental attachment to the possessions, the fear of losing important information, a desire to avoid being wasteful, or—typically—a combination of these factors [9]. The prospect of discarding or parting with possessions causes substantial distress to the individual (Criterion B).

These difficulties result in the disorganized accumulation of possessions that congest and clutter active living areas and substantially compromise their intended use (Criterion C). Affected individuals may not be able to sleep in their beds, cook in the kitchen, or sit on the sofas in their living rooms. Frequently, the clutter extends beyond the person’s actual home, with accumulation of possessions taking place in garages, gardens, vehicles, and even workplaces. Some individuals may pay for private storage spaces or ask family members or friends to keep items in their homes. Criterion C can still be met if the living areas are uncluttered only because of the intervention of third parties (for example, family members, cleaners, or authorities). Because children and adolescents typically do not control their living environment and have limited acquisitive power, the possible intervention of third parties (for example, parents keeping the spaces useable and thus reducing interference) should

be considered when making the diagnosis. Young individuals with HD who live at their parent's home may not have unduly cluttered bedrooms but still fulfil all other diagnostic criteria.

Criterion D requires that the difficulties with discarding and/or clutter cause clinically significant distress or impairment in social, occupational, or other important areas of functioning, including maintaining a safe environment for self and others. In severe cases, hoarding can put individuals at risk for fire, falling, poor sanitation, and other health risks. Some individuals, particularly those with poor insight, may not report distress, and the impairment may only be apparent to those around the individual. However, any attempts to discard or clear the possessions by third parties result in high levels of distress. Quality of life is often severely impaired, and family relationships are frequently strained [10]. Legal proceedings ranging from forced clearings to evictions and, where relevant, the removal of dependents from the home (for example, children, elderly) are relatively common [11].

A diagnosis of HD can only be given once other general medical conditions (Criterion E) and mental disorders (Criterion F) have been ruled out (see Differential diagnosis, p. 1024).

For a diagnosis of HD, all six criteria must be met. For individuals fulfilling the diagnostic criteria for HD, clinicians may also assess the presence of two specifiers: excessive acquisition and insight.

The *excessive acquisition* specifier is endorsed when the individual engages in excessive acquisition of free items, excessive buying, or—less frequently—stealing items that are not needed or for which there is no space available. Approximately 63–90% of persons with HD engage in excessive acquisition [12–15]; these individuals typically experience distress if they are unable to acquire items or are prevented from acquiring items. Reducing excessive acquisition is one of the main goals in the treatment of HD (see Treatment, p. 1027).

The *insight* specifier has three categories (good/fair, poor, and absent/delusional) and refers to the degree to which the individual recognizes that hoarding-related beliefs and behaviours are problematic. A substantial proportion of sufferers lack insight into their difficulties and are reluctant to seek help for their problems [16].

Increasing motivation for change is an integral part of the current psychological treatment for HD (see Treatment, p. 1027).

Other common features of HD include indecisiveness, perfectionism, avoidance, procrastination, difficulty with planning and organizing tasks, and distractibility [9]. Some individuals with HD live in various degrees of unsanitary conditions (*squalor*) that may be a logical consequence of severely cluttered spaces and/or related to planning and organizing difficulties [17]. However, the majority of individuals living in severe domestic squalor do not meet the criteria for HD; rather, squalid homes are typically seen in other medical or neurocognitive conditions (see Differential diagnosis, p. 1024).

Some individuals are known to accumulate large number of animals. In *animal hoarding*, there is generally failure to provide minimal standards of nutrition, sanitation, and veterinary care for the animals and failure to act on the deteriorating condition of the animals and the environment. It is unclear if animal hoarding is a special manifestation of HD, but most individuals who hoard animals also hoard inanimate objects [18].

Differential diagnosis

A diagnosis of HD can be made only after other medical conditions and mental disorders that can lead to excessive accumulation of possessions have been ruled out. A careful psychopathological interview is necessary to establish the differential diagnosis of HD. The presence of cluttered living spaces alone does not necessarily signal the presence of HD, because cluttered (and sometimes unhygienic) living spaces may be the consequence of multiple conditions (Fig. 99.1).

Other medical conditions

HD is not diagnosed if the symptoms are judged to be a direct consequence of another medical condition (Criterion E), such as traumatic brain injury, surgical resection for the treatment of a tumour

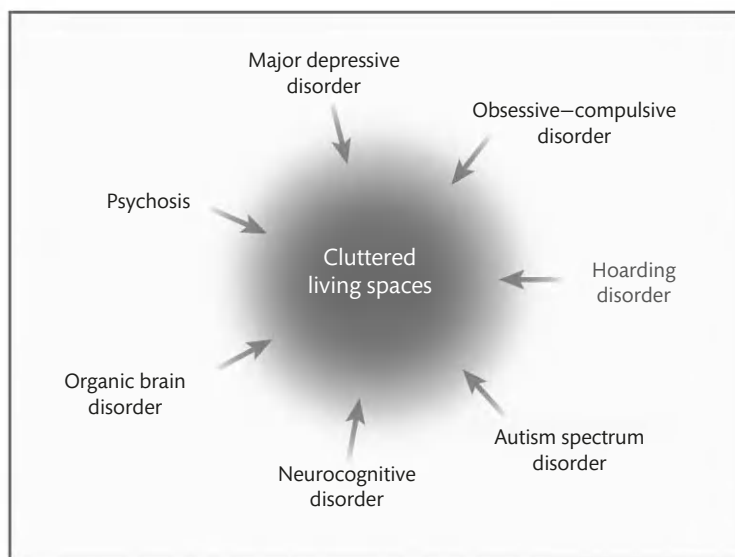

Fig. 99.1 Differential diagnosis of hoarding disorder.

or seizure control, cerebrovascular disease, infections of the central nervous system (for example, herpes simplex encephalitis), or neurogenetic conditions such as Prader–Willi syndrome [3]. Damage to the anterior ventromedial prefrontal and cingulate cortices has been particularly associated with the excessive accumulation of objects [19, 20]. In these individuals, the hoarding behaviour is not present prior to the onset of brain damage and appears shortly after brain damage occurs [19]. Some of these individuals appear to have little interest in the accumulated items and are able to discard them easily or do not care if others discard them, whereas others appear to be very reluctant to discard anything [20].

Neurodevelopmental disorders

HD is not diagnosed if the accumulation of objects is judged to be a direct consequence of a neurodevelopmental disorder such as autism spectrum disorders (ASD) or intellectual disability. Individuals with ASD may, for example, excessively acquire or retain possessions that correspond to a particular sensory preoccupation or ‘special interest’. The relevance of these behaviours should be investigated [for example, ‘Do the objects you save largely share a particular physical characteristic (for example, material, texture, shape)?’].

Schizophrenia spectrum and other psychotic disorders

HD is not diagnosed if the accumulation of objects is judged to be a direct consequence of delusions or negative symptoms in schizophrenia spectrum and other psychotic disorders [3, 21].

Major depressive episode

HD is not diagnosed if the accumulation of objects is judged to be a direct consequence of psychomotor retardation, fatigue, or loss of energy during a major depressive episode.

Obsessive–compulsive disorder

OCD warrants particular consideration, given the previous conceptualization of hoarding as a symptom of OCD [3]. HD is not diagnosed if the symptoms are judged to be a direct consequence of typical obsessions or compulsions such as fears of contamination, harm, or feelings of incompleteness. In such cases, OCD should be diagnosed instead [22]. Symmetry obsessions and compulsions are most commonly associated with this form of hoarding. The accumulation of objects can also be the result of persistently avoiding onerous rituals (for example, not discarding in order to avoid endless washing or checking rituals) [3, 21].

Some additional clinical features are helpful in differentiating HD from OCD. In OCD, the behaviour is generally unwanted and highly distressing, and the individual experiences no pleasure or reward from it. Excessive acquisition is usually not present; if excessive acquisition is present, items are acquired because of a specific obsession (for example, the need to buy items that have been accidentally touched in order to avoid contaminating other people), not because of a genuine desire to possess the items. These individuals are also more likely to accumulate bizarre items such as trash, faeces, urine, nails, hair, used diapers, or rotten food [23]. Accumulation of such items is very unusual in HD.

Both disorders may be diagnosed when severe hoarding appears concurrently with other typical symptoms of OCD but is judged to be independent of these symptoms [3].

Neurocognitive disorders

HD is not diagnosed if the accumulation of objects is judged to be a direct consequence of a degenerative disorder such as neurocognitive disorder associated with fronto-temporal lobar degeneration or Alzheimer’s disease. Typically, onset of the accumulating behaviour is gradual and follows the onset of the neurocognitive disorder. The accumulating behaviour may be accompanied with self-neglect and severe domestic squalor (where there is trash, rotten food, or excrement), alongside other neuropsychiatric symptoms such as disinhibition, gambling, rituals/stereotypies, tics, and self-injurious behaviours [17].

Normal collecting

While technically not a differential diagnosis, it is worth delineating the differences between normative or healthy collecting and pathological hoarding [24]. This is particularly relevant because quite a few individuals meeting the criteria for HD define themselves as ‘collectors,’ as they perceive this term as being somewhat less pejorative [24]. Normative collecting is a common activity that is both benign and pleasurable. Most children and up to 30% of adults collect items at some point [25]. Collectors report the acquisition of, attachment to, and reluctance to discard objects, but they do not have the disorganized clutter, distress, and impairment that is characteristic of HD. In contrast to hoarding, the process of collecting is highly structured and planned, very selective (that is, confined to a narrow range of items), pleasurable, and often a social activity. Most collectors, even those who might be considered eccentric, are unlikely to meet the diagnostic criteria for HD [24, 25].

Comorbidities

Although approximately 5–10% of patients with OCD display hoarding symptoms, the majority of individuals (>80%) with hoarding problems do not display other OCD symptoms [12, 13, 23, 26]. In fact, hoarding symptoms may be equally prevalent in individuals with anxiety disorders other than OCD, although these symptoms often go unnoticed as clinicians do not ask about them [27].

The most common psychiatric comorbidities among hoarding cases are generalized anxiety disorder (31–37%), major depressive disorder (26–31%), OCD (15–20%), panic disorder (17%), social anxiety disorder (14%), and post-traumatic stress disorder (14%) [12, 13, 15, 21, 28]. Symptoms typical of ADHD, particularly inattention, are also commonly reported [7, 13]. These comorbidities, rather than hoarding, may often be the main reason for clinical consultation [27].

General medical conditions may also be highly frequent in patients with HD. The presence of HD has been associated with both poorer perceived physical health and higher rates of disability [15]. These limitations may be particularly evident in elderly individuals, who appear to have a disproportionately high rate of medical complications of HD, compared with age-matched control subjects [29].

Course and prognosis

Retrospective reports indicate that hoarding difficulties begin early and span well into the late stages of life. Hoarding symptoms may

first emerge around the age of 11–15 years, start interfering with the individual's everyday functioning by the mid-20s, and cause clinically significant impairment by the mid-30s [30–32]. Problems with acquisition, when they do emerge, appear to do so (or become more evident) earlier than problems with discarding [30]. Participants in clinical research studies are usually in their 50s [12, 23]. A steady worsening of symptoms is typically reported over each decade of life [33]. Once symptoms begin, the course of hoarding is often chronic, with a few individuals reporting a waxing and waning course [32]. Given the absence of treatment studies with long follow-up periods, it is currently unknown what the long-term prognosis of treated HD is.

Epidemiology

Initial prevalence estimates, primarily from questionnaire studies conducted in Europe and the United States, estimated the point prevalence of clinically significant hoarding to be approximately 2–6% among adults [21] and 2% among adolescents [34]. However, in the only epidemiological study to date to employ the current DSM-5 criteria, conducted in England, the prevalence was estimated to be approximately 1.5% in both adult men and women [15]. This estimate, which was obtained principally through diagnostic interviews conducted face-to-face in the participant's homes, contrasts with some prior work in its suggestion that rates of HD are balanced across the genders. Help-seeking clinical samples are predominantly female, perhaps reflecting better insight and motivation for change. Epidemiological studies are more consistent in their finding that the prevalence of HD seems to increase with advancing age [15, 21].

Individuals with HD are more frequently unemployed and more often unmarried, separated, or divorced than individuals from the general community [15, 24, 35]. Additionally, they are more likely to feel that their hoarding difficulties impair their social and occupational functioning [10, 15]. The functional impairments caused by the disorder typically extend to the relatives or carers of the person who hoards [10].

Aetiology

Genetic and environmental factors

Although controlled family studies have not yet been carried out, patient self-report suggests that hoarding runs in families [23]. Consistently, a handful of twin studies conducted in large population-based adult twin samples suggest that this familiarity is largely attributable to additive genetic factors (with heritability ranging between 36% and 50%), with the remaining variance attributable to non-shared environmental factors and measurement error [36–38]. Interestingly, a twin study in adolescents indicated possible sex-based variations regarding the role of genes and the environment in hoarding symptoms, suggesting that the aetiology of HD may be dynamic across the lifespan, with the roles of genes and the environment varying over time and between the sexes [34].

On the other hand, research in twins suggests substantial, yet incomplete, genetic overlap between core symptoms of HD (difficulties discarding and excessive acquisition), while non-shared environmental influences appear to be more specific to each of these

traits [39]. Together with the fact that not all individuals with HD also excessively acquire, these twin modelling results support the current placement of excessive acquisition as a specifier in DSM-5, rather than as a core diagnostic criterion for HD.

The mechanisms by which either genetic or environmental factors, or their interaction, confer risk to the development of HD remain unknown. Specific genes implicated in HD have not yet been identified. Although research has suggested some unique environmental risk factors (for example, traumatic life events), small samples and retrospective self-report methods leave unclear the role of such exposures in the onset or exacerbation of HD [31, 36]. Anecdotal links between material deprivation (for example, childhood poverty) and hoarding have received no support in the literature [31].

Future work is warranted to understand how specific genetic and environmental risk factors interact to confer risk to individuals carefully diagnosed as having HD. It is likely that these genetic and environmental risk factors will be, at least in part, shared with related conditions such as OCD and other related disorders [40]. The potential aetiological overlaps between HD and other neuropsychiatric conditions (for example, anxiety and mood disorders, ADHD) remain to be explored.

Neurobiology

The neural substrates of hoarding behaviour have been well studied in animals that naturally display hoarding behaviours as part of their behavioural repertoire (for example, rodents, birds), as well as primates. These studies clearly implicate subcortical limbic structures (nucleus accumbens, ventral tegmental area, amygdala, hippocampus, thalamus, hypothalamus) and the ventromedial prefrontal cortex in the mediation of hoarding behaviour [20]. Research with animals also suggests that the dopaminergic system plays a crucial role in hoarding behaviour (for a review, see [20]). Whether the known involvement of the dopaminergic system in hoarding among animals can explain the relatively poor response of hoarding individuals to serotonergic drugs [41] is an attractive hypothesis that remains to be investigated.

Much less is known about normal and abnormal hoarding behaviour in humans. Useful clues come from case studies of brain-damaged patients and of individuals with dementia, particularly of the fronto-temporal type. This research suggests that the ventromedial prefrontal/anterior cingulate cortices, as well as medial temporal regions, may be implicated in hoarding behaviour [20]. One theory is that the former cortical regions modulate or suppress subcortically driven predispositions to acquire and collect and adjust these predispositions to the environmental context [19]. Damage to these cortical regions may result in dysregulated collecting and hoarding behaviour.

The neuroimaging literature of 'non-organic' hoarding has also implicated the ventromedial prefrontal/anterior cingulate cortices and subcortical limbic structures (for example, amygdala/hippocampus) in hoarding patients [42–44]. However, the evidence is preliminary, obtained from small samples, and confounded in many cases by the presence of comorbid OCD symptoms [20].

Similarly, it is difficult to draw firm conclusions from early reports on the neurocognitive profile of HD [20]. Many of the initial neuropsychological studies recruited OCD patients with hoarding symptoms (with different degrees of severity), whereas others recruited

individuals with severe hoarding, but predominantly without OCD. The neuropsychological tests employed have been heterogeneous and have tapped into different domains, and few employed psychiatric control groups. Findings to date suggest possible impairments in spatial planning, visuo-spatial learning and memory, sustained attention/working memory, organization, response inhibition, set shifting, probabilistic learning, and reversal [20, 45].

Future work in this area should include carefully characterized samples of individuals meeting strict criteria for HD.

Assessment

The diagnosis of HD is usually made on the basis of a direct interview with the person being evaluated to establish whether the diagnostic criteria are met. The Structured Interview for Hoarding Disorder (SIHD) [46] is available for this purpose.

Because hoarding may not always be the initial reason for consultation [27], clinicians often need to ask direct questions such as ‘Do you find it difficult to discard or part with possessions?’ or ‘Do you have a large number of possessions that congest and clutter the main rooms in your home?’ An affirmative answer to these questions can initiate a dialogue that may lead to diagnosis.

A home visit is recommended for the assessment of clutter, impairment, and associated risks. If a home visit is not feasible, the clinician should try to gather additional information from reliable informants such as a spouse or relative (with the patient’s consent). This is particularly important for affected persons with limited insight, because they may underestimate the extent and consequences of their difficulties. Informants may also help establish whether the current presentation is long-standing or transient, whether third parties have intervened to clear away some of the clutter, and whether there are potential risks that require attention.

Photographs of the patient’s home can also be very useful in helping to document the presence of clinically significant clutter and to track treatment outcomes [47, 48], particularly when home visits are not possible or are impractical. However, photographs should not be a substitute for a thorough psychopathological interview.

The diagnostic interview provides an opportunity to carry out a thorough risk assessment. Attention should be paid to potential fire hazards, the risk of a clutter avalanche, the presence of rodent or insect infestation, and unsanitary living conditions that pose a risk to health. In addition, it is important to establish whether other vulnerable persons (for example, children and elderly people) live with the person who is hoarding.

Numerous clinician and self-administered measures of hoarding severity exist and can be used to quantify the severity of various aspects of hoarding such as difficulties discarding, clutter, distress, etc. While useful, these measures do not allow a diagnosis of HD, primarily because it is not possible to rule out other disorders that may cause hoarding. Therefore, they should be restricted to quantify the severity of hoarding in already diagnosed individuals or to screen individuals in population-based studies.

Some of the most widely used clinician administered measures include the Hoarding Rating Scale-Interview (HRS-I) [49] and the Clutter Image Rating (CIR) [47]. Among the most widely used self-administered measures are the Hoarding Rating Scale-Self Report (HRS-SR) [50], the Saving Inventory-Revised (SI-R) [51],

the UCLA Hoarding Severity Scale (UHSS) [52], and the Hoarding Disorder Dimensional Scale (HD-D) [53]. Typically, these measures have empirically derived cut-offs, which give an indication of whether the person is likely to have clinically significant hoarding problems. Supplementary measures that assess saving cognitions (for example, Saving Cognitions Inventory) [54], problematic acquisition (for example, Compulsive Acquisition Scale) [55], self-reported squalor (for example, Home Environment Index) [56], and caregiver burden and accommodation (for example, Family Impact Scale for Hoarding Disorder) [57] are available and may prove useful for clarifying the clinical picture and monitoring treatment outcomes.

Treatment

Few treatment studies have specifically included individuals fulfilling the DSM-5 criteria for HD, and therefore, the evidence to guide treatment choice is currently weak.

Psychological treatment

Currently, the intervention that has the strongest evidence base for HD is a multicomponent psychological treatment that is based on a cognitive behavioural model [9]. The intervention includes office and in-home sessions; motivational interviewing methods to address ambivalence about therapy; education about hoarding; goal-setting; organizing, decision-making, and problem-solving skills training; exposure to sorting, discarding, and not acquiring; and cognitive strategies to facilitate this work [58].

Tolin and colleagues [59] conducted a meta-analysis of all open or randomized controlled trials (RCT) of CBT or behavioural therapy for hoarding in adults. The eligible studies used hoarding-specific outcome measures, and HD was the primary condition being studied, as opposed to hoarding measured in the context of another psychiatric disorder (for example, OCD). Ten relevant studies—comprising 12 samples—were identified, of which three were RCTs, including a total of 103 patients. Four samples used individual CBT, whereas the remaining eight used a group format. Three samples employed a peer-directed, bibliotherapy-based programme of CBT, with no professional therapist present. The number of CBT sessions ranged from 13 to 35 (mean = 20.2 sessions), and the number of visits conducted in patients’ homes ranged from 0 to 33 (mean = 5.6 sessions). Overall HD symptom severity decreased significantly across studies with a large effect size (Hedges’ $g = 0.82$ for the overall HD severity score). Significant effects were evident on all outcome domains. The strongest effects were seen for difficulty discarding (Hedges’ $g = 0.89$). Clutter and acquiring showed effects in the moderate range (Hedges’ $g = 0.70$ and 0.72 , respectively). Functional impairment (which was not used in the calculation of overall HD symptom severity) showed the smallest effect in the moderate range (Hedges’ $g = 0.52$) [59].

Thus, although encouraging, the clinical outcomes of CBT interventions for hoarding are relatively modest (many individuals still require additional treatment), and there is still significant room for improvement. The long-term benefit of such interventions is unclear, but data from a single trial suggest that the treatment gains of CBT for HD were largely maintained at 12-month follow-up [60]. Studies with even longer follow-up times are needed.

Pharmacological treatment

Pharmacotherapy has also been suggested as a treatment for HD. However, data regarding the use of such treatment are limited and derived from small, uncontrolled studies. While no RCTs of medication for HD have been conducted, some data are available from studies in OCD patients with hoarding symptoms. In patients diagnosed with OCD, the presence of hoarding symptoms is associated with a worse response to serotonin reuptake inhibitors (SRIs), alone or in combination with CBT [41]. Specifically, OCD patients with hoarding symptoms are, on average, 50% less likely to respond to SRIs than non-hoarding OCD patients [41].

In an open-label study of paroxetine that included 79 OCD patients (32 patients meeting criteria for 'compulsive hoarding syndrome' [9] and 47 patients with non-hoarding OCD), hoarding symptoms improved as much as other OCD symptoms. However, paroxetine was not well tolerated (with adverse effects including sedation, fatigue, constipation, akathisia, headache, and sexual dysfunction), and the overall response was moderate in both groups.

To date, only three studies (two open-label trials and one case series) have included samples of individuals diagnosed with HD according to the DSM-5 criteria. An open study evaluated the efficacy of a 12-week trial of venlafaxine and classed 16 of 24 participants as responders (defined as at least 30% reduction in UHSS and SI-R scores, as well as a rating of at least 'much improved' on the Clinical Global Impression-Improvement) [61]. Two other studies have used ADHD treatments to treat hoarding symptoms. The first of these studies was a case series of four patients treated with methylphenidate extended-release for 4 weeks. Of the four patients, two had a modest reduction in hoarding symptoms (25% and 32% decrease in the SI-R) [62]. More recently, another uncontrolled trial reported that nine of 12 participants with HD showed some degree of reduction in their hoarding symptoms in a 12-week trial of atomoxetine [63]. Eleven patients completed the trial, and of these, six were classified as full responders based on the UHSS (mean reduction of 57%); three other patients were classified as partial responders (mean reduction of 27%).

Future directions

Further controlled clinical trials are needed to assess the short- and longer-term efficacy of psychological and pharmacological treatments, alone and in combination, in carefully diagnosed individuals with primary HD. Additional behavioural interventions that have shown promising results and require further research include those aimed at improving cognitive functioning (for example, attention, organization) in individuals with HD [64, 65] and the development and evaluation of interventions for carers of individuals with HD [10, 66]. The development of interventions adapted for special populations (for example, hoarding symptoms in individuals ASD or intellectual disabilities) is also warranted [67, 68].

While the current psychological treatments emphasize the importance of motivational interviewing techniques, the patients included in the trials described had sufficient insight to at least seek help. It is currently unclear how to best approach individuals with absent or delusional insight and who may only come to the attention of mental health services against their will. The clinical management

of these cases may require an unprecedented level of inter-agency co-ordination. Several countries have set up local or federal multi-agency task forces (often including mental health, fire, pest control, housing, legal and social services) to tackle the most severe cases of hoarding who do not voluntarily seek or want help [69].

Body dysmorphic disorder

Megan M. Kelly and Katharine A. Phillips

‘The dysmorphic patient is really miserable; in the middle of his daily routines, talks, while reading, during meals, everywhere and at any time, he is caught by the doubt of deformity ...’

Enrico Morselli, 1891 [1]

Introduction

Body dysmorphic disorder (BDD) (previously called ‘dysmorphophobia’) is a common, often severe psychiatric disorder that has been described for more than a century [1–3]. BDD is characterized by distressing or impairing preoccupations with non-existent or slight defects in physical appearance [4]. In addition, BDD consists of repetitive behaviours (that is, compulsions and rituals) that, at some point during the course of the illness, have been performed in response to the appearance concerns [4]. BDD is classified as an obsessive–compulsive and related disorder in DSM-5 [4]. In ICD-10, BDD is classified as a type of somatoform disorder, but recommendations for ICD-11 are to classify BDD in a new category of obsessive–compulsive and related disorders [5]. Psychosocial functioning is often markedly impaired in BDD [6]. In addition, BDD is characterized by high rates of suicidality and comorbid substance use [7, 8]. Despite its prevalence, severity, and negative effects on functioning, BDD is under-recognized in clinical settings [2, 3].

Clinical features

Demographic characteristics

BDD occurs in all age, racial, and ethnic groups [2, 3, 7, 9]. BDD appears slightly more prevalent in women than men [2, 3, 7]. Most individuals with BDD have never been in a primary relationship [10]. Occupational and academic functioning is often substantially impaired, and unemployment rates are elevated, which often appears attributable to BDD symptoms [2, 3, 6, 7].

Bodily preoccupations

People with BDD are preoccupied with the idea that some aspect of their appearance is ugly, unattractive, deformed, flawed, or defective in some way when it actually is not [1–3, 6–7]. Concerns usually focus on the face or head but can involve any body area [1–3, 7]. Concerns with the skin (for example, perceived acne, scars, lines,

or pale skin), hair (for example, perceived thinning or excessive body or facial hair), and nose (for example, size or shape) are the most common. Concerns about perceived asymmetry of body areas occur in about a quarter of individuals (for example, concerns about perceived unevenness or asymmetry of the hair, breasts/chest, eyes, face, jawline, or lips) [11].

Most patients with BDD are preoccupied with multiple body areas; the number of body areas of concern may range from only one to virtually every aspect of one’s appearance. BDD concerns may also focus on one’s overall appearance. People with BDD often believe that they are unacceptable and will be rejected by others because they look abnormal [2, 3].

Muscle dysmorphia is an often more severe form of BDD and bodily preoccupation, characterized by distress over a perceived ‘small’ and insufficiently muscular body build, which occurs primarily in men. Individuals with muscle dysmorphia appear to have even poorer quality of life and higher rates of suicidality and substance use disorders—in particular, anabolic steroid use—than those with BDD who are preoccupied with other body areas [12]. Muscle dysmorphia may also be associated with particularly adverse psychological and medical sequelae, including an increased risk of violent behaviour, which may, in part, reflect abuse of anabolic–androgenic steroids [13].

Insight/delusionality

BDD-related insight is typically poor but can range from good to absent insight (delusional beliefs); the latter is characterized by complete conviction that the person looks abnormal, ugly, unattractive, or deformed. Studies have found that 36–60% of individuals with BDD currently have delusional beliefs about their appearance [14, 15]. Poor insight or delusional BDD beliefs may limit patients’ recognition that their appearance concerns are due to a mental illness and make them unwilling to accept mental health treatment [2, 3, 16].

In addition, a majority have ideas or delusions of reference, believing that others take special notice of the supposed appearance defects—for example, staring at them or mocking them because of

how they look [16]. Referential thinking can fuel feelings of anger and rejection, as well as social isolation. These findings are consistent with evidence that individuals with BDD have an interpretive bias for threat. Compared with other groups, those with BDD more often misinterpret neutral facial expressions as contemptuous and angry, and they similarly more often misinterpret ambiguous scenarios (appearance-related, social, and general scenarios) as threatening [17, 18].

Compulsive and safety behaviours

Compulsive behaviours, also referred to as repetitive behaviours or rituals, occur in response to preoccupations with perceived physical defects. Like the compulsive behaviours that occur in obsessive-compulsive disorder (OCD), they are usually distressing, time-consuming (occurring over an average of 3–8 hours a day), and difficult to resist or control [2, 3]. The behaviours usually aim to examine, improve, hide, or obtain reassurance about the perceived defects. These behaviours typically do not alleviate BDD-triggered distress and may even worsen it.

Common compulsive behaviours and their occurrence in those with BDD are described in the American Psychiatric Association's DSM-5 [4]. Individuals with BDD often compare their appearance to others, including people in newspapers or magazines or on television or social media. Other compulsive behaviours include repeated checking of mirrors and other reflective surfaces (for example, windows), excessive grooming (for example, hair styling, make-up application), reassurance seeking, and excessive exercise or weightlifting.

Several compulsive behaviours have potential medical risks. Compulsive skin picking, which 27–45% of BDD patients do to try to improve the appearance of their skin, can cause considerable skin damage [2, 3]. Emergency surgery is sometimes required—for example, when sharp implements are used for picking ruptured major blood vessels. Compulsive tanning to darken 'pale' skin or minimize perceived acne, scarring, or 'marks' can cause skin damage and increases cancer risk [2, 3].

Some compulsive behaviours, such as camouflaging disliked body areas (for example, hiding perceived balding with a hat or 'asymmetrical' eyes with sunglasses), may also be conceptualized as safety behaviours, as they are motivated by the desire to prevent a feared outcome. However, these behaviours may also be repetitive (for example, repeatedly reapplying and fixing make-up), and thus they may also sometimes be compulsive in nature.

Psychosocial functioning and quality of life

BDD is associated with very poor quality of life and marked functional impairment [2, 3, 6]. Mental health-related quality of life scores in BDD are poorer than for depression, OCD, schizophrenia, and bipolar disorder [6]. Most individuals with BDD also have marked impairment in activities of daily living; many have been housebound due to their BDD symptoms [2, 3, 18]. In addition, BDD is associated with high lifetime rates of psychiatric hospitalization [19, 20]. Prospective research on the course of BDD demonstrates that functional impairment tends to be chronic over time [21], although in treatment studies, functioning usually improves when BDD symptoms do.

Social functioning is notably poor in BDD. Individuals with BDD often avoid other people because they are afraid of being rejected because of their appearance [2, 3, 10]. As a result, many people

with BDD have difficulty forming and maintaining relationships with others. BDD is also associated with high rates of unemployment and often marked impairment in occupational and academic functioning [18]. In a broadly obtained sample of convenience of individuals with BDD, 38% were currently unemployed [18]. Unemployment due to BDD is associated with greater current severity of BDD and depressive symptoms, a more chronic course of BDD, and poorer current social functioning and quality of life [18]. BDD may not only negatively affect a person's ability to hold a job, but it also often impairs one's concentration, work quality, and work productivity [18]. High rates of academic impairment are also common in BDD. In one study, 18% had dropped out of elementary school or high school primarily because of BDD symptoms, and in another study, 22% of youth dropped out of school because of their BDD symptoms [22, 23].

In population-based epidemiologic studies, compared to individuals without BDD, those with BDD were more likely to be divorced and less likely to be married; they also had a lower educational level, lower household income, and greater unemployment and sick leave [24].

Other associated features

BDD preoccupations may trigger a broad range of negative emotions. BDD is associated with an increased frequency of depression, anxiety, and social anxiety, as well as high levels of these symptoms: feelings of shame and low self-esteem; hostility and anger; rejection sensitivity; and high levels of neuroticism, introversion, perfectionism, and perceived stress [11]. Pursuit of cosmetic treatment, such as surgery and dermatologic and dental treatment, is a common feature of BDD that often leads to poor treatment outcomes.

Common core beliefs, which are addressed in cognitive behavioural therapy (CBT), include: 'I am inadequate', 'I am defective', 'I am worthless', and 'I am unlovable'. Negative core beliefs such as these are compatible with the high rates of depression and suicidality that occur in BDD.

Suicidality

Suicidal ideation and attempts are very common in BDD. Reported lifetime rates of suicidal ideation and suicide attempts in clinical samples and broadly ascertained samples of convenience are 78–81% and 24–28%, respectively [8, 19]. In a population-based epidemiologic study, 20% of participants with BDD reported suicidal thoughts specifically because of appearance concerns, and 7% had attempted suicide because of appearance-related concerns, whereas only 1% of the non-BDD group had attempted suicide. In another epidemiologic study, 31.0% in the BDD group vs 3.5% in the non-BDD group had suicidal ideation due to appearance concerns, and 22.2% of those with BDD vs only 2.1% of those without BDD had attempted suicide specifically because of appearance concerns [24].

The rate of completed suicide, while preliminary, appears markedly high. In a prospective study, the annual suicide rate was 0.35%, which is approximately 45 times higher than for the population in the United States (adjusted for age, gender, and geographic region) and higher than for most other psychiatric disorders [25].

Preliminary evidence suggests that adolescents and Veterans with BDD, as well as those with muscle dysmorphia, appear to have significantly higher rates of suicidality than other BDD groups [25].

Variables that are independently associated with suicidal ideation and/or suicide attempts in BDD are greater BDD symptom severity; comorbid major depressive disorder, PTSD, a substance use disorder, social anxiety disorder, OCD, and three or more comorbid Axis I disorders; onset of BDD before the age of 18; being unemployed; childhood maltreatment; and BDD-related restrictive food intake [25].

BDD is associated with many risk factors that have been shown more generally to predict completed suicide. These risk factors include high rates of suicidal ideation and attempts, depression and substance use disorders, history of perceived abuse, functional impairment and social isolation, unemployment, disability, being single or divorced, and psychiatric hospitalization, as well as high levels of anxiety, depression, poor self-esteem, anger, and feelings of humiliation and shame [25]. Whether these risk factors predict completed suicide in BDD is unknown and warrants investigation.

Comorbidity

Lifetime major depressive disorder is the most frequent comorbid disorder, occurring in about 75% of individuals with BDD [26]. The other most common co-occurring Axis I psychiatric disorders are social anxiety disorder, OCD, and substance use disorders [26]. Axis I comorbidity is associated with greater functional impairment and morbidity. In particular, the presence of comorbid major depressive disorder is associated with poorer quality of life and more functional impairment [26]. Comorbid personality disorders occur in 40–100% of individuals with BDD, with Cluster C disorders—in particular, avoidant personality disorder—occurring most frequently [26].

Gender

BDD is slightly more common in women than in men in both clinical and non-clinical samples, with the exception of cosmetic and dermatological settings [27]. Men and women appear to have largely similar clinical features [7, 19, 28, 29]. However, there are some notable gender differences, some of which reflect gender differences in the general population. Men are more likely to be single, have a substance use disorder, and be preoccupied with thinning hair and small body build (muscle dysmorphia) [19, 29]. Women are generally more likely to be preoccupied with their weight, hips, and excessive body hair and are more likely to pick their skin and use their hands or make-up for camouflage [19, 29]. One study ($n = 58$) [28] found that women are more likely to be preoccupied with their breasts/chest and legs, check mirrors, and use camouflaging to hide disliked body areas. In addition, concerns about genitals are more common in men, and a comorbid eating disorder is more common in women [19, 28, 29].

BDD in children and adolescents

BDD usually begins during early adolescence and can occur in childhood [30]. While data are limited, BDD's clinical features in youth appear largely similar to those in adults [30]. Youth with BDD typically have very poor psychosocial functioning and mental health-related quality of life. BDD often causes academic underachievement, social avoidance, and other types of psychosocial impairment; it may also lead to school refusal and school dropout, which can derail healthy adolescent development [30]. Suicidal ideation and attempts, physical aggression, and substance use disorders are risk behaviours that commonly occur in youth with BDD [30].

Preliminary findings suggest that BDD may be more severe in youth than in adults. Of note, children and adolescents appear to have lifetime rates of functional impairment similar to those in adults, despite having had fewer years over which to have developed these problems [30]. In addition, adolescents appear more likely than adults to have delusional BDD beliefs (as opposed to better insight), and they have a significantly higher lifetime suicide attempt rate (44% vs 24%, respectively). These findings underscore the importance of recognizing and treating BDD in this age group [30].

Cross-cultural aspects of BDD

Case reports and case series from around the world suggest that BDD's clinical features are generally similar across cultures, but that cultural factors may produce nuances and accents on a basically invariant, or universal, expression of BDD [2, 3]. In east Asian cultures, a form of social anxiety disorder—*taijin kyofusho* (*shubokyo-fu*—‘the phobia of a deformed body’) [31]—has many features of BDD. Thus, in Asian cultures, BDD is considered more closely akin to social anxiety disorder; in Western countries, BDD is considered closely related to OCD due to prominent obsessive and compulsive features. Much more research has been done on BDD's relationship to OCD than to social anxiety disorder; it is likely that BDD is closely related to both of these disorders.

Diagnosis

BDD can be diagnosed using questions at the top of **Box 100.1**, which are consistent with DSM-5's diagnostic criteria. Clinicians should adequately probe for examples of clinically significant distress and impairment in social, occupational, academic, and other aspects of functioning. BDD is diagnosed if the person is excessively preoccupied with one or more non-existent or slight physical flaws (for example, thinking about it for at least an hour a day) and the preoccupation causes clinically significant distress or clinically significant impairment in psychosocial functioning. In addition, at some point during the course of the illness, the appearance pre-occupations must have caused repetitive behaviours such as mirror checking, excessive grooming, skin picking, reassurance seeking, or comparing one's appearance with others [4]. Finally, the appearance concerns should not be better explained by an eating disorder. However, BDD and eating disorders may co-occur, in which case both disorders should be diagnosed.

In addition, DSM-5 contains two new specifiers for BDD: muscle dysmorphia and level of BDD-related insight (good or fair, poor, or absent insight/delusional beliefs) [4]. It should be emphasized that delusional BDD beliefs should be diagnosed as BDD, not as a psychotic disorder, as this has significant implications for pharmacologic treatment. BDD-triggered panic attacks may be designated by DSM-5's panic attack specifier, which can be used for any disorder that triggers panic attacks; in BDD, common triggers are feeling scrutinized by others, looking at perceived defects in mirrors, and being under bright lights [32].

The bottom of **Box 100.1** includes questions that are *not* recommended to screen for, or diagnose, BDD. The word ‘imagined’ is problematic, because most patients have poor or absent insight and do not think their appearance problem is imagined. Terms such as ‘deformed’ or ‘disfigured’ are too extreme for some patients to endorse. Asking if

there is something wrong with one's body is too broad a question, as patients may interpret this as referring to bodily functioning.

ICD-10's description requires that patients persistently refuse to accept the advice and reassurance of doctors or healers that they do not have an abnormality. However, many people with BDD do not disclose their appearance concerns to doctors or even seek medical care because they are housebound, ashamed of their appearance concerns, believe they cannot be helped, lack health insurance, or do not have access to health care for other reasons. Using these criteria will underdiagnose BDD.

BDD usually goes undiagnosed in clinical settings [2, 3]. Sufferers often conceal their symptoms due to embarrassment and shame [2, 3]. They may volunteer only depression, anxiety, or discomfort in social situations. The compulsive and safety behaviours may be clues to BDD's presence.

BDD may also be misdiagnosed as another disorder [2, 3]. BDD may be mistaken as social anxiety disorder because of social anxiety

and isolation related to appearance concerns and anxiety over being rejected by others due to the perceived appearance defects. BDD may also be misdiagnosed as OCD due to obsessional preoccupations and compulsive behaviours. Individuals with delusional BDD are sometimes misdiagnosed with schizophrenia, psychotic depression, or another psychotic disorder. People with BDD may be misdiagnosed with panic disorder because of the occurrence of panic attacks that are triggered by appearance concerns, which should instead be diagnosed as BDD with the panic attack specifier. BDD symptoms may also be misdiagnosed as trichotillomania (hair pulling disorder) when hair is repeatedly cut or plucked to improve perceived flaws in its appearance (for example, 'bushy' or uneven eyebrows). BDD may be misdiagnosed as excoriation (skin picking) disorder when skin is picked in an attempt to diminish perceived skin flaws. To diagnose BDD, patients must usually be asked directly about BDD symptoms, using questions such as those in [Box 100.1](#).

Box 100.1 Questions to diagnose BDD according to DSM-5 diagnostic criteria

Questions to evaluate diagnostic criteria

Criterion A: preoccupation with non-existent or slight appearance defects or flaws

- 1 'Are you very worried about your appearance in any way?' OR 'Are you unhappy with how you look?'
- 2 Invite the patient to describe their concern by asking, 'What don't you like about how you look?' OR 'Can you tell me about your concern?' Listen to the patient's description; do not provide reassurance about, or comment on, their appearance.
- 3 Ask if there are other disliked body areas—for example, 'Are you unhappy with any other aspects of your appearance, such as your face, skin, hair, nose, or the shape or size of any other body area?'
- 4 Ascertain that the patient is preoccupied with these perceived flaws by asking, 'How much time would you estimate that you spend each day thinking about your appearance, if you add up all the time you spend?' OR 'Do these concerns preoccupy you?'

Criterion B: repetitive behaviours in response to the appearance concerns

- 5 Ask 'Is there anything that you do over and over again in response to your appearance concerns?' ... 'For example, do you compare yourself with others, check your appearance in mirrors or other reflecting surfaces, ask other people if you look okay or what they think of your appearance, touch the disliked areas, or pick at your skin?' ... 'Do you do anything else to try to check, fix, hide, or be reassured about your (fill in disliked body areas)?'

Criterion C: clinically significant distress or impairment in functioning resulting from appearance concerns

- 6 Ask 'How much distress do these concerns cause you?' Ask specifically about resulting anxiety, social anxiety, depression, panic, shame, hopelessness, guilt, and suicidal thinking.
- 7 Ask about effects of the appearance preoccupations on the patient's life—for example, 'Do these concerns interfere with your life or cause problems for you in any way?' Ask specifically about effects on work, school, other aspects of role functioning (for example, caring for children), relationships, intimacy, family and social activities, household tasks, and other types of interference. Examples of interference include:
 - Decreased focus and concentration.
 - Being late for, or missing, school or work.

- Interruption of school, work, or household routines by BDD rituals (for example, leaving class to check the bathroom mirror or reapply make-up).
- Dropping or failing grades.
- Dropping out of school.
- Quitting a job or being fired; being unemployed.
- Not dating.
- Marital conflict or divorce.
- Sexual difficulties.
- Not seeing friends as often or at all.
- Missing family events.
- Turning down or avoiding social gatherings.
- Difficulty caring for children or managing a household, going shopping, or doing chores.
- Avoiding activities like going to the gym.
- Using drugs or alcohol to cope with BDD.

Criterion D: the appearance preoccupation is not better explained by concerns with body fat or weight if these symptoms meet diagnostic criteria for an eating disorder.

Individuals who have excessive and problematic concerns with the belief that they weigh too much or that their overall body or parts of their body are too fat should be evaluated for the presence of an eating disorder (anorexia nervosa, bulimia nervosa, and binge eating disorder). If one of these disorders explains these body image concerns, then the concerns do not count towards a diagnosis of BDD.

Questions to evaluate specifiers

With muscle dysmorphia

Ask 'Are you preoccupied with the idea that your body build is too small or that you're not muscular enough?'

Insight

Elicit a global belief about the perceived defect(s) (rather than asking about specific body areas): 'What word would you use to describe how bad all of these areas (fill in all disliked areas) look?' If the patient has difficulty choosing a word (often because of embarrassment), ask 'Some people use words like unattractive, ugly, deformed, hideous; do you think any of these apply to you?' Then ask 'How convinced are you that these body areas look (fill in the patient's global descriptor)?'

Source: data from *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, DSM-5, Copyright (2013), American Psychiatric Association.

Epidemiology

In large population-based epidemiologic samples ($n = 2129$ to 2891), the point prevalence of BDD ranges from 1.7% to 2.9% [24]. In military and Veteran samples, BDD's point prevalence has been much higher, ranging from 11% to 15% [33, 34]. BDD also appears fairly common in cosmetic treatment settings. A prevalence of 3–15% has been reported in cosmetic dermatology outpatient settings (weighted prevalence of 9%) [24], 11% in acne dermatology clinics, and 4–29% in general outpatient dermatology settings (weighted prevalence of 11%) [27]. In general cosmetic surgery settings, the prevalence of BDD has been found to be between 6% and 53%, with a weighted prevalence of 13% [24]; in orthognathic surgery settings, the weighted prevalence is 11%. The prevalence is higher than this in rhinoplasty samples (weighted prevalence of 20%), consistent with findings that rhinoplasty is the most common surgery received by people with BDD [24].

In samples from mental health settings, the prevalence of BDD has been reported to be 8–37% in patients with OCD, 11–13% in social phobia, 26% in trichotillomania, and 14–42% in atypical major depression [24]. In psychiatric inpatient samples, the point prevalence of BDD ranges from 6% to 13% [24].

Pathogenesis

BDD's pathogenesis is likely complex and multifactorial, involving both 'proximal' factors, such as aberrant visual processing, as well as 'distal' factors, such as genetic predisposition, and perhaps evolutionary influences—for example, physical appearance judgments, such as those involving symmetry, are relevant to efforts to attract and secure reproductively healthy mates [35]. BDD likely involves a complex interplay of genetic and environmental risk factors [36].

BDD appears to be familial [36]. It also appears to have high familiarity with OCD. For example, BDD is more common in first-degree relatives of individuals with OCD than in first-degree relatives of probands without OCD [36]. A family history study determined that 7% of BDD patients had a first-degree relative with OCD, which is elevated, compared to OCD's prevalence in the general population (about 1–2%) [36].

Twin studies, which can determine the relative contribution of genetic vs environmental factors, indicated that approximately 44% of the variance of 'dysmorphic concern' (a construct similar to BDD) is due to genetic factors [37]. BDD appears to have shared genetic liability with OCD and other obsessive-compulsive and related disorders, as well as unique disorder-specific genetic factors. Preliminary data indicate an association of the *GABA_A-γ2* gene with BDD [38, 40].

Environmental influences for BDD and other obsessive-compulsive and related disorders appear largely disorder-specific [37]. Little is known about specific environmental risk factors in BDD, but they may include perceived childhood neglect and/or abuse, teasing, and low parental warmth [2, 3]. A role is also likely for sociocultural pressures [2, 3].

Research on BDD's neurocircuitry is still limited, but increasing, and indicates that there is likely a complex interplay of dysfunction in

several neural systems [36]. Structural and functional neuroimaging studies demonstrate abnormalities within regions of the brain involved in visual processing, the limbic system (that is, the amygdala), and the orbitofrontal cortex, in addition to broadly observed changes in the white matter [36]. Findings of hyperactivity in the orbitofrontal cortex and the caudate are similar to findings in OCD [36].

Neuropsychological and neuroimaging studies indicated a tendency to focus on isolated details of visual and verbal stimuli, rather than more global, configurational attributes [39]—consistent with clinical observations that patients selectively attend to specific aspects of their appearance or minor flaws. Cognitive processing studies indicate that BDD patients tend to misinterpret ambiguous social (and other) situations as threatening and misinterpret self-referent facial expressions as contemptuous and angry [16, 17]. It can be theorized that these interpretive biases may combine with rejection sensitivity, perfectionism, and a focus on aesthetics to contribute to BDD's development [2, 3]. High neuroticism and low extroversion may also play a role [2, 3]. Many potential risk factors (for example, neuroticism) are not specific to BDD, but the overall combination of risk factors may be.

Course and prognosis

Prospective and retrospective studies of individuals ascertained for BDD indicated that BDD is usually chronic [19, 40]. Greater severity of BDD symptoms predicts a lower likelihood of remission from BDD and a greater likelihood of relapse following remission. A longer duration of BDD also predicts a lower probability of remission [40]. However, when BDD is accurately identified and its treatment optimized, the prognosis is much more favourable.

Treatment

BDD's treatment is described in more detail elsewhere, including in a guideline from the UK's National Institute of Health and Care Excellence (NICE) [41–43]. Serotonin reuptake inhibitors (SRIs, or SSRIs) and CBT that is specifically tailored to BDD are currently recommended as first-line treatments [41–43]. Cosmetic treatment appears ineffective for BDD [43]. Treatment studies are still limited, and more research and treatment development are needed. However, available data consistently indicate that a majority of patients improve with these treatments [41–43].

Essential groundwork for treatment

It can be challenging to engage and retain patients with BDD in psychiatric treatment. Most have poor or absent insight, believing that they probably or certainly look abnormal. For this reason, many prefer cosmetic treatment. Depressive symptoms may cause hopelessness and decrease motivation for treatment. A number of approaches can help clinicians engage and retain patients in treatment, which are discussed in more detail elsewhere [44]:

1. First try to engage the patient and establish an alliance, so they are willing to try treatment. This can be difficult to accomplish, as many patients are delusional, prefer cosmetic treatment, are

rejection-sensitive, and do not want other people (including a clinician) to see them.

2. Empathize with the patient's suffering.
3. Take the patient's appearance concerns seriously, neither dismissing their concerns about how they look nor agreeing that there is something wrong with their appearance. Avoid debating or arguing with the patient about how they look. Trying to convince patients (especially delusional patients) that their beliefs are irrational or that they look normal is usually not helpful. It can be helpful to say that people with BDD see themselves differently than others see them and to note the findings from visual processing studies.
4. Instead, focus on the potential for psychiatric treatment to diminish their distress and preoccupation and improve their functioning and quality of life.
5. Provide psychoeducation about BDD and recommend reading.
6. For patients who wish to pursue cosmetic treatments, explain that such treatment appears ineffective for BDD.
7. Provide education about recommended treatments. It can be helpful to explain, for example, that SRIs are usually well tolerated, are not habit-forming, appear to normalize the brain (and do not cause brain damage), and often diminish suicidal thinking in people with BDD. CBT is a practical and doable 'here-and-now' treatment, in which patients actively collaborate with the therapist and learn helpful skills by attending sessions and doing homework. When patients fully adhere to, and participate in, these treatments, a majority will improve.

Treatment should be initiated with an SRI and/or CBT. SRIs are also the first-line medication for delusional BDD. All severely ill patients, especially those who are highly suicidal, should, in the authors' opinion, receive an SRI. Patients with severe comorbid depression also warrant SRI treatment. Other comorbidity may warrant additional medication.

Surgical, dermatologic, and other cosmetic treatment

A majority of patients with BDD seek and receive often costly cosmetic treatment [3, 8, 9, 12, 26]. Some patients, including those who are turned down by physicians or cannot afford treatment, perform their own surgery [2, 3, 6]—for example, cutting open their nose with a razor blade and trying to replace their nose cartilage with chicken cartilage in the desired shape. Dermatologists and surgeons are most often consulted, but cosmetic treatment may be requested of virtually any type of physician. It appears that most BDD patients are dissatisfied with such treatment [2, 3, 26] and that cosmetic treatment is not effective for BDD. Occasional dissatisfied patients sue, or are violent towards, the physician. Thus, cosmetic treatment is not recommended for BDD.

Pharmacotherapy and other somatic treatments

Serotonin reuptake inhibitors: first-line pharmacotherapy for BDD

All SRI studies to date indicate that SRIs are often efficacious for BDD [2, 3, 41] (Table 100.1). These studies include a placebo-controlled fluoxetine study ($n = 67$), a controlled and blinded crossover study comparing the SRI clomipramine to the non-SRI desipramine ($n = 29$), and open-label trials of fluvoxamine, citalopram, and

escitalopram ($n = 15-30$). In these studies, 53–73% of patients responded to the SRI in intention-to-treat analyses (response rates were higher in completer analyses). The crossover trial found greater efficacy for clomipramine than desipramine, suggesting that SRIs are more efficacious than non-SRIs for BDD. This important finding is consistent with clinical series and retrospective data suggesting that SRIs are more efficacious than a broad range of non-SRI medications for BDD [2, 3, 41].

A more recent relapse prevention study treated 100 participants for 14 weeks with the SRI escitalopram (mean dose 26.2 ± 7.2 mg/day), with an intention-to-treat response rate of 67% and a completer response rate of 81% (Table 100.1) [45]. Escitalopram responders were randomized to continuing to take escitalopram or were switched to placebo treatment for another 6 months. Time to relapse was significantly longer among patients who continued to receive escitalopram. The proportion who relapsed while continuing escitalopram was 18%, whereas 40% relapsed after being switched to placebo. Thus, continuation of escitalopram protected against relapse.

No methodologically rigorous prospective study has compared different SRIs to one another, although they are likely all about equally efficacious. The second author often first uses escitalopram or fluoxetine; these are the best studied SRIs for BDD and are usually well tolerated, and escitalopram has the advantage of having few drug–drug interactions. Clomipramine is often reserved for use when selective SRIs (SSRIs) have not been helpful, because SSRIs are usually better tolerated. Citalopram is the least desirable choice, because the FDA dosing limit is lower than the dose typically needed to effectively treat BDD [41].

High SRI doses (higher than typically used for depression) appear to often be needed to effectively treat BDD [2, 3, 41]. Doses may sometimes need to exceed the manufacturer's maximum dose, although this is not recommended for clomipramine or citalopram. Response to an SRI usually develops gradually and may require up to 12–16 weeks of treatment (while reaching a relatively high dose) to be evident [2, 3, 41].

Response to medication usually includes a decrease in appearance preoccupations, distress, and compulsive/safety behaviours, as well as improved functioning. Suicidality, depressive symptoms, anxiety, and anger–hostility often improve [2, 3]. Of note, delusional patients often improve with SRI monotherapy, whereas limited data suggest that dopamine antagonist monotherapy is usually *ineffective* for delusional BDD [2, 3, 41]. Thus, SRIs are recommended for patients with delusional (absent insight) BDD beliefs.

If an optimal 12- to 16-week SRI trial—during which a high SRI dose is reached if needed and tolerated—improves BDD symptoms by at least 30%, it is recommended that the SRI be continued, because BDD symptoms may further improve with additional time [41].

Approaches if an SRI is not adequately effective

Before concluding that an SRI is ineffective, it should be tried for 12–16 weeks, reaching the highest dose recommended by the manufacturer or tolerated by the patient (if necessary) for at least 3–4 of those 12–16 weeks. Because medication adherence is often poor, the clinician should determine whether medication adherence has

Table 100.1 Prospective controlled and open-label medication studies in adults with body dysmorphic disorder*

Medication	Study design	Sample size	Trial duration and endpoint mean dose (mg/day)	Response of BDD symptoms**	Reference
Serotonin reuptake inhibitor (SRI, SSRI) monotherapy					
Fluoxetine (Prozac®) vs placebo	Randomized, double-blind, placebo-controlled, parallel group trial	74 enrolled; 67 randomized	12 weeks: 77.7 ± 8.0	Fluoxetine significantly more effective than placebo; response rate of 53% vs 18% on BDD-YBOCS; effect size $d = 0.70$	Phillips KA, et al., 2002 [60]
Clomipramine (Anafranil®) vs desipramine	Randomized, double-blind, controlled crossover trial	40 enrolled; 29 randomized	16 weeks (8 weeks on each medication) CMI: 138 ± 87 DMI: 147 ± 80	Clomipramine significantly more effective than desipramine; response rate of 65% vs 35% on BDD-YBOCS	Hollander E, et al., 1999 [61]
Escitalopram (Lexapro®) vs placebo	Open-label trial with escitalopram; responders to open-label treatment were randomized to double-blind continuation treatment with escitalopram vs placebo for 6 months	100 in open-label phase; 58 in double-blind phase	14-week open-label phase: 26.2 ± 7.2 6-month randomized phase: 28.7 ± 4.6	Open-label trial: BDD symptoms significantly improved; 67% of subjects (intention-to-treat) and 81% of completers responded on BDD-YBOCS Time to relapse significantly longer with escitalopram than placebo Relapse proportions: 18% for escitalopram vs 40% for placebo In continuation phase, BDD significantly improved in escitalopram-treated subjects; 36% of subjects further improved	Phillips KA, et al., 2016 [45]
Fluvoxamine (Luvox®)	Open-label trial	15	10 weeks: 208.3 ± 63.4	BDD symptoms significantly improved; ten subjects responded on CGI	Perugi G, et al., 1996 [62]
Fluvoxamine (Luvox®)	Open-label trial	30	16 weeks: 238.3 ± 85.8	BDD symptoms significantly improved; 63% of subjects responded on BDD-YBOCS	Phillips KA, et al., 1998
Citalopram (Celexa®)	Open-label trial	15	12 weeks: 51.3 ± 16.9	BDD symptoms significantly improved; 73% of subjects responded on BDD-YBOCS	Phillips KA & Najjar F, 2003 [63]
Escitalopram (Lexapro®)	Open-label trial	15	12 weeks: 28.0 ± 6.5	BDD symptoms significantly improved; 73% of subjects responded on BDD-YBOCS	Phillips KA, 2006 [64]
Serotonin-noradrenaline reuptake inhibitor (SNRI) monotherapy					
Venlafaxine (Effexor®)	Open-label trial	17	12–16 weeks: 163.6 ± 30.3	BDD symptoms significantly improved; 45% responded on BDD-YBOCS	Allen A, et al., 2008 [65]
Anti-epileptics					
Levetiracetam (Keppra®)	Open-label trial	17 (monotherapy in 12 cases; SRI augmentation in five cases)	12 weeks: 2044 ± 1065	BDD symptoms significantly improved; 53% responded on BDD-YBOCS	Phillips KA & Menard W, 2009 [66]
SRI augmentation studies					
Pimozide (Orap®) vs placebo augmentation of fluoxetine (Prozac®)	Randomized, double-blind, placebo-controlled, parallel-group trial	28	8 weeks: 2 mg	Pimozide was not more efficacious than placebo; 18% of subjects responded to pimozide and 18% to placebo	Phillips KA, 2005 [67]

* Case reports, case series, cross-sectional, and retrospective studies are not included in the table but are described in the text.

** Results are reported for an intention-to-treat analysis, except for the clomipramine/desipramine trial, which used a minimum treatment analysis, and the venlafaxine study, which used a completer analysis for the primary outcome. Intention-to-treat analyses are more conservative because they include study dropouts; response rates for those who completed the full trial (intention-to-treat sample) are higher than reported in this table.

Most studies defined response as 30% or greater decrease in total score on the Yale-Brown Obsessive Compulsive Scale (YBOCS).

Modified for body dysmorphic disorder (BDD-YBOCS). Other symptoms, such as depression, usually improved, as did psychosocial functioning and quality of life.

been adequate; improving adherence may convert medication non-response to response.

As a next step, the second author often raises the SRI dose even further until the following maximum doses are reached if tolerated: escitalopram 60 mg/day, fluoxetine 120 mg/day, sertraline 400 mg/day, fluvoxamine 450 mg/day, paroxetine 100 mg/day, citalopram

40 mg/day, and clomipramine 250 mg/day (with blood levels). It is recommended that an ECG be checked at a higher escitalopram dose and when using clomipramine. These doses are consistent with those in the American Psychiatric Practice Guideline for OCD [46].

If this approach does not produce the desired response, another SRI can be tried, as this may lead to a response [2, 3, 41].

Regarding SRI augmentation, a small double-blind randomized controlled trial found that the antipsychotic pimozide was not more efficacious than placebo as a fluoxetine augmenter [2, 3, 41]. However, clinical observations suggest that other dopaminergic drugs, such as aripiprazole, may be helpful as SRI augmenters and may be especially appealing for patients who are highly delusional, agitated, anxious, and/or aggressive. Clinical series suggest that augmentation of an SSRI with buspirone or clomipramine may be helpful [2, 3, 41]. (SSRIs may increase clomipramine blood levels, however, which may cause toxicity; thus, if this approach is tried, clomipramine should be started at a very low dose, with monitoring of levels.) Clinical observations suggest that SSRI augmentation with venlafaxine or bupropion may be helpful for some patients [2, 3, 41]. SRIs can also be augmented with CBT. No studies have evaluated the relative efficacy of these approaches, although clinical experience indicates that all of them may be effective.

Monotherapy with non-SRI medications

Monotherapy with agents other than SRIs has not been well studied [2, 3, 41]. A small open-label trial ($n = 11$) suggested that the serotonin–noradrenaline reuptake inhibitor (SNRI) venlafaxine may be efficacious [2, 3]. Another small open-label trial ($n = 17$) suggested efficacy for the anti-epileptic levetiracetam [41]. For severe and treatment-refractory cases, an MAO inhibitor may be worth trying (but should never be combined with an SRI).

It appears that long-term treatment with effective medication may be needed; efficacy appears to usually be sustained over time [2, 3, 41]. For patients who appear at high risk of suicide or violence, lifelong treatment with an effective SRI is recommended, as suicides have been known to occur after SRI discontinuation.

Other somatic treatments

Available case series and case reports, while very limited, suggested that ECT is generally ineffective for BDD and secondary depressive symptoms [2, 3, 41], although it should be considered for severely depressed and highly suicidal patients.

Improvement in BDD symptoms has been noted in case reports with a modified leucotomy, capsulotomy, bilateral anterior cingulotomy plus subcaudate tractotomy, and anterior capsulotomy, and with deep brain stimulation that targeted the ventral capsule/ventral striatum. Neurosurgery should be considered only when a patient has not responded to many adequate medication trials and to intensive CBT using an empirically based treatment manual for BDD.

Cognitive behavioural therapy

Research findings on CBT for BDD

In recent years, great strides have been made in understanding the cognitive behavioural processes that contribute to BDD's development and maintenance. CBT for BDD that is based on this theoretical understanding is highly effective in reducing BDD symptom severity, as well as associated symptoms [47].

In an initial small randomized controlled trial of 19 individuals with BDD who were randomized to 12 sessions of CBT or a waitlist control, the CBT group showed significantly greater improvement

in BDD symptoms and depressive symptoms [48]. Another randomized controlled trial of 12 sessions of CBT, compared to an anxiety management treatment, for 46 individuals with BDD found that the CBT group showed significantly greater improvement in BDD symptoms than the anxiety management group [49]. A study of a modular 22-week CBT treatment for BDD vs a 12-week waitlist condition (followed by crossover to CBT) for 36 individuals with BDD showed that 50% of those who participated in CBT responded to CBT, compared to 12% in the control group, at week 12, a significant difference [50]. After 22 weeks of treatment, 81% of all participants (immediate treatment group plus waitlisted patients subsequently treated with CBT) who completed treatment were responders. A meta-analysis also showed that CBT is associated with more improvement in BDD symptoms than a waitlist or psychological placebo [51], resulting in a reduction in BDD symptoms, depressive symptoms, and improvement in insight and delusionality [51]. Improvement appears to be sustained over months, and even years [47, 52].

Elements of CBT for BDD

CBT must be tailored to BDD's unique symptoms; in the authors' experience, CBT for OCD, social anxiety disorder, or other disorders will not adequately treat BDD. The authors recommend use of an empirically based CBT treatment manual, because BDD is a complex disorder that can be difficult to treat without a manual. Two such therapist manuals are available [53, 54].

Many experts recommend weekly hour-long outpatient sessions for 6 months, although some patients improve with fewer sessions and others require longer or more intensive treatment in an intensive outpatient or residential treatment setting.

CBT for BDD typically includes [53, 54]: (1) *cognitive restructuring* to identify cognitive errors and develop more accurate and helpful BDD-related thoughts and beliefs; (2) *exposure* to avoided situations (for example, leaving the house, attending social gatherings), combined with *behavioural experiments* to test the accuracy of BDD beliefs; (3) *ritual (response) prevention* to decrease or stop compulsive behaviours (for example, stopping excessive mirror checking, limiting grooming time); (4) *advanced cognitive strategies* to address maladaptive core beliefs; (5) *perceptual retraining and mindfulness*, which involves learning to see one's entire body in a non-judgemental and 'holistic' way (rather than focusing on disliked areas), while refraining from excessive mirror checking; and (6) *relapse prevention*.

One of the previously noted empirically supported treatment manuals includes the following optional modules for patients with relevant symptoms [53]: (1) *skin picking and hair pulling or plucking*; (2) *muscularity and weight/shape concerns*; (3) *cosmetic treatment*; and (4) *depression/mood management*. Motivational interviewing is often needed to engage and keep patients in treatment and may be used any time during treatment as needed.

Patients who are not improving with CBT may need motivational interviewing to increase engagement in treatment and homework completion, more frequent sessions, longer sessions, or a change in the current CBT focus. Maintenance/booster sessions following CBT may reduce relapse risk. It may be helpful to add an SRI to CBT if CBT alone is insufficient or the patient is too depressed to participate in CBT.

Additional treatment considerations

Therapy and support

Only limited research has been conducted on third-wave therapies, like acceptance and commitment therapy (ACT), although preliminary evidence from one small study is promising [55]. Clinical experience suggests that concomitant insight-oriented or supportive therapy—in addition to an SRI and/or CBT—may help some patients cope with their illness or with co-occurring problems or disorders [2, 3]. Families can be an invaluable support and facilitate treatment [2, 3]. Mental health professionals may need to interface with dermatologists, plastic surgeons, and other physicians from whom patients have requested or are receiving cosmetic treatment.

Suicidality

Treatment approaches for more highly suicidal patients are discussed in more detail elsewhere [54]. Such patients should always receive an SRI, which has been shown to decrease suicidal thinking and protect against worsening of suicidal ideation in BDD [56]. Concomitant medication may also be helpful, depending on the patient's specific symptoms. The authors also recommend CBT for BDD if BDD appears to be the main cause of suicidal thinking. For highly suicidal patients, we recommend the use of an evidence-based CBT treatment manual that focuses on suicidal thinking [57]. Supportive therapy may be additionally helpful, depending on the patient's specific situation, and a higher level of care may be needed.

Substance use

Substance abuse is common in individuals with BDD and often reflects attempts to self-medicate BDD-induced distress [58]. In such cases, successful treatment of BDD may reduce or eliminate problematic substance use. However, substance abuse often needs to be a major focus of treatment, using evidence-based medication (for example, naltrexone) and psychosocial treatment approaches for substance abuse, in addition to treatment for BDD.

Conclusions

BDD is a common, but under-recognized, disorder that is often severely impairing and can lead to suicide. Research and knowledge of BDD are greatly increasing, but more research is necessary to better understand the features of this disorder and increase education, so clinicians recognize this disorder and implement recommended treatment. SRIs and CBT for BDD often improve BDD symptoms and associated symptoms such as depression, anxiety, and poor or absent insight. Clinicians should specifically screen patients for BDD in order to recognize this common disorder and provide effective treatment.

Further information

Further information about BDD and its treatment is provided in references [2–4], [43], [53–54], and [59].

The eating disorders

Christopher G. Fairburn and Rebecca Murphy

Introduction

Eating disorders may be defined as ‘a persistent disturbance of eating behaviour or behaviour intended to control weight, which significantly impairs physical health or psychosocial functioning’ [1]. It is conventional to divide them into diagnostic categories, based on their clinical presentation. The three main diagnoses are anorexia nervosa, bulimia nervosa, and binge eating disorder. In addition, there are similar presentations that fall just outside these three diagnoses. We will term these the ‘other eating disorders’ or OEDs.

Classification and diagnosis

The classification of eating disorders and their principal diagnostic criteria are shown in [Box 101.1](#). Anorexia nervosa was first named and formally described in 1873 [2, 3]; the concept of bulimia nervosa was introduced in 1979 [4], and binge eating disorder was formally recognized in 2013, although the phenomenon was described in the 1950s [5]. The OEDs came to attention in the 2000s when they were encountered in large numbers with the opening of community-based eating disorder clinics [6]. The American term for OEDs used to be ‘eating disorders not otherwise specified’, but in DSM-5, it was changed to ‘other specified feeding and eating disorders’.

Other disorders of eating are recognized. In DSM-5, these are pica, rumination disorder, and avoidant/restrictive food intake disorder. These states are quite different from the three main eating disorders and are mostly seen in children or those with intellectual disability. They are not covered in this chapter.

General clinical features

Anorexia nervosa, bulimia nervosa, and OEDs share a common and distinctive ‘core psychopathology’. This is the over-evaluation of shape and weight and their control. This psychopathology is not usually present in binge eating disorder. It is characterized by the judging of one’s self-worth largely, or even exclusively, in terms of one’s shape and weight and one’s ability to control them. In contrast, most people judge themselves on the basis of their perceived

performance in a variety domains of life, such as their performance at work, at sport, and at parenting, and the quality of their relationships.

Most features of these disorders stem from the over-evaluation and its consequences. There are repeated intense feelings of fatness, and most people either closely monitor their shape or avoid seeing it altogether. The desire to control body weight leads to persistent and strict dieting, together with other forms of extreme weight control behaviour, including self-induced vomiting, laxative misuse, and over-exercising. Strict dieting is highly impairing, as it requires a great deal of effort, often provokes anxiety, and can make socializing difficult, if not impossible. It may also lead to weight loss or binge eating, or both.

Generally, people with an eating disorder view dieting as an accomplishment, rather than a problem. It is not something that they want to change. However, in bulimia nervosa, the strict dieting is interrupted by repeated episodes of loss of control over eating, in which large amounts of food are eaten (binges). These binges are highly aversive, and as a result, they lead people to seek help. Their help-seeking is hindered, however, by the shame and secrecy that typically accompanies binge eating.

Anorexia nervosa

In anorexia nervosa, the pursuit of weight loss is successful in that significantly low weight is achieved. In most instances, there is no true anorexia as such. The loss of weight is primarily the result of a deliberate severe and selective restriction of food intake, with foods viewed as fattening being excluded. In some people, restriction over food intake is encouraged by additional motives, including asceticism, a desire to feel ‘special’, and a wish to punish themselves. Self-induced vomiting and other extreme forms of weight control behaviour are practised by some. Many also engage in a driven form of over-exercising, which can also contribute to their low weight.

There is a constellation of clinical features which are a direct result of being significantly underweight and is seen in other starvation states. These features include obsessional features, low mood, irritability, impaired concentration, loss of sexual appetite, and poor sleep. Typically, these features get worse, as weight is lost, and improve with weight regain. Interest in the outside world also declines as people become underweight, with the result that most become socially withdrawn and isolated. This feature is also reversible. Some

Box 101.1 Classification and diagnosis of the eating disorders**Definition of an eating disorder**

There is a definite disturbance of eating habits or weight control behaviour. Either this disturbance or the associated 'core psychopathology' (see text) results in clinically significant impairment of psychosocial functioning or physical health. The behavioural disturbance is not secondary to any general medical disorder or to any other psychiatric condition (for example, major depression).

Principal diagnostic criteria*Anorexia nervosa*

- 1 Over-evaluation of shape and weight (that is, judging self-worth largely or exclusively in terms of shape and weight).
- 2 Active maintenance of an unduly low body weight (for example, body mass index <18.5 kg/m²).

Bulimia nervosa

- 1 Over-evaluation of shape and weight (that is, judging self-worth largely or exclusively in terms of shape and weight).
- 2 Recurrent binge eating (that is, recurrent episodes of uncontrolled eating in which an unusually large amount of food is eaten for the circumstances).
- 3 Extreme weight control behaviour (for example, strict dietary restriction, frequent self-induced vomiting, or laxative misuse).
- 4 The diagnostic criteria for anorexia nervosa are not met.

Binge eating disorder

- 1 Recurrent binge eating (that is, recurrent episodes of uncontrolled eating in which an unusually large amount of food is eaten for the circumstances).
- 2 The absence of extreme weight control behaviour (for example, strict dietary restriction, frequent self-induced vomiting, or laxative misuse).

Other eating disorders

Eating disorders of clinical severity that do not conform to the diagnostic criteria for anorexia nervosa, bulimia nervosa, or binge eating disorder.

people have times when they lose control over eating, although the amounts eaten may not be large.

Bulimia nervosa

The main feature that distinguishes bulimia nervosa from anorexia nervosa is that attempts to restrict food intake are interrupted by repeated 'binges' (episodes of eating during which there is an accompanying sense of loss of control and an unusually large amount of food is eaten for the circumstances). The amount consumed varies greatly but is typically between 1000 and 2000 kcal. In most instances, binge eating is followed by self-induced vomiting or laxative misuse, in an attempt to avoid absorbing what has been eaten. The episodes of binge eating, together with strict dieting, result in a body weight which is generally unremarkable, providing the other obvious difference from anorexia nervosa. Depressive and anxiety features are prominent in bulimia nervosa, and as in some cases of anorexia nervosa, there is a subgroup who engage in substance misuse or self-injury, or both.

Binge eating disorder

In binge eating disorder, there is just one primary feature. This is the occurrence of repeated episodes of binge eating. Unlike in bulimia nervosa, where the binges occur in the context of extreme attempts to diet, little or no extreme weight control behaviour is seen in binge

eating disorder. Indeed, if there is a disturbance of eating outside the binges, it is generally overeating, rather than undereating. For this reason, binge eating disorder often co-occurs with a raised body weight or frank obesity. As in bulimia nervosa, there is distress over the binge eating and accompanying shame and self-criticism.

Other eating disorders

The OEDs are clinical states which meet the general definition of an eating disorder but do not fulfil the diagnostic criteria for any of the three specified eating disorders. They include presentations which closely resemble anorexia nervosa, bulimia nervosa, or binge eating disorder. For example, the patient's weight might be just above the diagnostic threshold for anorexia nervosa or the frequency of binge eating might not be high enough to allow a diagnosis of bulimia nervosa or binge eating disorder. Other presentations are 'mixed' in form, with features of both anorexia nervosa and bulimia nervosa being present. For instance, there may be extreme dietary restraint, pronounced over-exercising, occasional binge eating, and a low-to-normal weight. Over-evaluation of shape and weight is present in most of the OEDs, although in the early stages of the eating disorder, the focus of the over-evaluation may be primarily on maintaining strict control over eating.

Development and course of the eating disorders

Anorexia nervosa typically starts in mid-teenage years with the onset of dietary restriction, which then proceeds to get out of control. In some instances, the disorder is short-lived and self-limiting, or only requires a brief intervention. These instances are most typical of young people. In others, the eating disorder becomes entrenched, although it is common for binge eating to develop and the weight to increase, with the result that the eating disorder evolves into bulimia nervosa. In 10–20% of people, the anorexia nervosa state persists and proves intractable [7]. This heterogeneity in the course and outcome of anorexia nervosa is often neglected in accounts of the disorder. Anorexia nervosa has been consistently found to be associated with a raised mortality rate, with the standardized mortality ratio being about 6 [8]. Most deaths are either a direct result of medical complications or due to suicide.

Bulimia nervosa has a slightly later age of onset than anorexia nervosa, although it usually starts in much the same way; indeed, in about a quarter of cases, the diagnostic criteria for anorexia nervosa are met for a time. Eventually, however, episodes of binge eating begin to interrupt the dietary self-control and, as a result, the body weight rises to normal or near-normal levels. The disorder tends to be highly self-perpetuating in the absence of effective treatment. The average length of history at presentation is about 5 years.

Little is known about the development and course of the OEDs. In many instances, they are preceded by anorexia nervosa or bulimia nervosa, in which case the current state is simply the latest expression of an enduring eating disorder.

Binge eating disorder differs from anorexia nervosa and bulimia nervosa in its course and outcome. Rather than running a persistent course, it tends to be phasic, with there being long periods free from binge eating. Indeed, there appears to be a high spontaneous remission rate, at least in the short term.

The transdiagnostic perspective on the eating disorders

An alternative way of viewing the eating disorders is to take a 'transdiagnostic' perspective [9]. This view is based on two observations. Firstly, anorexia nervosa, bulimia nervosa, and most of the OEDs have many highly distinctive clinical features in common. These include the over-evaluation of shape and weight, a characteristic and persistent form of dieting, and a tendency to engage in extreme weight control behaviour. And secondly, patients frequently move between these diagnoses. Temporal migration between supposedly distinct mental disorders is a most unusual phenomenon outside the eating disorders, and it casts doubt over the validity of the diagnostic distinctions. However, the fact that eating disorders do not evolve into other mental disorders supports the distinctiveness of the diagnostic category as a whole.

Basic mechanisms and potential for treatment of weight and eating disorders

Johannes Hebebrand, Jochen Antel, and Beate Herpertz-Dahlmann

Introduction

In light of the current difficulties in treating feeding, eating, and weight disorders, the overall pragmatic goal is to find novel portals of entry for successful pharmacological and non-pharmacological interventions that prove superior to those currently pursued in terms of both efficacy and safety. The ongoing elucidation of the basic mechanisms underlying feeding, eating, and, in particular, weight disorders, should ideally help to develop novel treatments. However, similar to other mental disorders or complex disorders per se, the sheer number of aetiological factors, their proven and assumed small effect sizes, and their complex interactions render this a formidable task. In addition, side effects of weight loss medications have led to the withdrawal of anti-obesity drugs, which, in turn, has reduced research investment of the pharmaceutical industry.

Because of the association of specific eating disorders with different body weight categories and the obvious clinical relevance of underweight in both anorexia nervosa (AN) and avoidant restrictive food intake disorder (ARFID) and obesity in binge eating disorder (BED), one potential avenue is to focus jointly on body weight and the specific eating disorder symptomatology. Both obesity and AN have been viewed as representing behavioural addictions [1, 2]; accordingly, consideration of a treatment strategy in accordance with an addiction hypothesis is also warranted. Alterations of the microbiome have been detected in patients with AN and obesity; in animal models, evidence has accumulated that body weight can be influenced by altering the microbiome.

The key conundrum: would patients with eating and weight disorders take a pill to restore their health?

Health care professionals are keenly aware of the hesitancy of patients with AN to readily embark on treatment schemes. In some ways, this hesitancy is similar to that observed for a substantial

subgroup—if not even the majority—of patients with obesity. To gain weight or lose weight requires commitment over an extended period of time—and even then, success is by no means guaranteed; in both AN and obesity, patients have difficulties in maintaining their achieved weights. For eating and weight disorders, dropouts and lost-to-follow-ups are frequent in clinical trials [3–5], indirectly signalling that patients are unable to adhere to, or are not content with, the currently available treatment regimens.

Indeed, conventional treatment schemes do not result in quick remedies. Eating disorders, and AN in particular, run a protracted course with persistent symptoms. The mean body weight of patients remains skewed—albeit to a not as extreme extent—towards the left (underweight) side of the distribution, even after recovery from full-blown AN [6, 7]. Recent evidence now links genetic factors involved in AN to constitutional underweight [8, 9], as was already suggested over 20 years ago [10]. Obesity in adolescence or adulthood seems to be even more difficult to overcome. Thus, a meta-analysis based on behavioural intervention trials focusing on both diet and physical activity and encompassing almost 3000 adults resulted in an average difference of -1.56 kg (95% confidence interval -2.27 to -0.86 kg) at 12 months, in comparison to controls [11], which is a rather marginal effect size.

Subgroups of individuals with AN or obesity reject a patient status. Instead exceedingly low or high weight is perceived as being within the ‘normal’ range of the body weight distribution. Thus, the mission of the National Association to Advance Fat Acceptance [12] is ‘to eliminate discrimination based on body size and provide fat people with the tools for self-empowerment through public education, advocacy, and support’. Similarly, ‘it’s not a diet, it’s a lifestyle’ is a slogan referenced in MyProAna [13]. Obviously, health care professionals are also aware of patients with eating disorders or obesity who do suffer and seek treatment. In part, this suffering is driven by comorbid somatic and/or mood disorders.

Accordingly, it is difficult to predict the extent to which patients with eating and weight disorders would indeed take a pill to overcome their disorder. Apart from ego-syntonicity, comorbidity, cultural influences, and lay beliefs, efficacy and safety represent key

determinants. In addition, if the disorder, in itself, in some way has a rewarding effect, treatment-induced removal of such an effect could also influence acceptability.

Energy homeostasis and body weight categories

A stable body weight results from a balance between energy intake and expenditure. Energy intake is a complex phenomenon which largely depends on internal (including emotional), social, time, and environmental cues to eat, feelings of appetite/hunger, food and beverage preferences, alcohol, tobacco and drug use, medication, and conscious efforts to influence eating behaviour. In sedentary individuals, total energy expenditure is determined as approximately 70% by resting energy expenditure (REE) largely accounted for by muscle and organ mass. The remaining 30% is accounted for by the thermogenic effect of food (the energy used to absorb, digest, and store nutrients) and activity subdivided into regular physical activity and non-exercise activity thermogenesis (NEAT) as in fidgeting [14].

This highly complex regulatory system has evolved to defend the individual against loss of body weight (fat and fat-free mass) and to allow adaptation to starvation [15–17]. Both intermittent experimental overfeeding and caloric restriction entail counter-regulatory adaptations of energy expenditure; upon cessation of such experiments, the body weight of participants frequently returns to the pre-intervention level. However, the recent obesity pandemic illustrates that the human organism is not well protected from the development of high body weight. In contrast, the signalling network to allow adaptation to hunger and starvation is extensive, because food supplies have repeatedly been scant during evolution.

Adult body weight categories are sub-classified according to body mass index (BMI) (Table 102.1) [18]. In healthy underweight (BMI <18.5 kg/m²) subjects, whose BMI is below the weight criterion threshold for AN, a long-standing history of underweight is the rule. Intermittent substantial weight loss is not observed, although weight loss may occur during stressful life events; furthermore, a family history of underweight and the virtual absence of obesity in first-degree relatives are common. Subjects with overweight (BMI ≥25 kg/m²) and obesity (BMI ≥30 kg/m²), including extreme obesity (BMI ≥40 kg/m²), have usually accumulated their excess adiposity over a prolonged time period; however, a more rapid weight gain leading to overweight can occur within

the context of specific time periods such as, for example, puberty, pregnancy, menopause, an episode of major depression (for example, atypical depression), cessation of smoking or during treatment with drugs that induce weight gain, and even binge eating as a side effect [19].

Complex interactions of environmental factors with individual genetic factors result in normal weight, underweight, or overweight/obesity. Whereas it has proven difficult to unequivocally attribute the development of obesity to specific environmental factors entailing an increased energy intake and/or reduced energy expenditure and, as a net effect, an energy surplus, the current obesity epidemic is attributed to environmental factors (obesogenic environment). Potentially, and similar to the genetic architecture of BMI [20], the number of environmental factors is large; overall, effect sizes of single factors may well prove to be rather small; nevertheless, in a given individual genome-environment, interactions may render specific environmental factors much more important than others. Within any given society, the obesogenic environment may not differ substantially, thus enabling genetic factors to play a larger role in explaining BMI variance of the respective population. Accordingly, BMI heritability estimates based on twin studies have remained stable over the past decades [21].

Despite the assumed importance of the environment for the obesity epidemic, there is no easy way to turn the clock back; this, by itself, points to the multitude of factors involved. In industrialized countries, sedentary office workplaces, a sedentary lifestyle, and even more so overconsumption of foods are perceived as major contributors to excess weight gain. Changes in the global food system, which is producing palatable, more processed, cheap, and effectively marketed food, are thought to entail 'passive' overconsumption of energy. Overweight and obesity can thus be viewed as a predictable outcome of market economies predicated on consumption-based growth [22]. Importantly, social class is a predictor of body weight in (post-)industrial and developing countries, albeit with partially opposite effects [23, 24].

Behaviour and emotionality undoubtedly contribute to the development of eating and weight disorders. However, among laypersons, these factors frequently are perceived as the sole factors. The lay perception that behaviour is important and modifiable is, to a large extent, responsible for the stigma associated with both groups of disorders. Such lay beliefs may even have an impact on body weight; for example, subjects who believe that obesity results from a lack of exercise had a higher BMI than those who considered a poor diet at the core [25]; this effect on body weight was not explained by other factors with an influence on body weight, co-assessed in the respective study. Quite a substantial number of patients with either AN or obesity have the perception that surmounting mental problems will enable them to achieve a normal body weight; relatives, friends, and health care professionals frequently contribute to this way of thinking. This mindset can just as well be found in patients, in whom the respective condition affects multiple family members, demonstrating that the complexity of the interaction of genetic and environmental factors in the aetiologies of these disorders is frequently confusing to those most concerned. Interestingly, the lay belief that genetic factors play a major role in obesity has been associated with reports of lower levels of both physical activity and fruit and vegetable consumption [26].

Table 102.1 Weight categories based on BMI

Category	BMI (kg/m ²)
Underweight	<18.5
Normal weight	18.5–24.9
Overweight	≥25
Pre-obesity	25–29.9
Obesity grade I	30–34.9
Obesity grade II	35–39.9
Obesity grade III	≥40

Disordered body weight regulation

Because eating and weight disorders are associated with weight loss (AN), weight stunting (AN, ARFID), weight fluctuations (AN, bulimia nervosa, BED), and weight gain (obesity), diverse regulatory mechanisms that normally serve to defend body weight are overridden. This perturbation can stem from, *and* entail, both somatic and psychological malfunctioning, resulting in a complex intertwinement of primary and secondary factors. [27]. Neuroendocrine findings in eating disorders primarily reflect the consequences of these perturbations (Table 102.2); major causal neuroendocrine mechanisms have not been identified for eating disorders. Knowledge of the induced neuroendocrine dysregulations helps partially to understand the respective clinical symptomatology. In addition, efforts to gain weight by a patient with chronic AN may be hampered by 'physiological' counter-regulation, in addition to the primary underlying disturbances; the long-standing underweight may have led to a reduction of the body weight set-point.

Elucidation of monogenic obesity opened the door to the neuroendocrine circuitry underlying body weight regulation and the physiological adaptation to starvation

Multifactorial obesity is the most common form of obesity in the general population [19]; this type of obesity results from the complex interaction of hundreds of polymorphisms and environmental factors. Currently, genetic variation at 941 independent loci has been detected via genome-wide association analyses; the mean allelic effects on body weight range from approximately 1.5 kg to <150 g. Approximately 6% and 22% of the BMI variance can be attributed to the currently identified polygenic loci or have been estimated to, in total, explain the polygenic contribution [20, 28].

Cloning of the leptin gene in 1994 and the identification of the rare mutations entailing the autosomal recessive phenotype of the obese mouse and the equivalent human leptin deficiency syndrome represented initial breakthroughs in our understanding of the molecular

mechanisms involved in body weight regulation and the behaviours associated with both an increased energy intake and a decreased expenditure [29]. Leptin-deficient humans for the first time revealed that extreme obesity without cognitive impairment can result from a monogenic disorder [30]; the voracious appetite and ensuing behaviours of these individuals are driven by the genetically based lack of this anorexigenic hormone.

Leptin is mainly synthesized in adipocytes and secreted into blood; circulating concentrations are correlated with BMI and fat mass in particular. Central leptin signalling is initiated via binding of leptin to its receptor at the cell surfaces of two different types of first-order neurons within the arcuate nucleus in the hypothalamus (Fig. 102.1). These neurons, in turn, convey the leptin signal to second-order neurons; brain-derived neurotrophic factor (BDNF) and its receptor are important downstream effectors of the leptin-melanocortinergic pathway, which projects to different neurotransmitter systems [15, 16, 28].

Prolonged reduced energy intake due to, for example, a famine reduces the endocrine function of adipose tissue, which is compounded by the ensuing loss of fat mass. Hence, circulating leptin drops to subnormal levels and, via this process, initiates neuroendocrine adaptation to starvation [15, 16]. Reduced leptin signalling affects the hypothalamus–pituitary axis, which down- or upregulates the functions of downstream end-organs, including the thyroid, gonads, and adrenals. In addition, growth hormone is upregulated, while others like insulin-like growth factor 1 (IGF-1), a neurotrophic polypeptide, are downregulated.

Other examples of autosomal recessive forms of monogenic obesity include those due to mutations in the genes for the leptin receptor, pro-opiomelanocortin (*POMC*) and proconvertase 1 [29]. All of the recessively inherited forms of monogenic obesity entail additional phenotypic features such as hypothalamic amenorrhoea associated with functional leptin deficiency or red hair and adrenocorticotrophic hormone (ACTH) deficiency in a subgroup of *POMC* mutation carriers; these associated phenotypes underscore the fact that the neuroendocrinology of body weight regulation is interwoven with other functions.

One of the second-order neurons expresses the melanocortin-4 receptor (*MC4R*) gene, which can harbour a vast range of functionally relevant mutations entailing dominantly inherited obesity in 1–5% of extremely obese children and adults. The anorexigenic effect of the leptin signal is diminished, if binding of the *POMC* cleavage product alpha-melanocyte stimulating hormone (α -MSH) to the *MC4R* is reduced as a consequence of such mutations. The net effects of such *MC4R* mutations result in body weight increments of approximately 15 kg and 30 kg in males and females, respectively. Obesity due to *MC4R* mutations is not associated with any readily easily recognizable associated phenotype [29].

Apart from the hypothalamus, several other subcortical and cortical brain regions, including those comprising the reward system [31], are involved in body weight regulation and adaptation to starvation. In addition to leptin, a number of peripheral hormones and peptides arising from the digestive system (gut–brain axis), muscle, and other organs provide the link between the periphery and the central nervous system via specific central receptors. Furthermore, endocrine and neurocrine pathways are assumed to be involved in gut microbiota-to-brain signalling; vice versa, the brain can alter microbial composition and behaviour via the autonomic nervous system [32].

Table 102.2 Endocrine alterations in AN and BN*

	AN	BN
Thyroid axis	↓ fT3, n (↓) fT4	n (↓)
Gonadal axis	↓ FSH ↓ LH pulsatility ↓ Oestrogens ↓ Androgens	n (↓) n (↓) n (↓) n (↓)
Adrenal axis	↑ cortisol n DHEAS	n (↑) n
Growth hormone	GH resistance (↑ GH/↓ IGF-1)	n (↑)
Appetite-regulating hormones	↓ leptin ↑ ghrelin (fasting) ↑ (n) PYY (fasting)	n (↓) ↑ N

↑, elevated; ↓, reduced; n, normal; fT3, free triiodothyronine; fT4, free thyroxine; LH, luteinizing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; IGF-1, insulin-like growth factor, type 1.

* [90, 91].

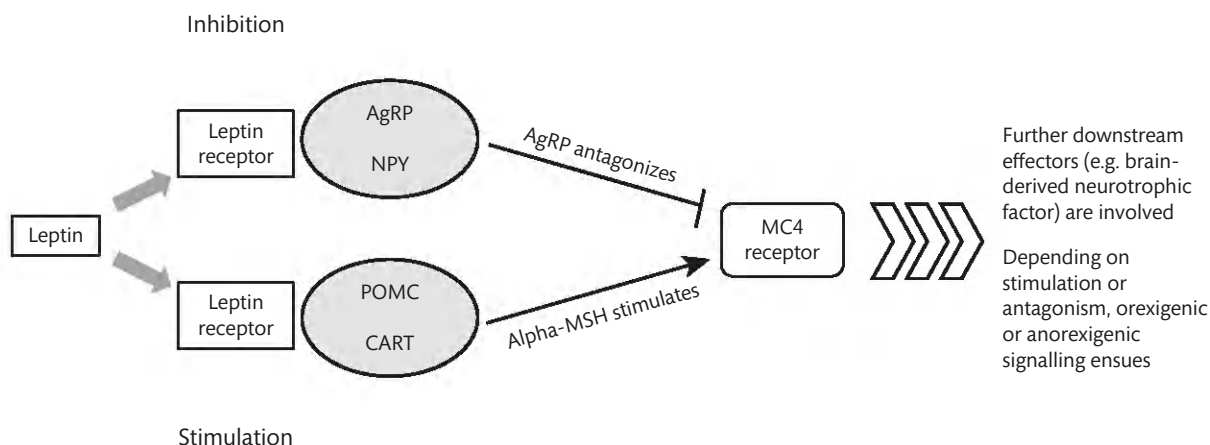

Fig. 102.1 Leptin has central effects on feeding behaviour, appetite, motor activity, and cognitive function, but also peripheral effects on the insulin-glucose axis. In the arcuate nucleus of the hypothalamus, leptin activates two different types of first-order neurons. One co-expresses the orexigenic peptides neuropeptide Y (NPY) and agouti-related protein (AgRP), the other the anorexigenic peptides cocaine- and amphetamine-related transcript (CART) and pro-opiomelanocortin (POMC). POMC is cleaved into different peptides, including α -melanocyte-stimulating hormone (α -MSH). AgRP and α -MSH compete for the MC4 receptor (MC4R). AgRP antagonizes MC4R activity, and α -MSH stimulates MC4R activity. Decreased MC4R activity generates an orexigenic signal, whereas increased activity conveys an anorexigenic signal.

Drug-induced weight loss and its potential for the treatment of obesity

Recent insight into the neuroendocrine regulation of body weight has led to the identification of many potential targets to influence body weight. As a consequence of the high prevalence of obesity, drug-induced weight loss has been the major focus of pharmacological research; however, AN, ARFID, sarcopenia, and cachexia due to infections, cancer, and other conditions also clearly warrant efforts to devise drugs that promote weight gain. The elucidation of polygenes in body weight regulation [20, 28] is of a too recent origin to have allowed their full exploitation with respect to a selection of drug targets. It is also questionable whether the low effect sizes of the identified genes will trigger research efforts in the pharmaceutical industry. However, the advances into treatment of different types of monogenic obesity underscore the potential of making use of the neuroendocrine mechanisms and of genetic variation underlying obesity in particular. Thus, daily treatment with subcutaneously applied recombinant leptin is able to normalize the eating behaviour of patients with inborn functional leptin deficiency within days; in the longer term, substantial weight loss ensues [30]. Two patients with a form of monogenic obesity due to *POMC* mutations benefited from treatment with the MC4R agonist setmelanotide; weight loss amounted to 51 kg and 20.5 kg after treatment for 42 and 12 weeks, respectively [33]. Functional rescue of stop mutations in *MC4R* has been demonstrated in a rodent model based on aminoglycoside-mediated read-through of stop codons [34]. MC4R agonists are currently being evaluated for the treatment of both obesity due to *MC4R* mutations and multifactorial obesity [35]. Case reports indicate that indirect sympathomimetic stimulants and atomoxetine may also induce substantial weight loss in individuals with *MC4R* mutations [36, 37].

In general terms, the known anti-obesity drugs can be classified as either centrally acting appetite suppressants and satiety enhancers (with or without additional peripheral actions) or peripherally acting agents [38]. As of today, no major clinical breakthrough has

been achieved in the pharmacological treatment of multifactorial obesity or eating disorders. Whereas some drugs or drug combinations have been shown to acutely induce weight loss, clinically significant and regulatory agency-required medium-term (1 year) weight loss mostly averaged in the range of 3–5 kg in excess of placebo. Weight regain typically sets in upon discontinuation of the respective medications [38].

Apart from these disappointingly low mean weight losses, the history of anti-obesity drug development is fraught with significant cardiovascular or central nervous system side effects that have frequently led to their market removal (for example, fenfluramine, sibutramine, rimonabant [39]) or failed clinical studies prior to any new drug approval (NDA) submission; interestingly, the rare emergence of AN represents one such serious adverse event [40]. As a consequence, all large pharmaceutical companies have stopped or significantly reduced their obesity drug development programmes; in light of the regulatory requirements, the financial risks currently appear too high. Currently, only startups or some mid-sized companies pursue this challenging indication. However, paradoxically, patients with grade III (BMI ≥ 40 kg/m²) or grade II ($35 \leq$ BMI < 40 kg/m²) obesity and obesity-related comorbid disorders are eligible for bariatric surgery, which entails a *mortality risk* of approximately 0.5% [41]. As such, a more positive and differentiated approach to pharmacological treatment appears warranted, according to which higher risks of adverse events during pharmacological treatment of extreme obesity should not automatically entail withdrawal of the respective drug. On the other hand, regulatory agencies are justifiably concerned with off-label use of drugs to promote weight loss in less obese individuals.

Interestingly, obesity drugs have failed because of side effects due to actions in pathways overlapping with the reward and other central nervous systems. Of 25 drugs withdrawn worldwide between 1964 and 2009, 23 acted via central mechanisms, with psychiatric side effects explaining seven withdrawals; drug abuse and dependence accounted for roughly 50% of these withdrawals [39]. A centrally acting drug that leads to weight loss (or gain) frequently also affects

mood, cognition, and/or behaviour. The serotonin–noradrenaline reuptake inhibitor sibutramine was originally developed as an antidepressant; due to an elevated cardiovascular risk profile and despite weight loss, which, in theory, should have reduced cardiovascular risks, the drug was taken off the market. The cannabinoid receptor-1 antagonist rimonabant (Acomplia[®]) was associated with depression and suicidal ideation in a small subgroup of patients, leading finally in 2009 to authorization by the European Medicines Agency (EMA) for its withdrawal from the market, 3 years after its approval in 2006; the US Food and Drug Administration (FDA) had never licensed the use of this drug in the United States due to concerns for neurologic and psychiatric side effects. The approved anticonvulsant topiramate (Topamax[®]), which induces weight loss in excess of both sibutramine and rimonabant, is associated with paraesthesiae, taste impairment, suicidal ideation, and psychomotor disturbances; in total, the adverse side effects again were deemed too problematic to market topiramate as a stand-alone anti-obesity drug [39]. However, low-dose combination with phentermine has received market approval.

Of the five drugs currently licensed by the FDA for the treatment of obesity, two represent combination drugs (phentermine–topiramate and naltrexone–bupropion). All five drugs are superior to placebo in inducing a weight loss of at least 5% within a clinical trial duration of 12 months. The proportions of patients meeting this threshold are shown in Table 102.3 [42].

Liraglutide and naltrexone–bupropion were associated with the highest odds of adverse event-related treatment discontinuation. Of these five drugs, the EMA has licensed the use of orlistat, naltrexone–bupropion, and liraglutide.

The ongoing elucidation of the pathways involved in energy homeostasis is continuing to turn up novel targets for anti-obesity drugs; similarly, the metabolic alterations after bariatric surgery have provided additional insight into the complex regulation of body weight [43]. Several drugs, including an MC4R agonist and an enhancer of fat oxidation, are in development for subtypes of obesity. A small number (in comparison to the era prior to 2007) of clinical trials are ongoing (see clinicaltrials.gov). Due to both the limited effect of a single drug and dose-dependent increases in side

effects, combination therapies and, in particular, polypeptide hormone combinations appear promising [44].

Despite the detection of numerous targets and ongoing drug development, the four new anti-obesity drugs approved by the FDA between 2012 and 2014 did not fulfil their market expectations. Acceptance by physicians in the United States was substantially lower than for other novel drugs; furthermore, patient acceptance has only picked up slowly [45]. Obviously, the frequent market withdrawals of anti-obesity drugs have contributed to a negative perception of pharmacological treatment of elevated adiposity. This history has reduced investment in drug development for this highly relevant disease for the foreseeable future. The expectations of both patients and physicians require a realistic discussion as to the pros and cons of drug treatment of elevated adiposity; in some countries, reimbursement issues by health insurances also need to be addressed. A stand-alone drug treatment of obesity is unlikely to be successful; for the time being, lifestyle modification will remain the cornerstone of weight management [38]. Central nervous system side effects and risks for drug dependence represent serious obstacles for the development and marketing of anti-obesity drugs.

Drug-induced weight gain and its potential for the treatment of AN and AFRID

No drugs have been specifically licensed for the treatment of AFRID or AN. As such, all medications currently used to treat these disorders symptomatically are prescribed off-label, for instance, to suppress severe eating disorder-specific cognitions. However, because starvation-associated underweight can figure prominently in both disorders, approaches for drug-induced weight gain represents a major therapeutic aim. Appetite stimulants/oraxigenic drugs clearly represent an option, although drugs that reduce energy expenditure and physical activity may have potential too. Additionally, drug treatment of sarcopenia [46] and cachexia associated with cancer [47, 48], chronic kidney disease, HIV, other infectious diseases, cancer, and chronic obstructive pulmonary disease also warrants scrutiny for potential application in eating disorders. For

Table 102.3 Obesity agents producing 5% weight loss or more (proportions of patients meeting this threshold shown as percentages)

Drug	Mechanism of action	% meeting threshold for significant weight loss
Phentermine Topiramate	Phentermine: non-selective stimulator of monoamine release Topiramate acts as multifactorial: enhances GABAergic neurotransmissions, blocks voltage-dependent sodium channels, activates L-type calcium channels, enhances inhibitory activity of glutamate at AMPA (amino-3-hydroxy-5-methyl-4-isoxazole-propionate) and kainate receptors, and inhibits several carbonic anhydrases isoenzymes [92]	75%
Liraglutide	Glucagon-like peptide 1 analogue	63%
Naltrexone–bupropion	Naltrexone: opiate antagonist Bupropion: previously seen as weak noradrenaline–dopamine reuptake inhibitor (NDRI), but potentially rather a noradrenaline and dopamine releasing agent (NDRA)	55%
Lorcaserin	Serotonin 2C receptor agonist	49%
Orlistat	Inhibitor of gastric and pancreatic lipases	44%
Placebo		23%

example, given the prominent role of the MC4R as a drug target for both induction of weight loss and weight gain, it is interesting that cachexia induced by lipopolysaccharide administration and by tumour growth is ameliorated by central MC4R blockade in rodent models [49].

Several licensed drugs, particularly psychopharmacological medications, show weight gain as an unwanted side effect. Clozapine and olanzapine have the strongest effect on body weight [50]. They act via an increase of caloric intake without affecting resting energy expenditure [51] and can induce binge eating attacks [52]. Weight gains exceeding 20 kg can occur in genetically susceptible individuals [53] who are treated for psychosis or other mental disorders; the mean average weight gain after 10 weeks is between 4 kg and 4.5 kg [50]. However, use of olanzapine and related drugs in AN to promote weight gain has proven unsuccessful, as revealed by meta-analyses of randomized controlled trials [54]. It is unknown if the unresponsiveness is due to cognitive restriction or to starvation-dependent dysregulation. Interestingly, our own clinical observation is that olanzapine can induce weight gain once patients have reached their target weight.

Systematic studies of dopamine antagonists are not available for AFRID and feeding disorders associated with low body weight. The young age of the respective patients should imply a restrictive approach to treatment with off-label medications. Three case reports based on pre-adolescent patients with feeding disorders suggest that risperidone may help to increase body weight [55]. A retrospective chart review of 127 children between 7 and 80 months with feeding difficulties not exclusively fulfilling the DSM-5 criteria for ARFID suggested that cyproheptadine, an antihistaminergic and antiserotonergic agent approved for use in cold urticaria in children and adolescents, can lead to weight gain and a positive change in mealtime and feeding behaviours within the context of a complex treatment programme [56]. Mild and transient side effects, such as drowsiness, irritability, and constipation, were reported in 14% of the children.

Ghrelin represents an example of a hormone which induces food intake as an appetite stimulant; the hormone is synthesized in the enteroendocrine cells of the stomach and released upon caloric restriction—it thus signals hunger. Consistent with the neuroendocrine adaptation to starvation, serum levels are elevated in patients with AN. Based on encouraging initial findings in a small number of patients with AN, a clinical trial is currently assessing the effects of the novel ghrelin receptor agonist RM-131 for treatment of AN [57]. Apart from other functions, the hypothalamic neuropeptide oxytocin is a regulator of food intake; a clinical trial in patients with AN is looking at the effects of intranasal oxytocin on smell and food consumption. In a double-blind, single-dose, placebo-controlled crossover study, oxytocin had no effect on the 24-hour calorie intake in AN patients, whereas patients with BN consumed less calories [58]. Because testosterone increases fat-free mass, a phase 2 clinical trial is investigating the effect of transdermal testosterone on BMI of patients with AN [57]. The cannabinoid agonist dronabinol [the international non-proprietary name (INN) for delta-9-tetrahydrocannabinol (THC)] induced a small (0.73 kg in excess of placebo), but significant, weight gain after 4 weeks of treatment in the absence of severe adverse events in an add-on, prospective, randomized, double-blind, controlled crossover study, which included 25 adult patients with chronic AN [59].

Pharmacological dissection of primary phenomena from starvation-induced symptoms in AN

Treatment of patients with AN with recombinant leptin appears to be a promising approach to ameliorate starvation-induced symptoms related to hypoleptinaemia [60]. Treatment with recombinant leptin has been shown to improve the function of the reproductive system, including resumption of menstruation in currently non-eating disordered females with hypothalamic amenorrhoea [61]. Amenorrhoea in patients with AN is induced by hypoleptinaemia [16]. The exact mechanisms linking the metabolic system with the reproductive system require further elucidation. Leptin binds to receptors on gonadotrophin-releasing hormone (GnRH) neurons. The signalling cascade for reproductive function includes gonadotrophin-inhibitory hormone (GnIH) and kisspeptin [62].

At the behavioural level, hyperactivity is encountered in a substantial subgroup of patients with AN. Hypoleptinaemia likely also plays a crucial role in the development of this phenomenon, which, if severe, substantially impedes treatment. In rats subjected to food restriction, running-wheel activity increases by 300–400%. This starvation-induced hyperactivity is assumed to facilitate food-foraging behaviour. The development of hyperactivity is completely suppressed by concomitant treatment with recombinant leptin [63]. Because removal of the adrenals also prevents the development of anorexia-based activity, it appears that leptin exerts its effects via the hypothalamic–pituitary–adrenal axis [64]. In agreement with the rat model, low serum leptin levels in patients with AN have been associated with increased activity levels [65], suggesting that the same mechanism applies. This may provide a unique example of a profound physiologically induced and hormonally determined change in activity levels. It certainly substantiates the pivotal role of leptin in the adaptation to starvation [15, 16].

Other findings supporting the role of leptin in the neuroendocrine adaptation to starvation include its suppression of growth stunting in rodent starvation models, its antidepressant effect in in-born leptin-deficient mice, and its effects on bone growth. Leptin has also been shown to have a neurotrophic effect; in leptin-deficient humans, treatment with recombinant leptin entails increments of the volume of specific brain regions [15, 16, 60]. Recombinant leptin has recently been licensed for the treatment of lipodystrophy by the FDA [66]; the EMA followed suit in 2018. Adverse effects occurred during treatment with metreleptin (Myalept[®]), but these seemed to be linked to the underlying disorder.

Such trials in patients with AN would enable the dissection of primary from secondary starvation-induced symptoms in AN; an amelioration of somatic, cognitive, and behavioural symptoms appears possible [66]. Patients with BN whose metabolism is in a semi-starved state might benefit as well. The risks of metreleptin treatment of patients with eating disorders might be manageable. Thus, leptin treatment of eight females with hypothalamic amenorrhoea was not associated with significant side effects [61]; in addition, long-term treatment of individuals with leptin deficiency [30] and a 24-week-long treatment of hypoleptinaemic (<5 ng/mL) adult females [67] were not associated with serious side effects. The production of antibodies neutralizing leptin has occurred after longer treatment and

was countered by intermittent discontinuation and application of higher doses.

Obviously, patients with AN would have to be closely monitored during a pilot study; in particular, adequate feeding during treatment is crucial, as an elevation of leptin may reduce appetite. Preferentially, initial attempts should be directed at adult patients with hyperactivity [60, 66]. The high costs of metreleptin treatment (currently approximately half a million dollars annually for the treatment of a patient with lipodystrophy [66]) represent an important obstacle to treatment acceptance.

Eating disorders and behavioural addictions

An addiction-like process has been suggested to explain the eating behaviour of subjects with AN [2], BED, and obesity [1]. Potentially, either overeating or caloric restriction can have a positive effect on mood, emotion regulation, and cognition in predisposed individuals. With respect to obesity, the terms 'food addiction' and 'eating addiction' illustrate the current controversy as to whether particular foods and substances (for example, sugar) can support an addictive behaviour as in substance use disorders or whether overeating is best categorized as a behavioural addiction or compulsion. The term 'paradoxical liveliness' has been coined to illustrate that some patients with AN appear more lively and become more focused and more ambitious when they initially develop their eating disorder [65]. The fact that all major religions have propagated short-term or intermittent fasting suggests that emotional and spiritual well-being may be positively influenced by the metabolic and physiological processes associated with the adaptation to starvation.

The function of leptin within the reward system warrants appreciation [1, 68]. The rewarding value of nutrients requires activation of midbrain dopamine (DA) neurons. Fasting enhances the rewarding value, whereas it is diminished by leptin. Via leptin receptors expressed on a subpopulation of midbrain DA neurons, leptin exerts an inhibitory effect on these neurons, thus potentially explaining a decreased nutrient reward and anorexia via downstream galanin-mediated inhibition of orexin neurons. Conversely, DA levels in the nucleus accumbens (NAc) are decreased in hyperphagic, leptin-deficient *obese* mice and increased by leptin injections. Food intake may thus result from DA deficiency in the NAc, entailing normalization of DA levels. Low levels of DA in the NAc have been postulated to underlie both the drive to eat in obese subjects and substance use in drug addicts [68].

Alterations of the brain reward circuitry have also been postulated to contribute to the development and maintenance of eating disorders. At the onset of AN, eating less food may be perceived as rewarding; afterwards, conditioning sets in. In the binge eating/purging type of AN, BN, and BED, patients report a strong urge to eat, together with a sense of loss of control of their energy intake and a transient reduction of negative emotional states after bingeing. Patients with eating disorders frequently present with anhedonia, meaning that they are less able to experience reward in comparison to healthy controls [69]. O'Hara and coworkers [2] hypothesized that, rather than a generalized inability to experience reward, a cognitively driven reluctance to gain weight may contribute to the aversive appraisal of food- and taste-related stimuli. Hypotheses focusing on a reduced experience of reward include inappropriate processing

of visual perception of food, distinct patterns of brain activation in response to gustatory stimuli, and 'reward contamination' (normal rewarding stimuli are experienced as aversive). Patients with eating disorders may activate dopaminergic motivational circuits differently, so that normally aversive stimuli become attractive [69].

Whereas a reward-centred model of AN, and thus an overlap with addiction, appears plausible, substantial differences are also apparent. Further research is required to assess potential implications for psychotherapeutic and psychopharmacological treatment of eating disorders [2]. Prevention and treatment of obesity, based on the assumption that it (partially) results from food or eating addiction, warrants further scrutiny [1]. The 5-HT_{2c} agonist lorcaserin, which has received FDA approval for the treatment of obesity, has further potential in substance use disorders, especially nicotine/smoking. In particular, the lorcaserin dose dependently reduces smoking rates and at the same time reduces/prevents the weight gain typically associated with cessation of smoking [70].

Obesity, eating disorders, and the microbiome

Microbiota transplantation experiments in mouse models first indicated that the gut microbiota influences weight regulation and modulates psychopathology. Stool extracts transferred from genetically or nutritionally induced obese to germ-free (GF) mice produced a marked increase in body fat within a relatively short period of time [71]. Moreover, obesity and obesity-associated metabolic phenotypes were transmissible by uncultured microbiota of humans to GF rodents. Conversely, cohousing the microbiota-transplanted obese mouse with a mouse harbouring the microbiota from a lean individual prevented the development of obesity and the associated metabolic complications [72]. Several studies, especially those following Roux-en-Y gastric bypass, demonstrated that obesity is related to a change in the relative abundance of two bacterial strains—the *Firmicutes*-to-*Bacteroidetes* ratio is increased in obesity and reduced with weight loss. However, it is still not clear whether these changes in microbial populations directly contribute to promote weight loss or result from it [73].

The microbiome of obese individuals has an increased potential to harvest energy from nourishment, for example by nutrition absorption and polysaccharide utilization. It produces bioactive metabolites, for example short-chain fatty acids (SCFAs) (specifically acetic acid, propionic acid, and butyric acid), by fermentation of partially digestible and non-digestible carbohydrates of dietary fibres. SCFAs affect the physiology of the host organism, for example the pH level of the colon, gut transit time, and glucose metabolism, thus modifying appetite and energy metabolism [74, 75]. Obese individuals, including children and adolescents, have a higher relative abundance of microbiota able to ferment polysaccharides. The consequence is a higher amount of SCFAs providing more energy for the host, which can be stored as fat tissue or converted into glucose. In adults fed on a Western diet, the extra energy supply by producing SCFAs has been estimated to add up to 10% of the overall daily caloric intake [76]. Moreover, these metabolites are able to cross the brain–blood barrier and impact neural circuits [77].

On the other hand, the microbiome also seems to play an important role in starvation-induced weight loss. Transplantation of frozen bacterial species from children with kwashiorkor, a severe

form of malnutrition often observed in developing countries, produced significant weight loss in GF mice, accompanied by severe metabolic changes. One-week application of an oral antibiotic significantly improved the nutritional status of malnourished Malawian children [78]. Significant changes of the gut microbiome were also found in the frequently used animal AN model of activity-based anorexia (ABA) [79], which stimulates weight loss by reduction of food and access to a running wheel [63, 64]. Because of the starvation- and hyperactivity-induced weight loss in the animal model, decreased thickness of the muscularis layer and significantly increased permeability of the intestine were observed [79].

Unfortunately, studies in patients with AN are still scarce. Two recent investigations found a significant difference between the abundance of certain bacterial groups in healthy controls and patients with AN, especially an increase in mucin-degraders and a decrease in butyrate producers in the latter group, which were only partly alleviated by weight gain [80, 81]. Mucin-degraders feed on mucus covering the intestinal wall and probably contribute to the increased intestinal permeability identified in the ABA model for AN mentioned previously [75].

Both in obesity and AN, there is emerging evidence for an increase in intestinal permeability, followed by low-grade inflammation, which, in turn, might contribute to the metabolic (and psychopathological) alterations found in both disorders [73]. The intestinal barrier prevents pathogenic microorganisms from spreading into the systemic circulation. However, a 'leaky gut' might facilitate the transfer of harmful microorganisms and toxins from the gut lumen to the lamina propria and mesenteric lymph nodes, from which they may reach the systemic circulation, especially if the immune system is dysfunctional. From this point, such so-called 'pathobionts' and other harmful substances could stimulate the production of pro-inflammatory peripheral and central cytokines, the latter having an impact on neuronal function (gut-brain interaction). Indeed, pro-inflammatory cytokines are known to be increased during the acute state of AN [82]. Similar processes are observed after several weeks of a high-fat diet in animals with an altered gut barrier function and elevated inflammation markers [83].

Implications for treatment of obesity and eating disorders may include changes of diet and the administration of pre- or probiotics or even of antibiotics. The composition of the human microbiome rapidly responds to a dietary change. In an informative study by David *et al.* [84], the researchers compared the effects of a shift from usual eating habits to either a vegetarian or an animal-based diet. In the group on the animal-based diet, changes in the gut microbiome occurred already 1 day after the new nourishment had reached the distal gut. The microbiome changed to an abundance of bacteria with high bile resistance (*Bilophila wadsworthia*), which is associated with the occurrence of intestinal bowel disease in mouse models. Interestingly, only this group, but not that fed on a vegetarian diet, showed significant weight loss. These findings are of potential importance for refeeding strategies in AN. After admission to hospital, the diet of the starved patient is often swiftly changed from a more plant-derived alimentation to high-calorie food rich in carbohydrates and fat to achieve weight gain. This may be doing more harm than good. Within a very short time, the microbiome of our patients is affected without considering probable consequences such as the growth of inflammation-inducing bacteria. Interestingly, an

increased risk for autoimmune disorders, especially Crohn's disease, has been described in AN [85].

Prebiotics are defined as 'non-digestible food ingredients that beneficially affect the host by selectively stimulating the growth/activity of certain bacteria in the gut' [86]. Probiotics are defined as living microbial components delivered to humans or animals, with health benefits for the host. To our knowledge, there are not sufficient data to judge the effect of either prebiotics or probiotics in obesity or eating disorders. However, with further understanding of the role of the microbiome in weight and eating disorders, there is hope that modification of the gut microbes can exert a positive impact on these disorders, at least in some individuals. This could foster a more personalized treatment in these often chronic diseases [73].

Changes in the gut microbiome are also associated with symptoms of psychiatric disorders. Infections of the gastrointestinal tract are followed by anxiety-like behaviour in a rodent model (for a review, see [87]). Inflammatory bowel disease is associated with a high prevalence of anxiety and depressive disorders, which is much more pronounced than in other chronic diseases of childhood or adulthood. Further, a large case-control study in the UK demonstrated that repeated use of antibiotics was associated with an increased risk for depression and anxiety [88]. In acute AN, levels of depression, anxiety, and eating disorder psychopathology were associated with the composition and diversity of the intestinal microbiota [80].

Conclusions

The recent years have witnessed a veritable knowledge explosion regarding the molecular mechanisms of body weight regulation [8, 9, 20, 28, 29, 89], which is currently continuing. The genetic predispositions to AN [8, 9], and possibly other eating disorders too, overlap with the molecular mechanisms involved in this complex physiology. In addition, the genetic predispositions to diverse mental and somatic disorders and quantitative somatic and mental traits overlap [89], suggesting that novel insights may have implications for the future treatment of eating disorders. Furthermore, substantial advances have been made with respect to the pathways involved in the adaptation to starvation and in considering addictive processes for both obesity and AN. Finally, microbiome-related research has come up with important findings. It appears likely that some of these novel findings will entail benefits for the treatment of patients with eating and weight disorders.

Unfortunately, pharmacological research into obesity has suffered from many setbacks that have entailed withdrawals of specific drugs. It is crucial to re-engage the pharmaceutical industry in research required to come up with novel treatments. The scientific basis for drug development in eating and weight disorders has never been as good as of today. The major challenge is to identify targets that will indeed allow the development of safe and effective drugs. The overlap of diverse functional pathways suggests that a certain degree of side effects must be taken into account in order to achieve this goal.

Epidemiology and primary prevention of feeding and eating disorders

Katherine A. Halmi

Incidence and prevalence

Almost all published incidence and prevalence studies of eating disorders are based on data using DSM-IV diagnostic criteria that were obtained over at least a decade ago [1]. Most of these studies were conducted in specific population settings, such as schools, colleges, and primary care clinics, as well as from medical records. Information was collected either from standardized interviews or via self-report questionnaires. Thus, comparing the incidence and prevalence of eating disorders among various countries is more likely to be approximate than accurate. Adequate incidence studies are restricted by the need for large population samples and costs. The incidence of eating disorders, which is the number of new cases in a population over a specific period of time, is usually expressed as 100,000 persons per year. Prevalence is usually expressed either as point prevalence, which is the number of cases with a disorder at a specific point in time, or lifetime prevalence, which is the proportion of persons that had the disorder at any time in their life. There are many more published prevalence, compared to incidence, studies of eating disorders. With varying sensitivity of assessments used in these studies, comparisons are difficult to make.

The incidence of anorexia nervosa (AN) remained relatively stable between 1980 and 2000. In the United Kingdom (UK), the number of new cases from 1988 to 1993 was 4.2 per 100,000, and that from 1994 to 2000 was 4.7 per 100,000 [2]. From 1985 to 1989, the Netherlands had 7.4 new cases of AN per 100,000, and from 1995 to 1999, there were 7.7 new cases per 100,000. The incidence of eating disorders was highest among females aged 15–19 and comprised 40% of all cases—56.4 per 100,000 in 1985 and 109.2 per 100,000 in 1995–1999 [3]. The incidence of males was less than 1 per 100,000 in both countries. Incidence studies in the United States (US) are restricted to the state of Minnesota where the overall age-adjusted incidence was 15 per 100,000 in females and 1.5 per 100,000 in males from 1935 to 1989. Among 15- to 24-year-old females, the incidence rates increased from 1950 to 1984 by 1.03 per 100,000 person-years per calendar year. The increased rate was especially present in females aged 10–14 [4].

Studies on the incidence of bulimia nervosa (BN) are sparse. The incidence of BN among Finnish females aged 15–18, including those who lacked one criteria, was 438 per 100,000 person-years [5]. The incidence of BN in a nationwide primary care study in the Netherlands was 8.6 per 100,000 person-years in 1985–1989 and decreased to 6.1 per 100,000 person-years in 1995–1999 [3]. Similarly, the incidence of BN in the UK decreased from 12.2 per 100,000 person years in 1993 to 6.6 per 100,000 person years in 2000. The incidence remained stable in women aged 10–19 at 40 per 100,000 person years in 1993 and 2000 [2]. In the US, incidence rates from 1980 to 1990 in Minnesota were 26.5 per 100,000 per year in females and 0.8 per 100,000 per year in males. The mean age of onset in females was 23 years. Among 15- to 24-year-old females, it has become over twice as common as AN [6].

There are no published incidence studies for binge eating disorder (BED) or DSM-IV eating disorder not otherwise specified (EDNOS), and there are no adequate incidence studies available for rumination syndrome (RS) and pica. Avoidant/restrictive food intake disorder (ARFID), an eating disorder diagnosis created by DSM-5 [7], has only been recently defined, such that there are no published epidemiology and prevention studies as yet.

Two large-sample studies reported a lifetime prevalence of AN in the US of 0.3% among 13- to 18-year-old females and males [8], and 0.9% among adult females and 0.3% among males [9]. An 8-year prospective study of adolescent girls in the United States reported a lifetime prevalence of AN of 0.6% by age 20 and 2.0% for atypical AN using DSM-IV criteria [10]. A population-based survey in six European countries reported a lifetime prevalence of AN of 0.9% among females and 0% among males [11]. In a Dutch community sample, over 2000 children were assessed from age 11 in 2001 to age 19–20 in 2010. At age 19–20, there was a lifetime prevalence of 1.7% of DSM-5 AN among women and 0.1% among men [12].

The lifetime prevalence in the US for BN was 1.6% among 20-year-old females who were followed up for 8 years [10]. In a study across six European countries, the lifetime prevalence of BN was 0.88% among females and 0.12% among males [11]. The point prevalence of BN among university women in the US decreased from 4.2% in 1982 to 1.7% in 2002 [13]. Initially, high rates for BN found in the

1980s were based on DSM-III criteria [14]. DSM-IV criteria from 1994 for BN were more restrictive. Since the criteria for BN have become again less restrictive in DSM-5, increases in BN prevalence may be expected with DSM-5 criteria.

BED appears to be the most common of the three major eating disorders, with a lifetime prevalence in the US of 3.5% among women and 2.0% among men [9]. In US adolescents aged 13–18 years, the lifetime prevalence of BED was 2.3% among females and 0.8% among males [8]. In a study involving six European countries, the lifetime prevalence of BED was found to be 1.9% among women and 0.3% among men [11].

Prevalence data on RS are scant. One survey of 2163 children aged 10–16 years in Sri Lanka found a prevalence of RS of 5.1% among boys and 5.0% among girls. Only 8.2% had daily symptoms, and 62.7% had weekly symptoms [15]. Likewise, adequate prevalence data on pica are not available. The prevalence of pica in populations considered to be at risk was found to be up to 77% among pregnant women, 15% among persons with intellectual disabilities, 74% among sub-Saharan African children, and 61% among persons with iron deficiency [16].

Outcome and mortality

Of psychiatric disorders, AN has one of the highest mortality rates. A meta-analysis of 36 studies showed a standardized mortality rate (SMR) of 5.86 for AN, with one in five persons dying by suicide [17]. In the US, a 20-year follow-up study reported 6.5% deaths with an SMR of 4.37 for lifetime AN. The duration of illness affected the SMR, such that those with AN for 0–15 years had an SMR of 3.25, and those with AN for 15–30 years had an SMR of 6.6 [18]. An analysis of 119 outcome studies found less than half of AN patients had full recovery, 33% improved, and 20% developed a chronic course [19]. A Dutch study found that age at the time of detection and treatment predicted recovery, with those aged 19 years and below having an odds ratio of recovery of 4.3, compared to those aged 20 years and above [20]. A US longitudinal analysis of mortality among those aged 8–25 years in 906 BN clinic outpatients found a crude mortality rate of 3.9% and an SMR of 1.57. There was a significantly elevated risk for suicide at 0.9%, which accounted for 23% of the deaths [21]. Outcome studies of BN reported recovery rates which varied from 48% [22] to 77% [23]. One large-sample, 12-year follow-up study of 68 German BED patients found a crude mortality rate of 2.9% and a non-significant SMR of 2.29 [24]. Most outcome studies of BED comprised EDNOS analyses. The overall summary is that BED remission is somewhat better than that of BN. Published outcome and mortality studies other than a few case reports are not available for RS and pica.

Ethnicity and sociocultural demographics

Global social and cultural changes associated with industrialization and urbanization have influenced the increasing prevalence of eating disorders among minority groups in Western Europe and North America, as well as in Asian and Arab countries [25]. The prevalence of eating disorders and disturbed eating behaviours is increasing in China, Singapore, South Korea, Egypt, Pakistan, United Arab Emirates, Oman, Lebanon, Kuwait, Iran, and Jordan [25].

In the twenty-first century, the NIMH Collaborative Psychiatric Epidemiological Studies (CPES) found no significant differences in prevalence for AN and BED in the US across Latinos, Asians, African-Americans, and non-Latino whites. BN was more prevalent among Latinos and African-Americans than among non-Latino whites [26]. Utilization of mental health services was lower in all ethnic minority groups, compared to non-Latino whites [27]. Contributing factors include lack of health insurance, lack of affordable and accessible treatment services, and beliefs about seeking treatment. African-American women presenting for BED treatment had a higher BMI and binge eating frequency than whites, and lower depression than white and Hispanic groups [28]. A survey among American college students found Arab Americans reported the highest prevalence of binge eating of 10% [29].

Social factors have also been identified to be associated with the development of eating disorders. In Curacao, cases of AN were found only in mixed-ethnicity women who reported that thinness allowed them greater acceptance in the more affluent white community [30]. Higher rates of eating disorders have been reported to be associated with activities in which leanness is valued, such as dancing and gymnastics, as well as among jockeys [31].
