Identification of risk factors is essential for the implementation of effective intervention strategies. Risk factors for eating disorders and disordered eating behaviour diagnosed according to DSM-IV and DSM-5 increase in early adolescence, on which most studies on eating disorder risk thus focus. The majority of these studies have used self-report questionnaires to assess for disordered eating behaviour, rather than discrete eating disorder diagnoses.

For specific eating disorders, female adolescents in sixth to ninth grades reporting social pressure to be thin and body image preoccupation showed a higher risk for onset of threshold or subthreshold BN or BED over a 3-year follow-up [32]. High-school females reporting weight and shape concerns and negative affectivity had a higher risk for onset of threshold and subthreshold BN over a 4-year follow-up [33]. High dietary restraint was associated with an increased risk for onset of any eating disorder among women aged 16–23 years [34].

A study examining six risk factors at ages 13, 14, 15, and 16 found body dissatisfaction was the most consistent and robust predictor of a future eating disorder. Five of the risk factors were highly significant predictors at age 14, suggesting this age may be a key developmental time point for preventative intervention. The authors proposed a combination of physical and cognitive maturational processes such as completion of puberty, increased capacity for abstract thinking, increased peer influence, and the onset of dating and sexual experiences at this age [34].

Moderating risk factors for AN were identified in a study of children and adolescents from the Danish Psychiatric Central Research Register. Risk factors included female sex, having a sibling with AN, affective disorders in family members, and five major comorbid disorders (affective, anxiety, obsessive-compulsive, substance use, and personality disorders) present in the AN proband [35]. Eating

disorders in either parent were independently associated with eating disorders in their female children in an analysis of the Stockholm Youth Cohort [36].

An analysis of obstetric records found maternal anaemia, diabetes mellitus, pre-eclampsia, placental infarction, neonatal cardiac problems, and hypoactivity were significant independent predictors of the development of AN. The risk of developing AN increased with the total number of obstetric complications. In the same study, obstetric complications significantly associated with BN were: placental infarction, neonatal hypoactivity, early eating difficulties, and low birthweight for gestational age [37]. There is some question on whether *in utero* exposure to a viral infection could increase the risk of developing AN. Exposure during the sixth month of pregnancy to the peak of chickenpox and rubella infections was significantly associated with the risk of developing AN [38]. A comparison of risk factors across AN, BN, and BED [39] showed that AN and BED were distinct from each other, with AN having greater exposure to perfectionism and BED reporting greater exposure to conduct problems, substance abuse, severe childhood obesity, and family overeating. BN shared risk factors with both AN and BED. On examining the AN subtypes, perfectionism carried a greater risk for restricting AN and family overeating while sexual abuse had a greater risk for the binge purge subtype of AN. Two-thirds of women with AN reported their eating disorder started with dieting, whereas two-thirds of women with BN and BED reported their eating disorder started with binge eating.

Risk factors have also been assessed for disordered eating and weight loss behaviours occurring without a designated eating disorder diagnosis. Depression-related symptoms and body dissatisfaction were found to be risk factors for disordered eating in overweight youths [40]. Dieting, depression, and body image distortion in adolescence predicted extreme weight loss behaviours and binge eating in young adulthood.

Prevention programmes

Meta-analytic reviews

Eating disorder prevention programmes that were controlled or those with systematic follow-up began in the 1980s. The outcome of these studies was determined by the decrease in related eating disorder symptoms, rather than identifying the occurrence of diagnosable eating disorders. Targeted populations have varied from at-risk individuals to all persons in specific age groups and in specific environments such as schools and colleges. A meta-analysis conducted in 2007 of 66 controlled outcome studies that targeted persons aged 15 and above with high levels of body dissatisfaction and weight concerns, using interactive paradigms administered by professionals, found small, but significant, effect sizes of these preventative interventions [41].

More recently, a study of an Internet-based prevention programme (Student Bodies) [42] and a meta-analytic review of six US and four German randomized controlled trials of 990 female high-school and college students [43] found that interventions produced moderate improvements in reduction of negative body image and the desire to be thin.

Further, a meta-analysis of 20 Internet-based programmes designed to reduce eating disorder symptoms and representing three

different interventions found these programmes effective both in individuals with a clinical diagnosis of an eating disorder and in those with symptoms only [44]. Compared with control conditions, these interventions reduced body dissatisfaction, internalization of the thin ideal, shape and weight concerns, dietary restriction, drive for thinness, bulimic symptoms, purging frequency, and negative affect.

In a systematic review of interventions involving parents in the prevention of body dissatisfaction or eating disorders in children, only 20 studies were identified. Of these, only four had high-quality data, with two reporting parental involvement significantly improved children's outcome on body dissatisfaction or disordered eating. Two studies were inconclusive on the role of parental involvement [45]. However, several considerations were noted—a child's perception of their parent's behaviour is more important than the parent's perception of their own behaviour; measuring and communicating a child's at-risk status does not improve parental engagement with prevention programmes; and parents of a child with the diagnosis of an eating disorder were more likely to access prevention programmes. The benefit of involving parents in eating disorder treatment is well established. The challenge is how to motivate parents to participate in preventative research.

Specific prevention programmes

The most frequently studied dissonance-based prevention programme is the Body Project. This paradigm is based on the proven theory that cognitive dissonance motivates participants to reduce their adherence to their original attitude. In the Body Project, participants are instructed to critique the thin ideal through verbal, written, and behavioural exercises. This is done in the context of small groups, with one or two clinicians, over four sessions. Home exercises include writing an essay about the costs of pursuing the thin ideal and standing in front of a mirror with minimal clothing while recording positive attributes about one's body. Group sessions include role plays and discussion assignments [46]. The Body Project was found to reduce caudate response to thin models in an fMRI study, providing evidence that this intervention reduces the idealization and significance attached to media images.

Another effective prevention programme tested in randomized controlled trials is the Student Bodies, which is an 8-week Internet-based programme focusing on reducing body weight and shape concerns. This programme uses cognitive behavioural therapy techniques and includes weekly exercises and journal log prompts. It is designed to create healthier behaviour patterns with eating, exercise, sleep, mood, and emotion regulation. After completion of the programme, participants are provided continued access to Student Bodies for 9 months for reviewing material as needed [47].

A mindfulness- and school-based eating disorder prevention programme of three sessions aimed to increase the capacity to refrain from automatic responses when confronted with the thin ideal and related sociocultural pressures and to reduce the impact of any experiences with a negative affective component. The sessions include common coping strategies, role play, and various guided exercises. This programme significantly reduced weight and shape concerns, dietary restraint, thin ideal internalization, eating disorder symptoms, and psychosocial impairment [48].

Targeted populations for eating disorder prevention

Several recent controlled studies have demonstrated either efficacy or effectiveness of school-based programmes in reducing risk factors for eating disorders in adolescents. A Spanish study based on the social cognitive model, media literacy education, and cognitive dissonance found the intervention group had greater reduction in beauty ideal internalization, disordered eating attitudes, and weight-related teasing, compared to the control group, at 1 year follow-up [49]. An Australian study using a similar intervention in girls and boys in seventh and eighth grades showed similar results [50]. A US web-based intervention—Staying Fit—was effective in reducing weight/shape concerns and improving fruit and vegetable consumption in ninth-grade students at risk for eating disorders [51].

College students participating in the online programme Student Bodies in their first college year had a reduction in body image and eating concerns, continuing into their sophomore year [52]. Body dissatisfaction and shape and weight concerns decreased, whereas self-esteem increased in college students participating in a brief conditioning intervention [53].

Women with subthreshold eating disorder syndromes responded to the Internet-based prevention programme Student Bodies with a reduction or abstinence in binge eating, purging, and other disordered eating symptoms [54].

Female adolescents reporting body image dissatisfaction were recruited from two primary care clinics. They responded to a brief dissonance-based eating disorder prevention programme with reduced thin ideal internalization, pressure to be thin, dieting, and eating disorder symptoms [55].

The Parent-Based Prevention (PBP) of eating disorders targeted risk factors and facilitated behavioural change in mothers with eating disorders and their spouses to mitigate negative outcomes in their children. This uncontrolled study suggested PBP produces decreased risk of eating and mental problems in these children [56].

Salient issues for primary prevention of eating disorders

The implementation of evidence-based eating disorder prevention programmes requires attention to issues delineated in the Consolidated Framework for Implementation Research (CFIR) model [57]. These issues, as applied to the eating disorder prevention programme Body Project, are well outlined by Shaw and Stice [58]. In summary: (1) a programme is more readily adopted if those delivering it perceive they had input into developing it; (2) there is belief among programme deliverers on the quality and validity of evidence for a desired outcome; (3) the programme has an advantage over alternative interventions; (4) the programme is accepted by participants and those delivering it and has low attrition; (5) the intervention can be adapted to meet local needs; (6) the complexity of the intervention does not inhibit its implementation; (7) design quality and packaging are appealing; and (8) costs, such as cost of manuals and related items, clinician training, and recruiting are reasonable.

For the Body Project, the most commonly reported barriers to including additional groups were limited time and high staff

turnover. For participants who do not respond to the prevention programmes, revisions such as increased intensity or creative adjustments are necessary.

The problems of recruitment, screening, implementing the intervention, and influencing the community culture have been addressed in the Healthy Body Image programme [59]. This programme targets intervention across socio-environmental levels that impact students' eating and activity patterns. It aims to improve body esteem and eating attitudes and behaviours and to change cultural norms around nutrition and body image for a healthier campus community.

Future directions

The changing demographics of eating disorders need to be continually monitored, so that all ethnic and socio-economic affected groups have access to adequate and financially feasible treatment programmes. Large population studies are needed to better ascertain the strength of the influence various moderating and mediating risk factors have on the development of eating disorders.

Specific risk factors that respond to specific treatment strategies need to be identified to create more effective preventative interventions. All interventions need to be assessed for adherence to the programme, attrition rate, and effectiveness over time.

Genetics of feeding and eating disorders

Christopher Hübel, Cynthia M. Bulik, and Gerome Breen

Introduction

Eating disorders are serious psychiatric illnesses that are associated with a broad range of somatic and psychiatric comorbidities, high disability-adjusted life years, and premature mortality [1–4]. The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) diagnostic category of feeding and eating disorders encompasses anorexia nervosa (AN), bulimia nervosa (BN), binge eating disorder (BED), avoidant and restrictive food intake disorder (ARFID), rumination disorder, pica, and other specified feeding and eating disorders (OSFED) [5]. Genetic research has primarily investigated AN, BN, and BED throughout the last 25 years, with very little research conducted into the remaining categories. This chapter therefore focuses on these three eating disorders.

Genetic methodologies

The aetiological understanding of eating disorders is closely linked to the understanding of complex disorder genetics, which has changed fundamentally in the last two decades. Genetic research has been divided into two major fields: quantitative and molecular genetics. In quantitative genetics, twin, adoption, and family studies are used to estimate the influence and relative contribution of genetic and environmental factors on human traits. Unlike family studies, twin and adoption studies have the advantage of being able to distinguish between shared and non-shared environmental factors, while generating an estimate of the total heritable contribution to risk for developing a disorder, called heritability. Shared environmental factors are those which siblings have in common, such as their shared family home (which increase sibling similarity), while non-shared environmental factors are those which they do not have in common, such as activities or sports in which only one sibling takes part (which decrease sibling similarity) [6].

Within this framework of an integrative model of genetic and environmental factors, every individual is assumed to have a certain genetic liability to developing an eating disorder. When individuals with a genetic liability that exceeds a threshold face common environmental pressures, this may induce symptoms. If the severity or duration of symptoms exceeds a defined clinical threshold, this individual may be diagnosed as mentally or physically ill [7]. Identifying

genetic and environmental risk factors could enable health care professionals to intervene at any possible stage of a disorder—before the onset, at the onset, during progression, and after remission—to guarantee the best possible prevention, diagnosis, and treatment. In practice, considerations of false positive rates mean that this is best done in high-risk populations, rather than the general population. However, the identification of genetic variants can also shed light on the underlying aetiopathology of a disorder; the identification and understanding of these biological changes may lead to the development of new medications. In molecular genetics, linkage, candidate gene, and genome-wide association studies (GWAS) have been conducted to detect genetic variants associated with some of the eating disorders. These methods differ in their underlying theoretical considerations and assumptions, particularly in how much of the genome they cover and the assumptions (or lack thereof) of what the underlying genetic architecture of a disorder is.

Linkage studies

Linkage studies are based on the ‘linkage’ (that is, the co-segregation of specific genetic regions with disorders in families), using a set of a few hundred to several thousand genetic markers and testing which appear to be inherited alongside a given trait or disorder. Co-segregation is tested in large family pedigrees or in many smaller pedigrees simultaneously. Linkage studies of eating disorders have yielded inconsistent results and have not been replicated. This may be due to a number of reasons, but fundamentally the evidence is that there are no genes with large effect size mutations in families with eating disorders that are detectable by linkage studies, which are unsuitable to detect genetic risk variants that have small effects. Linkage studies are thus currently out of favour.

Association studies

Association studies, such as candidate gene studies and GWAS, are an alternative method to investigate the genetic underpinnings of disorders by comparing frequencies of the different alleles of genetic markers between cases and healthy controls. Candidate gene studies were popular in the 1990s and 2000s and are hypothesis-driven studies that only included the analysis of one or a few genetic markers in single or several genes, with both the genes and genotyped markers selected mostly based on their biological function/impact. Single-nucleotide polymorphisms (SNPs) are used as genetic

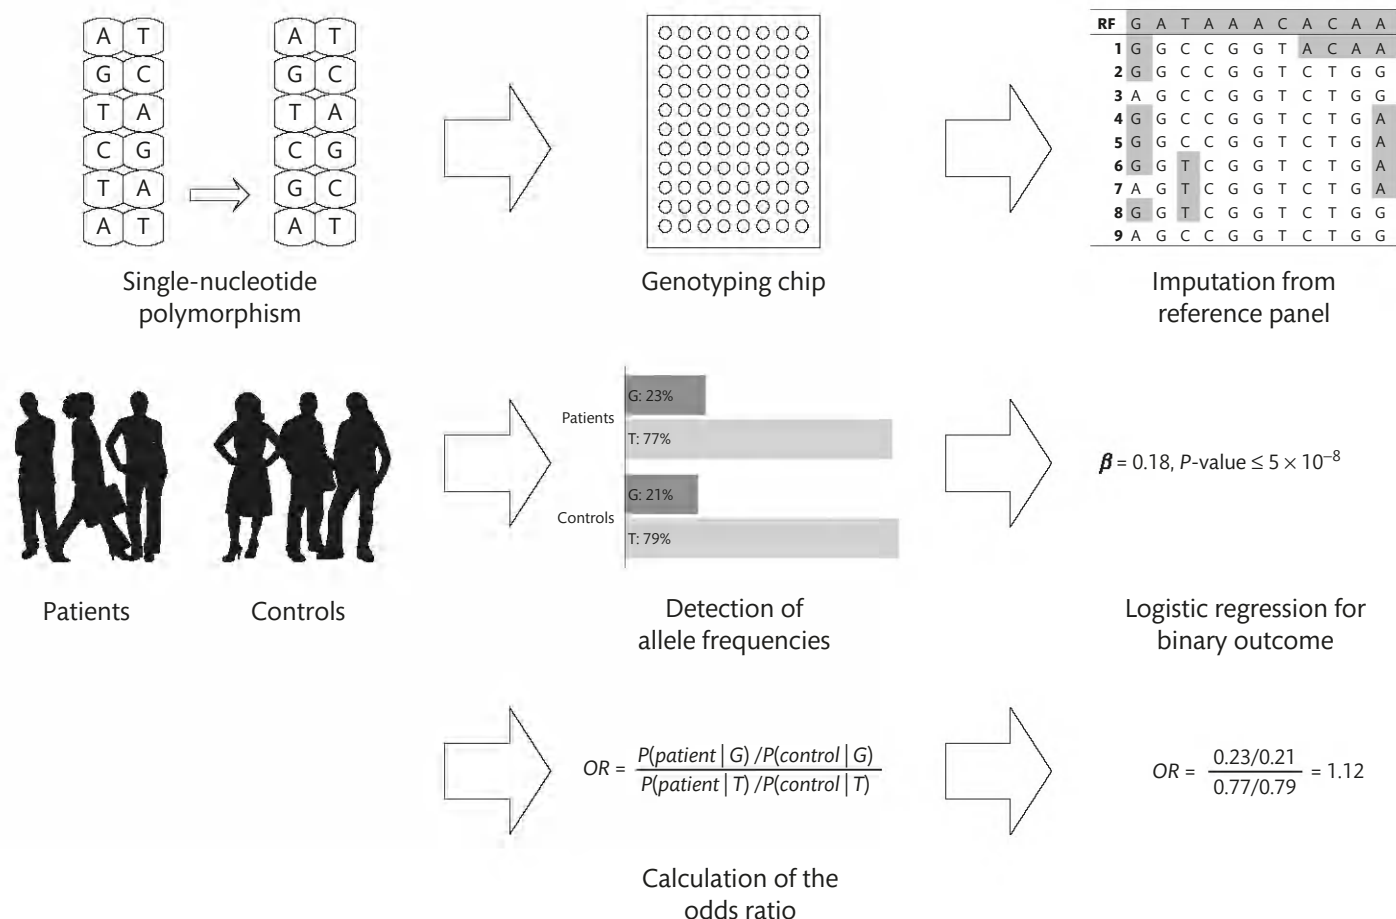

Fig. 104.1 Genome-wide association study. Single-nucleotide polymorphisms (SNPs) are used as genetic markers for specific genetic loci. Genotyping chips can assay up to several millions of these genetic markers, and coverage of the genome can then be increased through the statistical method of imputation. Imputation predicts genotypes at unassayed locations on the basis of reference panels of the human genome. After genotyping of patients and controls, allele frequencies are compared between them and a logistic regression is performed to calculate β (the standardized regression coefficient) and odds ratios (ORs). SNPs are defined as genome-wide significant if they reach a P -value of 5×10^{-8} , which is $P = 0.05$ corrected for all the tests done in a GWAS.

markers and are the most common variants in the human genome. They are characterized by the replacement of a single nucleotide with another. For example, the base cytosine might appear at a specific base location in the majority of the population but might be replaced with guanine in an individual. Variable numbers of tandem repeats (VNTRs) and microsatellites are regions of the genome with variable numbers of a particular sequence, with a repeating unit of between two and 50 or more bases. Candidate gene studies used these VNTRs, microsatellites, or SNPs to identify which variant of a gene (that is, allele) may be associated with a symptom of disordered eating or an eating disorder, but large-scale attempts at replication of these findings have not been successful and this approach has fallen out of favour in psychiatric genetics in general [8].

Genome-wide association studies

GWAS investigate the genetics of mental disorders using information from, and coverage of, the whole genome in a hypothesis-neutral manner (Fig. 104.1). Depending on the genotyping chip used, 500,000–1,000,000 SNPs are tested for association with a trait under study. In GWAS, SNPs are used because they are chemically easy to assay and a dense map of SNPs can ‘tag’ associations with a disorder

at genetic loci across the genome. GWAS are limited by the fact that they only detect chromosomal regions which can be multigenic and often do not clearly indicate the causal variants. Causal variants can be detected in further analyses such as fine mapping, exome sequencing, or whole-genome sequencing [9]. Fundamentally, GWAS are highly dependent on sample size, as shown by the results on schizophrenia [10] with, in general, >15,000 cases needed for multiple robust single genetic associations to be detected.

GWAS for eating disorders have not yet reached this sample size. However, smaller GWAS can still be used with methods such as linkage disequilibrium score regression, which uses summary statistics of GWAS to calculate the degree to which genetic variants are shared by two traits or disorders. The degree of common genetic variants shared between two traits or disorders is called a genetic correlation (r_g).

Genetic architecture of mental disorders

Despite clear evidence from twin studies that eating disorders are substantially heritable, their complex genetic architecture (alongside

Fig. 104.2 Heritability estimates of eating disorders derived from twin studies. Heritability estimates are expressed in percentages. Genetics (white), shared environment (striped), and non-shared (black) environment normally add up to 100%. Each bar represents one study.

a poor understanding of their neurobiology) has stymied both linkage and candidate gene studies. A large body of evidence collected over the past decade suggests that the genetic risk for psychiatric and other complex disorders is—in large part—accounted for by thousands of different genetic variations with small effect sizes [11]. For instance, GWAS on schizophrenia emphasize that this highly heritable disorder is highly polygenic, consistent with the picture in bipolar disorder and major depressive disorder (MDD) [10]. The GWAS approach also affords better estimation and control of type I errors, allowing accurate estimation of individual DNA sample quality, as well as fine-scale adjustment for ancestry differences in case-control studies—both of which can generate spurious associations and which have been considerable problems in candidate gene studies.

A complete review of a largely unsuccessful decade or more of candidate gene and linkage studies on eating disorders can be accessed elsewhere [12–15]. Our chapter focuses on the period of modern genomic approaches and the genetic overlap across the various eating disorders, as well as with common comorbid conditions. We start with the emergence of the first GWAS of AN and the formation of the Eating Disorders Working Group of the Psychiatric Genomics Consortium (PGC-ED) in 2013. We now review the quantitative and molecular (GWAS) genetic findings for AN, BN, and BED, contrasting these findings with GWAS results in food addiction, obesity, and BMI.

Anorexia nervosa

Family studies of anorexia nervosa

Anorexia nervosa runs in families, although sporadic cases also do occur. First-degree relatives of affected individuals are 11 times more likely to develop AN than relatives of unaffected individuals [16]. Reflecting the considerable diagnostic crossover seen during the course of eating disorders, relatives of individuals with AN are

also at increased risk for a range of eating disorders, including full and partial AN syndromes, as well as OSFED [16, 17].

Twin studies of anorexia nervosa

A series of twin studies in European ancestry populations have suggested a fairly wide range of heritability point estimates (Fig. 104.2); the heritability of varying definitions of AN ranges from 0.28 to 0.74. Apart from genetic influence, twin studies report a significant contribution of non-shared environmental factors of 24–68%, but strikingly negligible influence of the shared environment [18–20]. As is the case with other psychiatric disorders, definitions of AN that meet the full syndrome diagnostic criteria are associated with higher heritability estimates than more loosely defined phenotypes [21]. Twin studies have also addressed the considerable diagnostic flux across eating disorder presentations, revealing that the common transition from AN to BN (and less commonly vice versa) may be due to shared genetic factors, with twin-based genetic correlations of between 0.46 and 0.79 being reported [22].

Twin studies and comorbidity

AN is commonly comorbid in both clinical and epidemiological samples with major depression, anxiety disorders, and obsessive-compulsive disorder (OCD) [23]. Twin studies suggest that these comorbid profiles may be, at least in part, due to shared genetic factors. Bivariate twin studies of AN have revealed genetic correlations of 0.34, 0.20, and 0.52 with major depression [24], generalized anxiety disorder [21], and OCD [25], respectively. They also showed a genetic overlap between AN and suicidality [26]. The genetic overlap between AN, MDD, and suicide attempts was robustly replicated [27]. OCD is the psychiatric disorder with the strongest genetic overlap with AN.

Developmental twin studies

Although no twin studies have been adequately powered to explore changes in heritability estimates for AN across development, this has

been examined in related phenotypes. In girls, the genetic effects on eating disorder symptoms increase with age [28]. Whereas environmental factors are the primary contributors to variance in eating disorder phenotypes during pre-adolescence, the cumulative additive genetic contributions significantly increase across adolescence and remain constant through mid life. Work by Klump [28] implicates puberty and its hormonal changes (with consequent frontal temporal and other maturation of the brain), rather than a direct effect of age in this transition.

Modern genomic approaches to anorexia nervosa

Genome-wide association studies

The first GWAS for AN was conducted by the Children's Hospital of Philadelphia (CHOP) and the Price Foundation Collaborative Group [29]. The analysis included 1033 AN cases and 3733 paediatric controls. Given the small sample size and as predicted by experience in other psychiatric disorders, no SNPs reached genome-wide significance ($P \leq 5 \times 10^{-8}$). Also complicating the design was the fact that the control group had not yet passed through the age of risk for developing AN (mean = 12.75 years; standard deviation = 4.2 years) and so were effectively unscreened for eating disorders and other genetically related psychiatric problems, resulting in a decrease in statistical power to detect association.

The second AN GWAS was performed by the Genetic Consortium for Anorexia Nervosa (GCAN) as part of the Wellcome Trust Case-Control Consortium 3 (WTCCC3). This GWAS included 2907 AN cases of European ancestry and 14,860 ancestry-matched female controls. Although this was a larger study, it is still a modest sample size for GWAS and no genome-wide significant loci were detected, although when 72 independent markers with the lowest P values were selected for replication, sign tests revealed that a highly significant 76% of these markers yielded results in the same direction in the discovery and replication samples [30]. These tests encouraged the field to continue GWAS efforts, as it suggested that the significant signal did exist in the data, but larger samples were required for detection. The controls selected for this GWAS were also not ideal as, although they were selected to be ancestrally compatible, they had been genotyped on similar (but not identical) platforms and at different times and in different laboratories (Fig. 104.3).

In an effort to unite research groups and consolidate findings, the PGC-ED was established in 2013. The first analysis of the combined CHOP and WTCCC3 data sets emerged in 2016 and has reported the first genome-wide significant locus for AN [31]. The GWAS comprised 3495 cases and 10,982 controls and now has been imputed to phase 3 of the 1000 Genomes Project to enable association statistics at millions of ungenotyped variants to be calculated [32]. A subsequent larger GWAS comprising 16,992 cases and 55,525 controls yielded eight significant loci and a pattern of genetic correlations implicating both psychiatric and metabolic origins of AN [33]. As has been seen in other mental disorders and the rest of common disorder medicine, it is reasonable to expect that the addition of samples will lead to further loci being identified, with an accelerated trajectory of significant loci.

Low-frequency and rare variants

A GWAS focuses on common genetic variants, which occur in >1% of the population. By definition, rare variants are present in <1% of the population. During the past 3 years, some studies were performed on rare variants in the aetiology of AN. A series of sequencing and genotyping studies by Scott-Van Zeeland *et al.* [34]

Fig. 104.3 Expected number of cases for anorexia nervosa GWAS. Through the joint international endeavours of the Psychiatric Genetic Consortium of Eating Disorders (PGD-ED), the depicted numbers of cases are expected to have GWAS data over the new few years. The increase in cases is accompanied by a considerable increase in power, for what other disorders have suggested as plausible effect size of GWAS risk variants. The power calculation assumes an OR of 1.1 and an allele frequency of 20%.

on cases from the CHOP/Price Foundation cohort focused on the coding regions and upstream sequence of 152 candidate genes in 1205 AN cases and 1948 controls. They reported associations with variants in the oestrogen receptor β (*ESR2*) and the epoxide hydrolase 2 (*EPHX2*) genes in AN, identified via targeted gene sequencing. Case-control allele frequency differences for variants in these two genes were also observed in the CHOP/Price Foundation GWAS data set [29]. Somewhat paradoxically, hypercholesterolaemia has been reported in a subset of individuals with AN [35, 36], rendering *EPHX2* an intriguing find, as it has been implicated in cholesterol metabolism [37].

Subsequently, Cui *et al.* conducted a high-throughput sequencing study with two families who were densely affected for AN and BN [38]. They initially conducted a linkage analysis on the first pedigree (20 individuals) and identified a region on chromosome 11 from 44.1 to 64.3 cM with a significant logarithm of odds score. They then conducted whole-genome sequencing on two family members who were affected with AN and detected a missense mutation in the oestrogen-related receptor α (*ESRRA*). This pedigree was also enriched for OCD. In the second pedigree, enriched for both AN and BN cases, exome sequencing identified a rare mutation in histone deacetylase 4 (*HDAC4*). HeLa cell and mouse cortical tissue analyses demonstrated a potentially functional interaction between *ESRRA* and *HDAC4*, and using transcriptional activity assays, it was reported that *HDAC4* may act as an inhibitor of *ESRRA* activity. Given the central role of histone deacetylases in the activation and repression of gene expression genome-wide, this interaction might not be unexpected.

In order to rule in or out more common rare and functional variation in AN, an exome-array rare variant GWAS was performed in 2158 cases from nine populations of European origin and 15,327 ancestrally matched controls [39]. Cases and controls were identified from those gathered for the GCAN/WTCCC3 cohort. Sixteen independent variants were selected for *in silico* and *de novo* replication (12 common, four rare). No findings reached genome-wide significance. The authors instead highlighted two common

variants—rs10791286, an intronic variant in *OPCML* ($P = 9.89 \times 10^{-6}$); and rs7700147, an intergenic variant located near *ANKRD50* ($P = 2.93 \times 10^{-5}$), reaching near suggestive significance.

Copy number variation

Copy number variations (CNVs) are 1kb DNA segments, or larger, occurring in an altered quantity, compared with a reference genome. The most common CNVs are duplications and deletions. A genome-wide analysis of CNVs was also conducted on the CHOP/Price Foundation cohort [29]. No evidence emerged supporting enrichment of AN cases for CNVs above controls, and rare or large CNVs were not notably overrepresented in AN cases. Although a recurrent 13q12 deletion (1.5Mb) disrupting the saccin molecular chaperone *SACS* was seen twice in cases and CNVs disrupting the contactin 6/contactin 4 (*CNTN6/CNTN4*) region was found in multiple cases, these observations were not statistically significant. Yilmaz *et al.* [40] conducted a case-only genome-wide CNV survey in 1983 female AN cases that were part of the GCAN/WTCCC3 AN GWAS. Their case-only approach explored whether pathogenic CNVs implicated in other psychiatric and neurodevelopmental disorders were also observed in AN cases. Four of these well-established pathogenic CNVs (deletions or duplications in 1q21.1, 7q36.3, 15q13.3, or 16p11.2) were found in a small number of AN cases. One case also had a large deletion in the 13q12 region [29], and 41 cases had deletions or duplications which were 1 Mb or larger. However, at this point, it is not clear whether large-effect CNVs play a demonstrable role in AN. Larger sample sizes are required before the effect of smaller-effect CNVs can be ruled out.

Genetic correlations with psychiatric phenotypes

A genetic correlation is an estimate of the genetic overlap between two traits. An analytic extension of linkage disequilibrium score regression [41] enables computation of cross-trait genetic correlations, and intriguing insights for AN have emerged. Bulik-Sullivan *et al.* [42] revealed a significant positive genetic correlation between AN and schizophrenia ($r_g = 0.26$), with positive, but non-significant, correlations with major depression and bipolar disorder. A second analysis replicated the positive correlation with schizophrenia ($r_g = 0.15$) and revealed a strong positive genetic correlation between AN and OCD ($r_g = 0.55$) [33, 43]. The high genetic correlation between AN and OCD parallels twin-based genetic correlations ($r_a = 0.52$) and reflects common comorbidity profiles seen clinically in AN [25, 44, 45]. The positive correlation with schizophrenia is less readily explicable, as this is not a commonly observed clinical comorbidity profile, but it should be noted that OCD also has a strong genetic correlation with schizophrenia and so could be mediating the observed correlation. However, comorbidity with schizophrenia has been documented in individuals with AN, although it has not been extensively explored [46]. The positive genetic correlation with schizophrenia thus does raise an intriguing question about whether some of the more perplexing features of AN, such as a distorted body image, as well as overvalued ideation about food and weight, may have a psychotic component.

Genetic correlations with metabolic phenotypes

Additional intriguing genetic correlations emerged between AN and an array of anthropometric and metabolic phenotypes.

Bulik-Sullivan *et al.* first reported a significant negative correlation between AN and obesity ($r_g = -0.20$) and BMI ($r_g = -.18$), suggesting that the same genes may influence extreme dysregulation of body mass in both directions. Other genetic correlations between AN and metabolic measures were with high-density lipoprotein cholesterol, fasting insulin, fasting glucose, and type 2 diabetes. Furthermore, AN was genetically correlated with physical activity [33].

Bulimia nervosa

Family studies of bulimia nervosa

BN has been shown to be familial and genetically overlaps with AN; individuals with relatives who suffer from either disorder are also more likely to develop either AN or BN [16, 17]. However, relatives of cases suffering from the restrictive anorexia subtype do not show an increased liability to develop BN [47], suggesting that the overlap between the restricting type of AN and BN is, at most, modest [12].

Twin studies of bulimia nervosa

The twin-based heritability for BN ranges between 0.55 and 0.62 [20, 22, 48, 49], suggesting that about 60% of the variance in liability can be explained by genetics (Fig. 104.2). The diagnosis of BN is somewhat unreliable in population-based samples but can be improved by including behavioural components of BN such as self-induced vomiting [50]. A twin study on specific BN symptoms showed that BN core symptoms are differentially heritable, such that specific symptoms, such as vomiting, are more heritable than, for example, the influence of weight on self-evaluation [51]. The genetic correlation reported by twin studies between the two key components of BN—binge eating and vomiting—is high, but not absolute ($r_g = 0.74$), and self-induced vomiting exhibited higher heritability of 72% vs 46% reported for binge eating alone [52]. Various twin studies have conclusively demonstrated that most of the variance in risk for BN can be explained by additive genetic effects [20, 22, 48, 49, 51]. One twin study confirmed the findings of family studies and reported the genetic correlation between AN and BN to be 0.79 [22]. This strong genetic correlation suggests that considerable overlap in the underlying biology of the two disorders may contribute to the observed diagnostic flux [12].

Twin studies and comorbidity

BN occurs with concurrent mental illnesses. Bivariate twin studies of BN revealed a genetic overlap with major depression [53], phobia, panic disorder [54], and substance use disorder [55]. BN patients are at increased risk of suicide, which is partly influenced by common genetics [26].

Modern genomic approaches to bulimia nervosa

Genome-wide association studies

Although there has been no genome-wide study testing BN per se, one major GWAS on eating behaviours investigated the bulimia subscale of the Eating Disorder Inventory-2. The study tested six eating-related traits, including drive for thinness, body dissatisfaction, bulimia, weight fluctuation symptoms, breakfast-skipping behaviour, and childhood obsessive-compulsive personality

disorder traits. Furthermore, an arbitrary cut-off for case/control status determination of the bulimia scale was used, and unfortunately this was a case definition which does not fully satisfy ICD-10 or DSM-IV diagnostic criteria. The study design utilized one discovery sample and two replication samples. The study tested samples that were relatively small (approximately 2500–3000) for a GWAS, with no genetic marker reaching genome-wide significance. However, the effect sizes in the discovery sample and the replication samples were significantly in the same direction. In this study, the strongest (although non-significant) association with the bulimia scale was intergenic, lying between the cyclin L1 (*CCNL1*) and the leucine glutamate, leucine-rich 1 (*LEKRI*) genes which had previously shown multiple associations with fetal growth, birth-weight, elevated insulin release, and breast cancer [56]. Effect sizes in the discovery and replication samples are concordant. GWAS of other psychiatric disorders have resulted in significant findings as sample sizes have increased. Together, these strongly suggest that increasing the sample size will enable eating disorder GWASs to reach sufficient statistical power in future.

Binge eating disorder

Genetic research on BED is in its infancy in part due to the fact that it only became an independent diagnosis in DSM-5 in 2013. Current research focuses on neurotransmitter systems, such as dopamine and endogenous opioids, which may underlie the human central nervous reward system. Changes in the reward system are associated with addictive behaviour.

Family studies of binge eating disorder

BED aggregates in families with a heritability of 57% [57]. Family studies [58] also showed a genetic overlap between obesity and BED. These results were replicated in additional twin studies.

Twin studies of binge eating disorder

Twin studies of both the disorder and its cardinal symptom—binge eating—revealed consistently moderate to strong heritabilities of between 33% and 69% [57, 59–61].

Twin studies and comorbidities

BED is associated with obesity and the metabolic syndrome [62]. Twin studies revealed that both obesity and BED are influenced by partly shared and partly different genetic factors [63]. The direction of causality between obesity and BED is not fully elucidated and must be further investigated. Furthermore, BED exhibits a significant genetic overlap with substance use disorder [64]. Similar to the observation about other eating disorders, BED has also a significant genetic overlap with suicidality [26].

All of these observations have emerged from quantitative genetic studies, as limited molecular genetic findings and no genome-wide findings for BED exist.

Modern genomic approaches to binge eating disorder

Genome-wide association studies

A GWAS on BED per se has not yet been conducted. However, the phenotypic overlap with obesity and parallel studies of phenotypes, such as food addiction, are relevant.

Food preference patterns and food addiction

Neuroimaging studies reported altered dopamine signalling in the fronto-striatal neuronal circuitry involved in reward and self-regulatory processes [65]. From an evolutionary biology perspective, supported by epidemiological and neuroscientific evidence, certain foods, such as processed foods high in sugar, fat, and salt, may have an addictive potential similar to psychoactive substances such as cocaine or alcohol [66, 67]. This provides the foundation for the so-called construct of ‘food addiction’, which is assessed by self-report using the Yale Food Addiction Scale (YFAS), based on the DSM-IV diagnostic criteria for substance use disorders. Food addiction is separate from BED but is an overlapping construct that has evolved from different clinical and research areas. Genetic findings for food addiction must also be interpreted cautiously because most results are inferred from small sample sizes [68].

Food addiction is highly prevalent in patients suffering from BED [69]. A 2013 study investigated food addiction in individuals with BED. Two subgroups of BED patients with or without food addiction were equivalent in age and BMI, but BED patients also suffering from food addiction reported higher rates of emotional eating and rated themselves more responsive to rewarding food types [70].

Twin studies of food preference patterns

Twin studies on the consumption of sugar through drinks (48%) [71], liking for sweet solutions (49%), liking for sweet foods (54%), use frequency of sweet foods (53%) [72], and food preference patterns (36–58%) [73] showed that these traits are moderately heritable.

Twin studies and comorbidities

One twin study showed that the association between high sugar consumption and substance use disorder is 59% genetically driven. These findings underpin the hypothesis that food addiction may be an independent entity.

Modern genomic approaches to food addiction

Genome-wide association studies

A quantitative trait GWAS on the modified form of the YFAS was performed by Cornelis *et al.* [74] in 9314 women and identified genetic loci associated with food addiction but produced limited evidence for shared genetics with substance use disorder. Two genome-wide significant hits close to protein kinase C α (*PRKCA*) and neurotrimin (*NTM*) were discovered. *PRKCA* is involved in insulin signalling, inflammation, and the mitogen-activated protein kinase (MAPK) pathway. Neurotrimin was associated with opioid binding protein/cell adhesion molecule-like (*OPCML*). *OPCML* was also associated with alcohol dependence and body fat distribution [74]. However, these results require replication.

Body mass index, obesity, and body fat genetics in relation to eating disorders

Obesity has been considered as a potential behavioural disorder, and the nature of the relation of eating disorders with BMI (body weight) and body fat is of considerable scientific and medical interest. Obesity, BMI, and body fat percentage are highly heritable, polygenic, and multifactorial human traits. Body weight is influenced

by a complex interplay of genetic, environmental, and psychosocial factors. These three factors affect energy intake and energy consumption mediated by the central nervous and metabolic systems in humans [75]. BMI is commonly used as a proxy measure for both weight and body fat. However, its application has been widely criticized in healthy individuals, as well as in eating disorder patients [76, 77].

Family and adoption studies of body mass index

Family studies generally report heritability for BMI ranging from 20% to 80%, with the observed heritability increasing with age. Data from adoption studies replicated these findings, with genetic factors accounting for 20–60% of the variation in BMI. Adoption studies showed no association between the BMI of adoptees and their adoptive parents, whereas the adoptee's BMI was associated with the biological parents' BMI [78].

Twin studies of body mass index and body fat

Twin studies

The (adult) twin-based heritability of BMI ranges between 59% and 64% [79, 80], with heritability estimates of about 70% for twins who were reared apart, affirming the high genetic influence [81]. Twin studies also estimated high heritability for body fat and its distribution. The heritability for total body fat is about 86%, for trunk fat about 82%, and for lower body fat about 83% [82, 83]. Parental overweight and adiposity are established risk factors for childhood obesity that are mainly genetically determined [84].

Developmental twin studies

An extensive developmental twin study performed by Silventoinen *et al.* [85] shed new light on the influence of age, sex, and socio-economic background on BMI. The heritability of BMI increases from 41% after the age of 5 to 78% at the age of 19 and remains stable for the rest of the lifespan. Despite the increasing heritability, the variance of BMI also increases after the age of 5. Two possible explanations are hypothesized—either children may be able to choose their food more independently after the age of 5 or neuronal pathways involved in appetite regulation may be influenced by age-dependent gene expression. Furthermore, sex differences in BMI and its heritability are a well-known phenomenon and were replicated, which means that different genes have differential effects in both sexes. Different sets of genes seem to influence BMI before and after puberty which may be influenced by hormonal changes.

North America and Australia showed regional differences in BMI, compared with Europe and East Asia, having a higher mean and a greater variance. Including poorer socio-economic regions into the heritability analysis of BMI led to lower heritability estimates, with an increasing influence of shared environmental factors [85]. This observation may be explained by a restricted presentation of the phenotype due to limited food resources in poorer areas.

Modern genomic approaches to weight and body fat

Genome-wide association studies

GWAS on human obesity detected 227 independent genetic variants that are associated with BMI. These 227 SNPs were narrowed down to 97 genetic loci. These genetic loci are enriched in various biological pathways such as central nervous and peripheral appetite

regulation, adipocyte differentiation, insulin and leptin signalling, lipid metabolism, and gut microbiota. In total, common SNPs are estimated to explain about 27–30% of the phenotypic variance of BMI [86], but the identified genome-wide significant obesity SNPs only explain about approximately 3% of this variance, indicating that this is a highly polygenic trait [87]. Only two of the 97 genetic loci showed sex differences, with stronger effects in women being observed in each case.

GWAS of body fat distribution investigating the waist-to-hip ratio found 49 significant genomic loci [88, 89]. The waist-to-hip ratio was adjusted for the effect of BMI, to avoid detection of genomic loci having an effect on BMI. With 19 of the 49 loci showing a larger effect size in women, compared with men, considerable genetic sex dimorphism was uncovered. A GWAS conducted on body fat percentage revealed 12 genetic loci that were genome-wide significant. Seven of the loci showed a larger effect on body fat percentage, compared with BMI, whereas the rest showed a larger effect on BMI, suggesting an association with both fat and fat-free mass [90].

Genetic correlations with eating disorders

As discussed earlier, Bulik-Sullivan *et al.* [41] achieved a major breakthrough when they developed the method of linkage disequilibrium score regression to calculate genetic correlations between different traits. They reported a significant negative correlation between AN and obesity ($r_g = -0.20$) and BMI ($r_g = -.18$), suggesting that shared genetic variants between AN and body fat may influence body mass in opposite directions. This negative genetic correlation paved the way for a more detailed exploration of AN as both a metabolic and a psychiatric disorder.

Comparing results from two genome-wide meta-analyses of AN and BMI, Hinney *et al.* [91] identified three independent genomic loci that were associated with both AN and a lower BMI. These three independent loci were marked by nine different SNPs. The analysis was stratified by sex and showed that the associated SNPs showed a sex-specific effect, such that the SNPs were more strongly associated with BMI in females, compared with males. The association with the region on chromosome 10 was mainly due to females. The four genes located closest to the chromosomal loci are involved in brown adipose tissue function and regulation, preadipocyte proliferation, and *BDNF* expression.

Conclusions

A large body of evidence shows unequivocally that eating disorders are influenced by genetics. However, these findings must be interpreted cautiously. Firstly, although genetics play a significant role in the aetiology of eating disorders, it is important to bear in mind that the development of an eating disorder is also substantially influenced by environmental factors. Secondly, genetics is a highly complex, quickly developing area of research that is often difficult to comprehend and is even more so for patients and the public. Finally, it is important to communicate results correctly and in an understandable manner. It should be explained that genetics underlying eating disorders are neither deterministic nor a genetic defect and that there is no evidence that one single gene causes any of the common eating disorders.

Large numbers of eating disorder patients need to be studied more systematically to redefine the phenotypes of eating disorders. This so-called 'deep phenotyping' as part of 'phenomics' allows us to clarify diagnoses. More specific diagnoses incorporating various quantitative measures might subsequently increase the power to detect genetic variants and environmental risk factors. Increasing the sample size is a further approach to increase statistical power. Both strategies are currently being utilized by the PGC-ED on an international level. This gives hope to identify more genetic variants, environmental risk factors, and critical developmental stages involved in the aetiology of eating disorders. These identified risk factors and critical periods may ultimately be translated into more effective preventive and curative measures, but this goal can only be reached by joint efforts and expertise of clinicians, epidemiologists, neuroscientists, and geneticists.

Imaging of feeding and eating disorders

Natalie Kurniadi, Christina E. Wierenga, Laura A. Berner, and Walter H. Kaye

Introduction

Neuroimaging has helped refocus thinking about the aetiology and formulation of the pathophysiology of eating disorders (EDs) in the past few decades [1]. Cultural pressures to be thin were once theorized to underlie or perpetuate anorexia nervosa (AN) and bulimia nervosa (BN) almost exclusively. It is now recognized that a biological basis exists for these disorders, and neuroimaging studies provide evidence that the behavioural symptoms of EDs are associated with altered brain function and structure [2]. New insights regarding the brain pathways involved in the processing of general and taste reward, cognitive inhibition, and interoception are of particular importance. This chapter will focus primarily on functional alterations in AN, BN, and binge eating disorder (BED). The feeding disorders, including pica, avoidant restrictive food intake disorder (ARFID), and rumination disorder, will also be briefly discussed.

EDs are severe psychiatric diseases with significant physical and mental health complications. EDs occur more commonly among females than males, with the typical age of onset during early adolescence [3]. AN has the highest mortality rate of all mental illnesses and is characterized by restriction of energy intake, leading to significantly low body weight, intense fear of gaining weight, and a marked disturbance in the experience of one's weight and shape [4]. Individuals suffering from the restricting subtype of AN (AN-R) limit their caloric intake and sometimes also over-exercise, whereas those with the binge eating/purging type eat large amounts of food in a short period of time, accompanied by a sense of loss of control, and/or engage in compensatory behaviours (that is, self-induced vomiting and use of laxatives or diet pills) to prevent weight gain [4]. BN is characterized by average or above average body weight and regular binge eating and compensatory behaviours. The binge eating episodes of individuals with BN tend to include sweet, high-fat foods, and dietary restriction between binge eating episodes is common [5]. Finally, BED is associated with an increased risk of obesity and is characterized by recurrent episodes of binge eating without compensatory behaviours and marked distress about binge eating [4]. Across diagnoses, EDs are difficult to treat and have a high rate of relapse [6].

A consistent body of evidence suggests that structural and functional alterations in circuitry involved in taste and reward processing, inhibitory control, and interoception may underlie eating

disorder pathology [7–12]. As such, this chapter will detail these neural circuits and associated findings in EDs. Directions for future research to better understand the aetiology of these complex disorders and implications for treatment will also be discussed.

Structural imaging

Growing evidence suggests structural brain abnormalities among eating-disordered individuals, with the majority of research focusing on differences in brain volume. Among participants with AN, the most pronounced differences are observed during the acute stages of illness [13]. A systematic review of structural MRI studies reveals significantly lower grey matter (GM) volume and greater cerebrospinal fluid (CSF) volume among ill AN patients, relative to controls [14]. Lower GM volume was found in areas including the dorsal and rostral anterior cingulate cortex (ACC), right frontal operculum, left cerebellum, and right insula. While one study shows lower global GM volume among individuals remitted from anorexia nervosa (RAN), relative to controls, another reveals no differences in GM, white matter (WM), or CSF volume between the two groups [14]. No differences were found in WM volume between acute AN, RAN, and age-matched healthy controls (HC) [15]. Longitudinal research in AN suggests that GM volumetric differences normalize upon recovery [14], suggesting state-specific findings are likely due to malnutrition.

Inconsistent findings are also seen among patients with BN, with one study finding no differences in GM, WM, or CSF volume, compared to healthy participants [14]. However, another reveals that those with BN show greater GM volume than HC in the medial orbitofrontal cortex (OFC) and striatum. Although not significant, individuals remitted from bulimia nervosa (RBN) showed larger GM volume in the insula, relative to HC [14]. Finally, individuals with BED showed increased GM volume of the ACC and medial OFC, relative to controls [14]. Alterations in structural volume among individuals with EDs may be related to the extreme eating patterns observed among these participants.

Structural connectivity

Only one study has examined structural connectivity among individuals with EDs. Diffusion-weighted MRI revealed that individuals

with RAN showed abnormal structural connectivity in regions involving frontal, basal ganglia, and posterior cingulate nodes [16], relative to HC. RAN individuals exhibited longer normalized mean path lengths in the right caudal anterior cingulate and right posterior cingulate, which correlated to poor insight. Such findings in neural systems involved in habit formation and reward may underlie the establishment and maintenance of compulsive behaviours characteristic of AN [16].

Functional imaging

Several studies have utilized resting-state functional magnetic resonance imaging (rsfMRI), a method that allows for making temporal correlations between brain areas using task-independent changes of blood oxygen level-dependent (BOLD) signals [17] to examine functional connectivity in EDs. A review of rsfMRI studies in AN suggests differences in functional connectivity between AN and HC in the dorsal ACC (dACC), thalamus, and right inferior frontal gyrus (IFG) [18]. AN exhibit decreased connectivity between the sensory-motor and visual networks, relative to HC [19]. Additionally, acute AN show decreased connectivity in the thalamo-insular subnetwork, relative to HC, reflecting alterations in neural systems involved in pain, body size perception, and hunger [20]. Increased functional connectivity in the default mode network (DMN), a region involved in introspective rumination, low-level arousal, and self-regulation [21], was found in AN, relative to HC [22]. Compared to HC, RAN subjects showed alterations in the DMN [23] and stronger functional connectivity between the dorsolateral prefrontal cortex (DLPFC) and medial OFC (mOFC) during a monetary incentive delay task [24]. The latter findings indicate greater cognitive control relative to motivationally salient cues among RAN. However, another study showed no differences, compared to controls [25]. Discrepant findings may be due to methodological differences, including participant characteristics and resting-state approaches [18].

Studies comparing AN, BN, and HC showed that AN individuals demonstrated stronger synchronous activity between the dACC and the retrosplenial cortex, while those with BN showed stronger synchronous activity between the dACC and the mOFC [26], relative to HC. AN and BN individuals showed stronger activity between the dACC and the precuneus, correlating to higher rates of concern with body shape on the Body Shape Questionnaire [26]. These findings indicate that greater synchrony between such regions may be associated with preoccupation with eating and body shape among individuals with EDs. Alternatively, one study using functional magnetic resonance imaging (fMRI), voxel-mirrored homotopic connectivity (VMHC), and regional interhemispheric spectral coherence (IHSC) revealed significantly reduced interhemispheric functional connectivity in patients with acute AN and BN, compared to HC [27]. Specifically, lower interhemispheric functional connectivity was shown in the precuneus, cerebellum, and posterior insula among AN patients vs HC, and in the frontal lobe of BN patients, compared to HC. Interhemispheric functional connectivity was higher in the Slow-5 band, a frequency range in which the majority of GM oscillations primarily occur [28], in all regions except the insula. There were no group differences in left-right structural asymmetries or in WM or GM volume. Functional connectivity anomalies, despite the

absence of structural differences between groups, indicate that the acute phase of EDs are associated with decreased interhemispheric connectivity in regions involved in cognitive control and reward processing [27].

General reward processing in eating disorders

Neuroimaging evidence supports a role for altered reward processing in the development and maintenance of EDs [29]. Briefly, ventral limbic neural circuitry, which includes the amygdala, rostral ACC, ventromedial prefrontal cortex (vmPFC), and anterior ventral striatum, is involved in identifying and processing rewarding or emotionally significant information and in generating affective responses to this information [30]. Through a series of non-reciprocal connections, dopamine (DA)-mediated reward and motor information travels via the limbic circuit to executive and sensorimotor areas of the striatum [31]. Together with cognitive control and sensorimotor circuits, these circuits code the rewarding value of food and non-food stimuli and evaluate and integrate reward predictions to guide behaviours [32]. The majority of research on illness-specific reward processing in EDs is based on studies examining responses to food and taste stimuli, though some studies have also examined general reward processing (for example, money) to avoid potentially eliciting symptoms caused by disorder-specific stimuli. Determining whether alterations in reward processing are specific to food or whether they generalize to secondary reinforcers (for example, money) can help elucidate neural mechanisms underlying ED pathology and identify shared and unique alterations across ED and non-ED psychiatric conditions.

Anorexia nervosa

Individuals with AN often display anhedonia and find little pleasure outside of the pursuit of weight loss [33]. They also tend to show an enhanced capacity to delay reward, relative to their healthy peers, though only when ill [34]. Many of these characteristics typically persist to some degree following remission [35], suggesting trait-, rather than state-, related symptoms of eating disorders [36]. Individuals ill with, and remitted from, AN (RAN) show altered DA function [37] and altered brain response, particularly in striatal circuits [1, 36, 38], suggestive of abnormal reward processing. Moreover, increased DA release in the precommissural dorsal caudate has been associated with increased anxiety in RAN [39]. Since ingestion of palatable foods is associated with an increase in striatal DA [40], food restriction is thought to be an effective means of reducing the stressful experience of endogenous DA release among individuals with AN [7].

In one study, RAN adults failed to show a difference in ventral striatal response to monetary gains vs losses, suggesting an insensitivity to the distinction between positive and negative feedback that may contribute to anhedonia, difficulty with making decisions, and decreased food intake [8]. Adolescents with AN also show exaggerated neural responsivity to punishment, relative to controls, suggesting an altered ability to code for both the value and valence of potential outcomes [9]. Moreover, in contrast to healthy control women, who exhibit a greater reward response when hungry, the reward response in RAN participants does not differ significantly between hunger and satiety during a delay discounting task, suggesting reduced sensitivity to the motivational drive of metabolic state when

determining the value of rewarding stimuli in AN [41]. Findings from this study suggest that hunger does not increase reward among RAN and that such individuals fail to integrate the physiological state and reward motivation into decision-making [41]. Reduced capacity to experience reward is thought to serve as a mechanism to ignore hunger and engage in prolonged periods of fasting, even in the face of physical starvation [41].

Bulimia nervosa

Individuals who engage in binge eating and purging behaviours are typically oversensitive to reward and often engage in sensation-seeking behaviours [35]. Alterations in reward circuitry are seen in individuals with BN. For example, reduced CSF concentrations of the DA metabolite homovanillic acid (HVA) are associated with increased frequency of binge eating behaviours among individuals ill with BN [42]. Positron emission tomography (PET) studies reveal a trend towards decreased D2/D3 receptor binding potential in the posterior putamen and caudate in ill BN participants, with an inverse association between binge eating and vomiting frequencies and striatal DA response [43]. Interestingly, individuals remitted from BN (RBN) and participants with the binge eating/purging subtype of AN have normal DA D2/D3 receptor binding and CSF HVA levels [39]. Similar to RAN women, RBN women also fail to differentiate between wins and losses in ventral-striatal regions during a monetary choice task, suggesting an inability to differentiate between positive and negative feedback [11]. These findings may indicate elevated sensitivity to both reward and punishment among BN individuals, even after recovery [44].

Binge eating disorder

Altered reward processing also has been observed among individuals with BED. Following treatment, obese individuals with BED, relative to obese individuals without BED, demonstrated diminished activation in reward circuitry during both the anticipation of rewards and actual reward processing [45]. Individuals with the greatest hypoactivation activation during reward processing engaged in more frequent binge eating [45]. In sum, research suggests that across ED diagnoses, altered reward processing, which may not be specific to food reward, likely contributes to disordered eating.

Taste and food reward processing

Appetite is a physiological motivational drive that depends on the interaction between an individual's homeostatic needs, the rewarding aspects of food, and the cognitive ability to choose alternative behaviours to eating [36]. Cortical taste circuitry is relatively well defined. Animal studies show that sweet taste perception is mediated by tongue receptors that send signals through the brainstem and the thalamus to the primary gustatory cortex in the insula [46]. In humans, the anterior insula receives chemosensory taste information from the mid insula where it is integrated with homeostatic drives and reward value to guide motivated eating behaviour [47, 48]. Together with the amygdala, which values the emotional saliency of food tastes and textures [49], the anterior insula projects along the ventral aspects of the striatum to regulate palatable food intake [50]. The mOFC assesses the pleasantness of taste or smell [51] and projects to the subgenual and rostral ACC. ACC subregions

integrate reward with automatic function and motor control [52] and contribute to appetite [53]. The OFC also processes how much food an individual has eaten and guides decisions about when to stop eating one food type, while still remaining interested in other types of foods [54]. This ventral (limbic) neurocircuit thus translates taste signals into food reward and guides the approach towards, or avoidance of, food [36] (Fig. 105.1).

Anorexia nervosa

One approach to examining food reward processing in EDs is to directly interrogate gustatory processing. Studying brain response to administration of actual tastes permits direct examination of whether individuals with EDs show alterations specific to encoding the rewarding aspects of food. Imaging studies in RAN show decreased ACC, insula, and striatal activation in response to expected sweet taste receipt, relative to controls (Fig. 105.2) [55, 56], although these studies do not directly compare responses when hungry vs satiated. Decreased brain response to palatable taste supports a role for altered reward processing of gustatory stimuli in AN. However, data from another study suggest striatal and insular activation in response to pleasant and aversive taste is increased in RAN when taste is less predictable, potentially indicating a hypersensitive salience response to unexpected food among this population [57]. Discrepant findings may relate to the predictability of the delivered taste, rather than to the tastes themselves. In addition, individuals with AN showed greater right amygdala and left medial temporal gyrus activity in response to chocolate milk than controls [58]. The amygdala is involved in the acquisition of conditioned emotional responses to neutral stimuli and is activated during fear [59]. Further research is needed to clarify the role of altered activation in response to tastes in AN.

Bulimia nervosa

Imaging studies of BN have been somewhat inconsistent. Some research suggests reduced reward response to expected taste receipt in BN, potentially suggesting reward habituation to food [60]. It is possible that a decreased subjective sense of reward while eating may contribute to overeating in predisposed individuals [61] or that recurrent episodes of binge eating over time contribute to blunted reward responses [62]. However, other findings showed reduced reward response to unexpected taste receipt among ill BN individuals, relative to controls [10]. Exaggerated hedonic response to predictable receipt of palatable foods also has been observed among individuals with BN [5, 55]. Responsivity of reward regions during anticipation, but not receipt, of palatable food is associated with increased negative affect among women with BN [63]. This relationship has been interpreted to suggest that greater reward anticipation activation during states of negative affect in BN may make individuals with BN more likely to consume high-energy foods, and negative affect could increase the rewarding value of food if used as a temporary tool to regulate mood [63].

Reward-based learning

Anorexia nervosa

As learning from feedback shapes behaviour, altered feedback learning could contribute to the onset and maintenance of

(Fig. 105.3) [66] and is implicated in EDs [1, 10]. RAN participants exhibited heightened anticipatory responses to food images [67], and individuals ill with AN showed a higher brain response to unexpected taste stimuli than controls, suggesting heightened anxiety and responsivity to anticipated and unanticipated food stimuli in AN [68]. Adolescents with AN, relative to controls, showed a

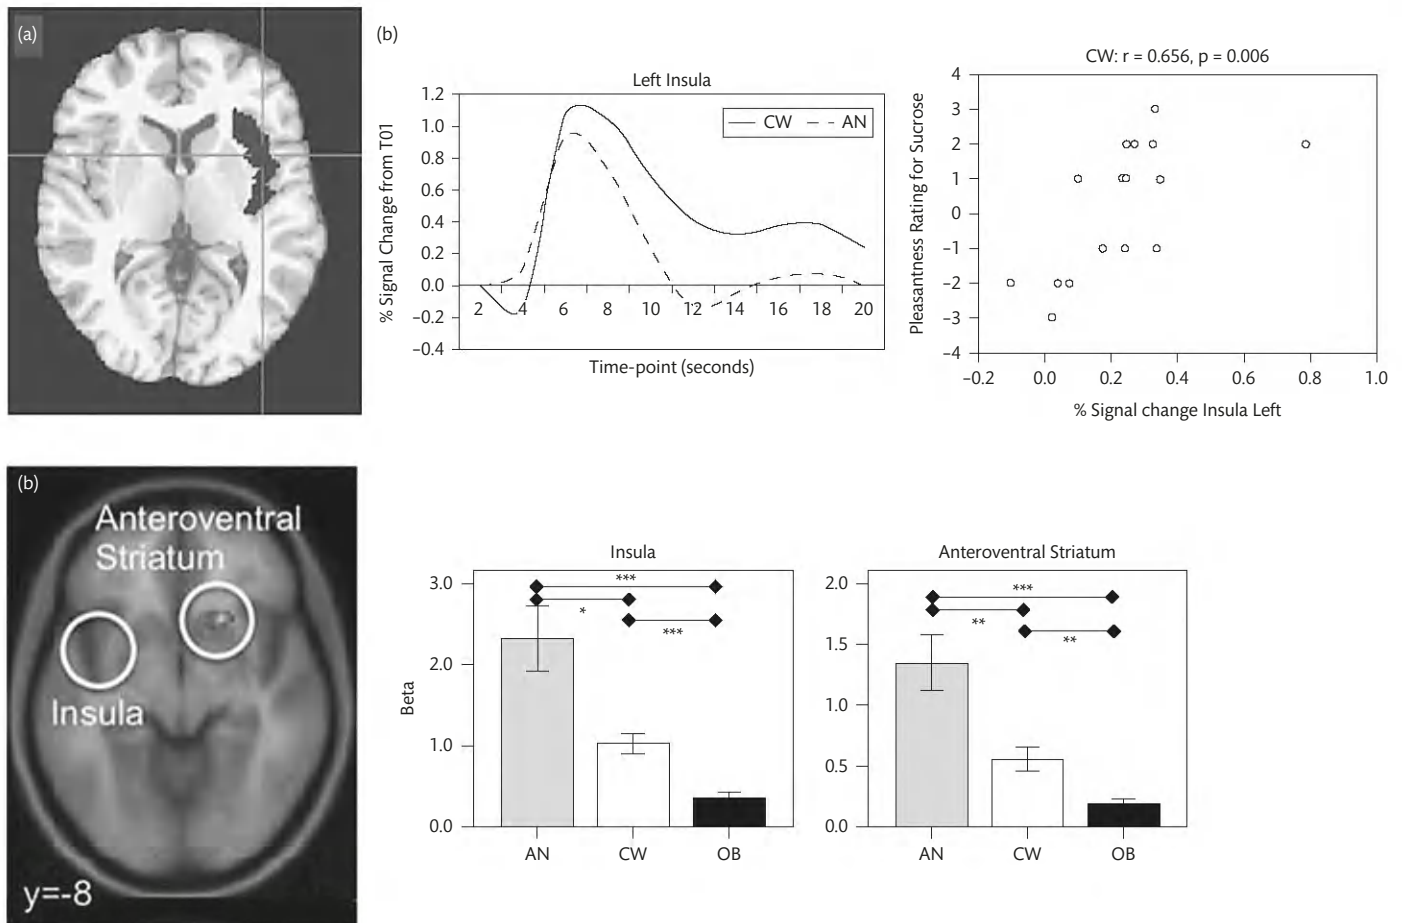

Fig. 105.2 Functional MRI studies examining taste reward processing in anorexia nervosa (AN) participants and control women (CW). (a) During taste processing of sucrose vs water, RAN, compared to CW, showed less activation of the ventral and dorsal striatum and the insula to sucrose and water. (b) Corresponding time points of the blood oxygen level-dependent (BOLD) in the left insula showed this decreased response to sucrose in RAN. BOLD response is correlated with pleasantness response for sucrose in the left and right insula in CW, but not in RAN. (c) By contrast, a taste reward conditioning tasks shows underweight AN have greater brain response in the anteroventral striatum, insula, and PFC compared to control and obese women, during taste anticipation.

Reproduced from *Neuropsychopharmacology*, 33(3), Wagner A, Aizenstein H, Frank GK, et al., Altered insula response to a taste stimuli in individuals recovered from restricting-type anorexia nervosa, pp. 513–23, Copyright (2008), with permission from Springer Nature.

greater prediction error response within the ventral caudate/nucleus accumbens, and the anterior and posterior insula during a monetary reward task [69]. They also showed an increased neural

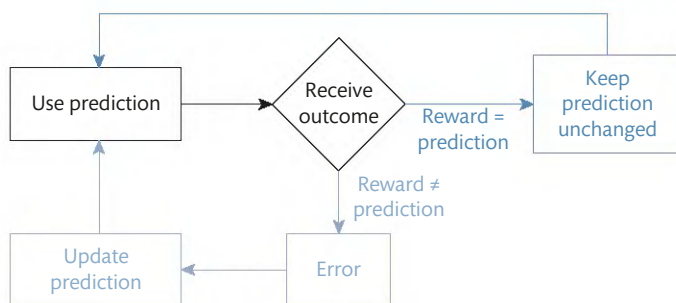

Fig. 105.3 Learning via prediction error. Light blue lines show when reward differs from its prediction, resulting in prediction error. Dark blue lines show when outcome matches the prediction, resulting in no error and unchanged behaviour.

Reproduced from *Dialogues Clin Neurosci.*, 18(1), Schultz W, Dopamine reward prediction error coding, pp. 23–32, Copyright (2016), with permission from Institut La Conférence Hippocrate.

response to unexpected reward receipt and to unexpected reward omission. Following treatment, prediction error and response to unexpected reward omission normalized, but unexpected reward receipt remained heightened. Caudate prediction error response was negatively associated with weight gain during treatment, indicating that a higher neural prediction error response may be a marker of illness severity or the treatment-resistant nature of adolescent AN [70]. Since depression and anxiety are significantly associated with intolerance of uncertainty and harm avoidance among AN individuals [68], an elevated prediction error in response to food could be related to higher rates of depression among AN participants, relative to controls.

Bulimia nervosa

Opposite findings have been observed among individuals with BN. Specifically, participants with BN exhibited reduced responses to unexpected taste stimuli, relative to controls [10]. Decreased prediction error response in BN is associated with higher binge eating/purge frequency [10], potentially suggesting that repeated binge eating and purging reduce DA response in BN. Contrasting

prediction error responses may play a role in the opposing patterns of food consumptions among individuals with AN and BN.

Reward response to food cues in eating disorders

Anorexia nervosa

The majority of research examining neural response to food among individuals with EDs uses visual food cues [2]. Functional magnetic resonance imaging (fMRI) studies investigating brain response to pictures of food revealed reduced reward brain response in AN in the inferior parietal lobe [70], OFC [71, 72], lateral PFC [72], hypothalamus [71], and insula [67, 71], but greater activation of the medial PFC and posterior cingulate [72], when viewing food images. Decreased neural responses to food images in AN may indicate innate differences in reward processing [1]. Notably, decreased reward response to food pictures in individuals with AN was significantly correlated with illness severity [70], suggesting that decreased reward sensitivity may contribute to an increased ability to restrict intake. Unlike healthy controls, both ill and weight-restored AN participants failed to demonstrate the expected associations between the levels of ghrelin, a 'hunger hormone', and brain response to visual food stimuli in limbic regions [71], suggesting a possible disconnect between brain reward response and physiological hunger signalling.

Rather than eliciting reward response, food cues may be associated with exaggerated attentional processing among ill and RAN individuals [1, 72, 73]. Early fMRI research shows that, unlike healthy controls, individuals with AN exhibited increased left amygdala response to high- vs low-calorie foods [73]. Pictures of high-calorie foods elicited high self-reported anxiety in AN individuals, along with increased left insular and ACC brain response [73], suggesting elevated fear of calorically dense foods. Elevated activation in the medial temporal gyrus when viewing high-calorie foods was also associated with self-reported anxiety [74]. More recent research showed that both ill and RAN individuals demonstrated increased activation in areas of executive function and error monitoring, relative to controls, when viewing food images [72]. Together, these findings could suggest heightened arousal, vigilance, or processing activity in response to food cues among AN individuals, possibly to predict and control the anxiety produced by food stimuli that may be experienced as unpleasant [7].

Tasks that permit examination of neural response to food images and during food-related decision-making have also been used to assess food-related processes in AN. For example, AN individuals showed greater activation of neural circuits associated with habit formation than controls when choosing low-fat vs high-fat foods [75]. Although it remains unknown whether reduced energy intake among AN individuals is a habit, these findings provide preliminary evidence that maladaptive behaviours in AN may be mediated by dorsal fronto-striatal circuits that underlie habitual behaviours [75]. Thus, alterations in these circuits may play a role in food choices in AN.

Bulimia nervosa and binge eating disorder

Limited research examining the response to visual food cues among individuals with BN and BED has thus far yielded inconsistent findings. Participants with BN showed greater activation in the mOFC,

ACC, visual cortex, and insula in response to pictures of palatable foods, relative to controls [76, 77], and heightened insular and ACC activation in response to food images, relative to participants with BED, suggesting enhanced reward processing of visual food stimuli [77]. An exaggerated response to visual food cues could increase the risk for binge eating among individuals with BN. However, other studies showed evidence of reduced reward response to food stimuli among BN, compared to controls [12, 78]. In addition, patients with BN showed decreased neural activity in the temporal lobe, inferior parietal lobule, and post-central gyrus in response to visual food stimuli [76].

Results in BED to date are similarly mixed. One study revealed increased medial PFC response, relative to controls [77], and another showed elevated response patterns of the left ventral striatum, compared to BN, in response to food pictures [79]. However, other findings revealed a negative correlation between body mass index (BMI) and neural reward response to food cues in BED, suggesting that chronic excessive caloric intake may contribute to changes in brain function or that individuals with a lower reward response are at a greater risk for weight gain [2]. It remains unclear whether functional alternations among BN individuals and those with BED are premorbid traits that contribute to binge eating behaviours or if such differences result from extreme overeating.

Inhibitory control in eating disorders

A growing body of research suggests that EDs are marked by an imbalance between reward and inhibitory control circuitry. Homeostatic mechanisms regulating appetite interface with reward and cognitive control circuitry to guide eating behaviours [51]. Cognitive processes involved in planning, inhibitory control, and decision-making integrate interoceptive cues (for example, information about the internal physiological state) and reward signals to determine food selection, portion sizes, and frequency of eating [80]. These systems can override homeostatic signals, giving rise to extreme patterns of over- or under-consumption [81].

A network consisting of the DLPFC, ventrolateral prefrontal cortex (VLPFC), insula, dorsal caudate, and posterior parietal cortex is associated with inhibitory control [82]. The dorsal cognitive circuit modulates selective attention, planning, decision-making, and effortful regulation of affective states [83]. The ventral limbic and dorsal cognitive circuits are involved in inhibitory decision-making processes, especially involving reward-related behaviours. Through its connections with the dorsal ACC, the insula is also involved in the cognitive valuation of salient stimuli such as food [84].

Anorexia nervosa

Individuals with AN-R often exhibit temperaments marked by behavioural inhibition, cognitive inflexibility, and emotional constraint [85]. Imaging data consistently provide evidence of alterations in dorsal inhibitory control circuits among AN and RAN individuals. Specifically, several fMRI studies revealed enhanced activity in inhibitory control regions among AN, relative to controls, during tasks requiring effortful control, cognitive inhibition, and error detection [86, 87]. RAN, relative to healthy control, participants also demonstrated enhanced activation of inhibitory control regions during both hunger and satiety [41] (Fig. 105.4). While behavioural

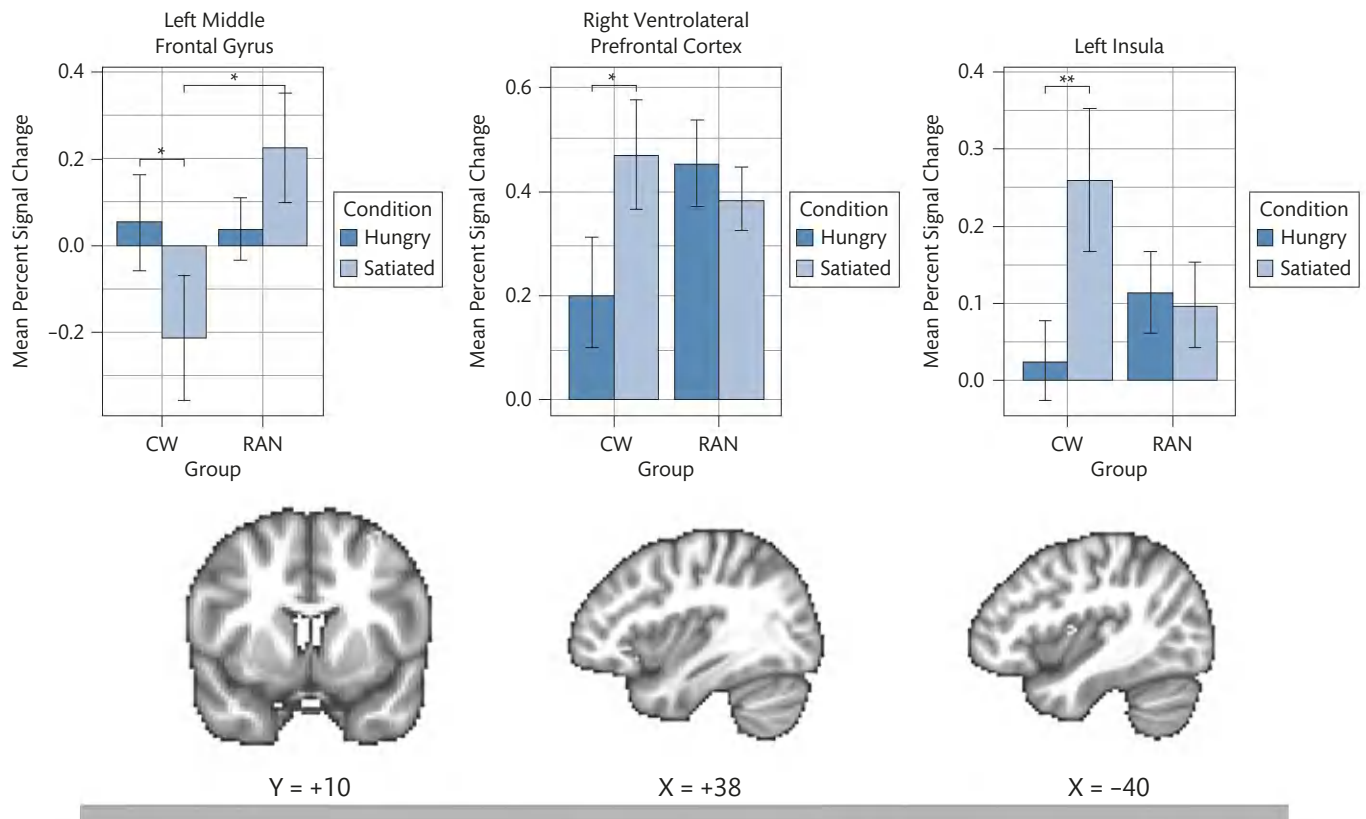

Fig. 105.4 Functional MRI response of cognitive circuitry during a monetary decision task in RAN and CW. Left: within the left middle frontal gyrus, CW responded more strongly when hungry than when satiated ($z = 2.6$; $P = 0.04$), whereas RAN responded more than CW when satiated ($z = 2.7$; $P = 0.03$). Middle: within the right ventrolateral PFC, CW responded more when satiated than when hungry ($z = 2.0$; $P = 0.02$). Right: within the left insula, CW responded more when satiated than when hungry ($z = 3.6$; $P = 0.002$). CW, healthy comparison women; RAN, women remitted from anorexia nervosa.

findings in regard to set-shifting among adolescents with AN are mixed [88, 89], adult AN and RAN participants showed decreased neural activity in frontal regions during set-shifting [90, 91]. Such findings call into question whether cognitive inflexibility may be associated with brain development or a trait marker for AN [85]. AN participants also showed a positive association between successful inhibition and increased activation of the inferior parietal cortex [87]. Increased activation of brain regions involved in planning, control, and evaluation of negative outcomes may underlie excessive behavioural inhibition and restricted food intake characteristic of AN. Furthermore, over-control may enable AN individuals to restrict food intake in order to achieve weight loss.

Bulimia nervosa

In addition to demonstrating high reward sensitivity, BN individuals are often emotionally dysregulated and behaviourally disinhibited [92]. They often engage in more impulsive and sensation-seeking behaviours than individuals with AN and healthy controls [93]. Inhibitory control processes are impaired in BN participants, as evidenced by poor performance on Stroop, Stop Signal, and Go/No-Go tasks [94]. Ill BN adolescents and adults, relative to controls, showed reduced frontostriatal activation during correct responding on incongruent trials of the Simon Spatial Incompatibility Task [12, 95]. However, a study conducted by Lock *et al.* [87] revealed increased activation of the right

DLPFC among adolescents with binge eating and purging during a Go/No-Go task [87]. Reduced activation during response inhibition is associated with illness severity [12, 95]. Individuals with BN also demonstrated behavioural impairments in inhibitory control in response to food stimuli [96], indicating that altered functioning of inhibitory control circuitry may underlie eating pathology in BN.

Binge eating disorder

Behavioural studies suggested that individuals with BED demonstrated significantly poorer performance on measures of decision-making and inhibitory control, relative to controls [97, 98]. Poor decision-making, coupled with difficulty delaying immediate rewards, may explain the tendency to binge eat despite delayed negative consequences (for example, weight gain, feelings of guilt). Imaging studies among individuals with BED showed alterations in cognitive control circuitry, namely in the prefrontal, insular, and orbitofrontal cortex in response to both food-specific and non-food stimuli [99, 100]. Obese participants with BED showed less activation in the vmPFC, IFG, and insula, compared to obese and lean controls, during a Stroop task [100]. Additionally, a negative correlation was found between activation in brain regions involved in impulse control and dietary restraint scores in the BED group, whereas no such association was found between obese non-BED and lean participants [100]. Dysregulation of these regions may contribute to

the development and maintenance of binge behaviours seen among individuals with BN and BED.

Interoception in eating disorders

Interoception refers to the brain's receipt of, and response to, continuous feedback of afferent signals that provide information about the representation of the body's physiological state [48]. Interoception includes respiration, heartbeat, pain, hunger, thirst, and intestinal tension, all of which are implicated in EDs [36, 101]. Key neural structures involved in interoception include the insula, midbrain reticular nuclei, ventromedial and ventroposterior thalami, and posterior insular cortex [48]. The insula evaluates interoceptive signals and plays a critical role in processing such sensations to guide behaviour. Evidence from neuroanatomical and functional neuroimaging indicates that the insula also plays an important role in regulating hunger, appetite, and thirst [48]. The insula receives exteroceptive signals from the spino-thalamo-cortical interoceptive pathway [48] and integrates such information with input from the hypothalamus and amygdala, creating a representation of one's internal and external environments [47]. This representation is projected to the anterior insula where it is integrated with information from cortical regions and limbic regions involved in motivation and saliency [47], evaluating how the stimulus may affect the body [102]. Ventral portions of the middle and anterior insula process social-emotional, cognitive, and sensorimotor information [48]. The mid insula also codes interoceptive prediction error, signalling a mismatch between expected and actual bodily arousal, which can elicit anxiety and approach or avoidance behaviour [47, 48, 102]. In fact, recent evidence suggests that several mood and anxiety disorders are rooted in altered interoception [103]. Altered interoception may be particularly relevant to Eds, given that individuals with AN and BN often exhibit comorbid depression and anxiety [104].

Anorexia nervosa

Emerging evidence suggests altered interoceptive processing in ED. For example, individuals with AN demonstrate less accurate detection of interoceptive sensations (for example, cardiorespiratory

changes) during meal anticipation [105]. Other studies suggested ill and RAN individuals, relative to controls, were less accurate in the perception of body signals and showed altered brain response to taste, pain, gastric interoception, and hunger [36, 105–107]. For example, despite comparable pain intensity ratings, relative to controls, RAN participants exhibited increased anterior insula response to anticipation of pain, but decreased activation to pain receipt [106]. Further, this altered right anterior insula functioning is associated with the alexithymic temperament characteristic of AN, with alexithymia possibly reflecting an inability to utilize interoceptive cues to evaluate outcomes [106]. The observed discrepancy between subjective pain experience and brain response among AN participants may indicate a disconnection between reported and actual interoceptive state [106]. Weight-restored individuals with AN showed reduced left dorsal mid-insula activity during a stomach interoceptive attention task and increased activation of the right anterior insula during heart interoceptive attention, relative to controls [107]. Altered anterior insula responsiveness, as evidenced by abnormal anticipation, interpretation, and integration of internal and external stimuli, is likely to interfere with eating, social interactions, and other reward-related behaviours among individuals with AN [36].

Bulimia nervosa

Altered interoception is also observed in BN. Patients with BN, relative to controls, reported more deficits in interoceptive awareness on the ED inventory, while also demonstrating a positive correlation between anticipatory anxiety, interoceptive awareness, and body image distortion [108]. Individuals with BN reported elevated panic and anxiety symptoms, compared to controls, following sodium lactate and isoproterenol infusions, despite exhibiting a similar sympathetic response [109]. However, RBN individuals demonstrated reduced heartbeat counting accuracy [110], and individuals with BN showed elevated thresholds for pain [111] and larger gastric capacity, in comparison to healthy controls and obese individuals [112]. Thus, findings regarding interoception among individuals with BN remain unclear, as results from these studies suggest both heightened and diminished responses to interoceptive signals among BN individuals [113]. For example, individuals with BN showed decreased baseline sympathetic tone, yet increased adrenergic sensitivity to

isoproterenol [114]. It is hypothesized that repeated binge eating and purging may contribute to habituation or sensitization of internal body states, as evidenced by reduced salivation to food presentation among BN individuals, which normalizes after treatment [115]. Further research in individuals across all stages of illness and in recovery is needed to clarify interoceptive processes among BN individuals [113].

No studies to date have examined interoceptive awareness among individuals with BED. Research is needed to investigate the role of interoception in binge eating.

Feeding disorders

Feeding disorders include pica, rumination disorder, and ARFID. Pica is characterized by the compulsive and persistent eating of non-nutritive substances, while the essential feature of rumination disorder is the repeated regurgitation of food occurring after feeding or eating over a period of at least 1 month [4]. Individuals with ARFID avoid or restrict food consumption, resulting in a clinically significant failure to meet nutritional requirements through the oral intake of food [4]. To date, no published neuroimaging studies of feeding disorders exist. Incidence of pica following acquired brain injury may suggest neural abnormalities among these individuals [116]. Further, some case studies suggest that selective serotonin reuptake inhibitors, in particular, are helpful in treating pica, suggesting possible serotonin dysfunction among affected individuals [117]. Although these findings support hypotheses for future investigation, imaging research is needed to better understand the neurobiological underpinnings of feeding disorders.

Conclusions

A consistent body of research provides evidence that individuals with EDs have altered functioning in reward, control, and interoceptive circuitry (Tables 105.1 and 105.2). Reduced motivational reward response and exaggerated cognitive control, coupled with

an altered ability to integrate taste, hunger, and body signals, are likely to facilitate and maintain prolonged periods of fasting in AN. By contrast, alterations in both anticipatory and actual responses to receipt of food, deficient inhibitory control circuit activation, and altered interoception are likely to underlie binge eating behaviour in BN and BED. These findings suggest potential ED phenotypes based on neural circuit abnormalities, but also provide insight for targeting behavioural and pharmacological treatment options [2].

However, many questions still remain regarding the neurobiology of EDs. For example, malnutrition, psychological comorbidities, and medication use often confound the findings of research conducted in ill individuals [1]. Many studies examine individuals in the remitted stages of illness, making it difficult to determine whether functional neural abnormalities are inherent traits or reflect scars of the illness [85]. Longitudinal studies may be one way to address this methodological question. Further research is also needed to elucidate whether neurobiological differences exist along a continuum or reflect discrete categories of eating pathology. Finally, although the hypothalamus is important in regulating food intake and body weight, evidence supporting the role of the hypothalamus in the aetiology of EDs is limited [36]. Studies combining the assessment of hypothalamic neuropeptide levels and neuroimaging may further contribute to the recent advances in understanding and treating these complex illnesses.

Management and treatment of feeding and eating disorders

Susan L. McElroy, Anna I. Guerdjikova, Nicole Mori, Paul L. Houser, and Paul E. Keck, Jr.

Introduction

Feeding and eating disorders are characterized by persistently disturbed eating behaviour that results in abnormal consumption or absorption of food that impairs health or functioning. In DSM-5, they include pica, rumination disorder, avoidant/restrictive food intake disorder (ARFID), anorexia nervosa (AN), bulimia nervosa (BN), binge eating disorder (BED), and a residual category (other specified feeding or eating disorder) that includes subthreshold AN, BN, and BED, purging disorder, and night eating syndrome (NES) [1]. The International Classification of Diseases, eleventh revision (ICD-11) will include similar disorders [2]. In this chapter, the management and treatment of these conditions are reviewed.

Pica

Pica is the recurrent eating of non-food items or substances such as paper, paste, wood, soap, chalk, pebbles, rubber gloves, clay, paint, or faeces [1, 2]. Data on the prevalence of pica are inconclusive. Pica occurs in people of all ages but may be more common in children, those with intellectual disabilities or autism, pregnant women, and those receiving dialysis [3–5]. The presentation and medical complications of pica are highly variable and associated with the specific ingested items or substances. Pica may become a focus of clinical attention because of medical complications, such as broken teeth, choking, bowel obstruction or perforation, infection, or poisoning, some of which are potentially fatal. Pica is significantly associated with an increased risk for anaemia, low haemoglobin, low haematocrit, and low plasma zinc, although the direction of causation is unknown [6].

Management of pica starts with a thorough medical and psychological assessment to detect medical complications and any possible contributing factors. If present, medical complications of the pica must be adequately addressed. If a contributing factor (for example, iron deficiency anaemia) is identified, addressing the factor (for

example, treatment with supplemental iron) may lead to resolution of pica, but this does not always occur [3].

There have been no adequately sized and designed randomized controlled treatment trials in patients with pica, and empirically derived treatment guidelines for pica do not exist. Treatment often requires a multi-disciplinary team with physicians, dieticians, and psychologists. In a review of 26 treatment studies in individuals with disabilities, it was concluded that behavioural treatments, especially those involving a combination of reinforcement response reduction procedures, were effective [7]. In another review, it was concluded that applied behaviour analysis was the most effective strategy [8].

Regarding pharmacotherapy, there are case reports of patients whose pica and attention-deficit/hyperactivity disorder (ADHD) both responded to methylphenidate, and of patients whose pica and depression or obsessive-compulsive disorder both responded to a selective serotonin reuptake inhibitor (SSRI) [9–11]. These cases suggest that treatment of comorbid psychiatric disorders might be helpful for reducing pica in some patients.

Nutritional supplements have been evaluated in pica, with negative findings. In a two-by-two factorial randomized, placebo-controlled trial of iron and multimicronutrient supplementation in 406 Zambian schoolchildren, 302 with geophagy, neither treatment was superior to placebo for decreasing geophagy prevalence [12]. Indeed, decline in geophagy prevalence was higher in children receiving placebo than those receiving iron (28.0% vs 22.3%; $P = 0.044$). There were also no interactions between iron and multimicronutrient supplementation. This trial was limited by an extremely high dropout rate. In a randomized, placebo-controlled trial of an intramuscular iron-dextran preparation in 31 African-American children with pica, improvement in pica was not significantly different at 2–3 months or at 9–10 months [13]. Patients with lower haemoglobin concentrations did not respond to iron more favourably than those with higher haemoglobin concentrations, or respond more favourably to iron than to placebo. Additionally, there was no correlation between changes in haemoglobin concentration and changes in pica severity.

Rumination disorder

Rumination disorder is repeated regurgitation of recently ingested food (bringing previously swallowed food from the stomach back into the mouth), which may be re-chewed, re-swallowed, or spat out, that is not better explained by a gastrointestinal or other medical syndrome [1, 2, 14–17]. Of note, the Rome VI diagnostic criteria designate ‘rumination syndrome’ as a functional gastrointestinal disorder [18]. Though DSM-5 and the Rome criteria are silent on the relationship between rumination disorder vs rumination syndrome, the definitions are similar.

The act of regurgitation in rumination disorder is usually effortless and may be preceded by urges to regurgitate and/or a belching sensation (but not by nausea or retching). Regurgitated material contains recognizable food that may have a pleasant taste. Regurgitation tends to stop once the regurgitant becomes acidic. Although prevalence data are inconclusive, rumination disorder occurs in infancy, childhood, adolescence, and adulthood. It may be more common in certain groups such as infants and individuals with intellectual disability. Rumination can be accompanied by halitosis, chronically chapped lips, malnutrition, growth delay, or weight loss and can be life-threatening, especially in infancy. Other medical complications include tooth decay and erosion; aspiration leading to recurrent bronchitis or pneumonia, reflex laryngospasm, or asthma; and premalignant changes of the oesophageal epithelium. Patients with rumination have also been observed to have high rates of co-occurring depression and anxiety [17].

Management of rumination disorder begins with a comprehensive medical and psychological evaluation. Haematologic and chemistry tests are needed to exclude anaemia secondary to gastrointestinal bleeding and electrolyte imbalances. Rumination must be differentiated from other gastrointestinal conditions that involve gastro-oesophageal reflux or vomiting, including oesophageal stricture, achalasia, hiatal hernia, gastro-oesophageal reflux disease, Sandifer syndrome, gastroparesis, and peptic ulcer disease. Some authorities recommend studies of manometry, combined with impedance, to distinguish rumination from gastro-oesophageal reflux disease [16].

There are no randomized controlled treatment trials for rumination disorder, and it is currently thought to be best addressed with behavioural techniques across all age groups. Strategies for children include changing the child's posture during and after feeding, distracting the child when he or she starts the behaviour, and aversive conditioning (placing something bad-tasting on the child's tongue when he or she starts the behaviour). Psychotherapy for parents of children with rumination disorder may also be useful. Teaching diaphragmatic breathing to compete with the urge to ruminate may be helpful in children, adolescents, and adults [19]. In one study where 28 patients with rumination syndrome were trained to modulate abdomino-thoracic muscle activity under visual control of electromyographic recordings, the number of regurgitations decreased from 27 to eight after three sessions [20]. This improvement was maintained at 6-month follow-up. Patients with rumination associated with supragastric belching may respond well to behaviour therapy with a speech therapist [16]. There are also anecdotal reports of beneficial effects from gum chewing [16, 18].

Protein pump inhibitors may be helpful for associated oesophageal or gastric damage, but not for rumination itself. Prokinetic

medications also are not effective for rumination and may worsen symptoms [17]. In an open-label trial using high-resolution manometry–impedance recordings in 12 patients with rumination or supragastric belching, treatment with the gamma-aminobutyric acid (GABA) B receptor agonist baclofen substantially reduced the number of gastrointestinal flow events, including ruminations [21]. Reduction in flow events correlated with an increase in lower oesophageal sphincter pressure and a reduction in swallowing. For treatment-resistant rumination, options include an inpatient multi-disciplinary programme [17]. Anti-reflux surgery (for example, Nissen fundoplication) has been reported to be effective, but further research is needed [16, 17].

Avoidant restrictive food intake disorder

ARFID is characterized by avoidance or restriction of food intake accompanied by weight loss or growth delay, malnutrition, dependence on oral nutritional supplements or enteral feeding, and/or marked functional impairment that is not due to lack of food or a culturally endorsed tradition [1, 2, 22–25]. Unlike those with AN, individuals with ARFID have no disturbance in how they experience their body weight or shape and lack fear of weight gain, drive for thinness, or preoccupation with body image. Rather, they are more likely to report fear of vomiting or choking, concerns with food texture, or abdominal pain as reasons for their eating difficulties or weight loss.

ARFID most commonly develops in infancy or early childhood and may persist into adulthood. Patients with ARFID have high rates of comorbid medical and psychiatric disorders, especially low bone mineral density scores and anxiety disorders. Compared to those with AN in one study, ARFID patients were younger, more likely to be male, more likely to have a comorbid medical condition or anxiety disorder, and less likely to have a mood disorder [23].

The prevalence of ARFID is unknown. Among paediatric eating disorder inpatients, rates of ARFID have ranged from 5% [22] to 14% [23]. Initial evaluation often begins with the primary care practitioner who should address the child's prenatal, birth, and medical histories, as well as parental coping and mental health. Potential medical causes must be ruled out such as gastrointestinal disease, food allergies, or occult malignancy. Potential co-occurring medical disorders or complications and psychiatric disorders must also be determined.

No randomized controlled treatment trials have been conducted in patients with ARFID, and empirically based treatment guidelines are not available [26]. Management of ARFID usually requires a multi-disciplinary team that provides medical management, nutritional rehabilitation, and psychological treatment. Family therapy is often needed to help parents manage their child's nutritional intake. In one study, ARFID patients hospitalized for acute medical stabilization at an academic medical centre relied on more enteral nutrition and had longer hospitalizations than AN patients but had similar rates of remission and readmission 1 year after discharge [24]. In a study of 14 adolescent medicine eating disorder programmes, there were no significant differences between the types of treatments or programmes in terms of weight restoration [27]. Patients with ARFID sometimes also receive psychotropic medications, such as SSRIs for co-occurring anxiety

and/or olanzapine to enhance weight gain, but the efficacy of these interventions is unknown [25].

Anorexia nervosa

AN is characterized by persistent energy intake restriction, leading to significantly low body weight or growth failure, in combination with intense fear of gaining weight or of becoming fat or persistent behaviour that interferes with weight gain, and distorted self-perceived weight or shape [1, 2, 26, 28–30]. Physical hyperactivity, obsessive-compulsive symptoms related to eating and food, depressive and anxiety symptoms, and impaired insight are also common features. Amenorrhoea occurs in many females with AN but is no longer required for the diagnosis. DSM-5 recognizes two subtypes of AN: restrictive (where there has been no binge eating or purging behaviour in the past 3 months) and binge eating/purging (where there has been recurrent binge eating or purging in the past 3 months) [1]. Severity of AN is often determined by BMI status, with greater severity linked with lower BMI. New to DSM-5 is the diagnosis of atypical AN, in which there has been significant weight loss, but the individual's weight is within or above the normal range.

The lifetime prevalence of AN by DSM-IV criteria is around 1% in females and <0.5% in males [30]. Because amenorrhoea is no longer a defining component, AN, as defined by DSM-5 criteria, may be more common. Peak age of onset of AN is in early to mid adolescence, but the disorder may occur at any age. AN is associated with substantial medical and psychiatric comorbidity [26, 28–31]. Complications arising from the effects of starvation, binge eating, and purging occur across multiple organ systems and include: bradycardia, hypotension, and arrhythmias; reduced core body temperature; hypoglycaemia, hypercholesterolaemia, and amenorrhoea; fluid, electrolyte, and acid-base imbalances; anaemia and neutropenia; acute pancreatitis, salivary gland enlargement, Mallory-Weiss tears, elevated liver enzymes, and constipation; impaired bone quality, low bone mineral density, and increased fracture risk; depressive symptoms and cognitive impairment; and tooth decay and gum disease [26, 28–32]. Patients with AN may have an increased prevalence of autoimmune disorders, particularly type 1 diabetes, which may precede the onset of AN. More than half of adolescents and adults with AN meet criteria for another psychiatric disorder, especially mood and anxiety disorders [33, 34]. The mortality of AN is the highest of all mental disorders, with most deaths due to starvation-related medical complications and suicide [30]. Of note, AN in children and adolescents, AN in adults, and severe and enduring AN likely require different treatment approaches [26]. Early access to treatment is important, as there may be a critical window for effective intervention within the first 3 years of illness onset, beyond which full recovery becomes more difficult to achieve [30]. For younger and recently ill patients, the goal of treatment is full recovery. For patients with severe and enduring AN, treatment should focus on improving quality of life and reducing harm more than achieving full recovery.

Management of AN begins with a thorough medical and psychological evaluation, so that it can be determined where the patient should be treated—in a general medical hospital, a psychiatric hospital, or as an outpatient [26, 28–30]. There is no evidence that inpatient treatment is superior to outpatient treatment, and most

patients can be treated on an outpatient basis [35]. However, a number of guidelines provide parameters for when a patient should be treated in a general medical or psychiatric hospital [26] (Table 106.1). No matter the location of care, most guidelines recommend a multi-disciplinary approach involving medical, dietetic, and psychological treatment. Whenever possible, it is crucial to involve family members or significant others in the treatment process.

Medical stabilization, refeeding, and restoration of body weight, nutritional status, and, among females, regular menses are the primary aims of initial management. There is some controversy as to how best restore body weight and nutritional status in patients with AN, as empirical data for this process are lacking and there is concern about the development of refeeding syndrome, a potentially fatal complication characterized by hypophosphataemia, hypomagnesaemia, hypokalaemia, and cardiac failure that may occur with refeeding, including with intravenous dextrose, after a sustained period of malnutrition [36–38]. The standard of care therefore is to commence refeeding at low caloric levels and increase slowly, with variable recommendations internationally as to precise caloric prescriptions. In the United States, refeeding is begun with around 1200 kcal/day and increased by about 200 kcal every other day. The Royal Australian and New Zealand College of Psychiatrists (RANZP) recommends that adult AN patients should start refeeding with 6000 kJ/day, which is then increased by 2000 kJ/day every 3 days until adequate intake for weight restoration is achieved [26]. For mildly or moderately malnourished patients, there is some evidence that refeeding should start at ≥ 1400 kcal/day so as to avoid undernutrition.

Refeeding methods include using food, high-energy liquid supplements, nasogastric or enteral feeding, and, on rare occasions, parenteral nutrition. The least intrusive method of refeeding that can provide adequate nutrition should be used. Routine monitoring during refeeding includes regular measurement of weight, electrolytes, liver function tests, electrocardiographic findings, and other aspects of physiological functioning. In the early stages of refeeding, supplemental phosphate (500 mg twice daily) and thiamine (at least 100 mg/day) are often provided. Some guidelines argue that refeeding methods should be highly individualized. However, a study in adolescents with AN showed that a standardized caloric prescription was superior to individual prescription in facilitating early weight gain without increasing the risk of refeeding syndrome [39]. Standardized caloric prescription was also associated with a lower incidence of bed rest. Once adequate weight gain is achieved, continued dietary and psychological treatment should be provided for weight maintenance.

A wide range of psychological treatments have been evaluated in patients with AN [26, 28–30, 40–43]. For children and adolescents, the RANZP guidelines concluded that empirical evidence for efficacy was strong for family-based treatment and Maudsley family therapy; moderate for family system therapy, adolescent focused therapy, and enhanced cognitive behavioural treatment (CBT-E); and weak to moderate for cognitive behavioural therapy (CBT) [26]. The core feature of family-based treatment for adolescents with AN is that the parents are guided on how to take control of their child's eating. Of note, a recently conducted randomized controlled trial found parent-focused treatment, where the therapist meets only with the parents and a nurse monitors the patient, was superior to family-based treatment for bringing about remission in adolescents

Table 106.1 Indicators for consideration for psychiatric and medical admission for adults with AN or BN

	Psychiatric admission indicated	Medical admission indicated
Weight	Body mass index <14 kg/m ²	Body mass index <12 kg/m ²
Rapid weight loss	1 kg per week over several weeks or grossly inadequate nutritional intake (<100 kcal daily) or continued weight loss despite community treatment	
Systolic BP	<90 mmHg	<80 mmHg
Postural BP	>10 mmHg drop with standing	>20 mmHg drop with standing
Heart rate		<40 bpm or >120 bpm or postural tachycardia >20 bpm
Temperature	<35.5°C or cold/blue extremities	<35°C or cold/blue extremities
12-lead ECG		Any arrhythmia, including QTc prolongation or non-specific ST or T-wave changes (including inversion or biphasic waves)
Blood sugar	Below normal range	<2.5 mmol/L
Sodium	<130 mmol/L	<125 mmol/L
Potassium	Below normal range	<3.0 mmol/L
Magnesium		Below normal range
Phosphate		Below normal range
eGFR		<60 mL/min/1.73m ² or rapidly dropping (for example, 25% drop within a week)
Albumin	Below normal range	<30 g/L
Liver enzymes	Mildly elevated	Markedly elevated (AST or ALT >500)
Neutrophils	<1.5 × 10 ⁹ /L	<1.0 × 10 ⁹ /L
Psychiatric symptoms	Suicidal ideation Active self-harm Moderate to high agitation and distress Psychosis	

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BP, blood pressure; bpm, beats per minute; ECG, electrocardiogram; eGFR, estimated glomerular filtration rate; g, gram; kg, kilogram; L, litre; mmHg, millimetres of mercury.

Adapted from *Aust N Z J Psychiatry*, 48(11), Hay P, Chinn D, Forbes D, *et al.*, Royal Australian and New Zealand College of Psychiatrists clinical practice guidelines for the treatment of eating disorders, pp. 977–1008, Copyright (2014), with permission from SAGE Publications.

with AN, though differences in remission rates were not different at 6- or 12-month follow-up [42].

For adults with AN, the RANZP guidelines concluded that there was moderately strong evidence of efficacy for CBT-E, focal dynamic therapy, Maudsley Model of Anorexia Nervosa Treatment for Adults (MANTRA), and specialist supportive clinical management (SSCM); and weak evidence for CBT, behaviour therapy, interpersonal therapy (IPT), psychodynamic therapy, and cognitive analytic therapy [26]. However, reviews of these treatments have concluded that no specific psychological therapy was consistently superior to any other specific approach [40, 41]. Thus, in a 2-year follow-up of a randomized clinical trial comparing MANTRA with SSCM in outpatient adults with AN, both treatments were comparable regarding improvement in BMI, eating disorder psychopathology, and clinical impairment [43]. In the only randomized clinical trial of psychotherapy in outpatients with severe and enduring AN, shifting focus from weight gain and recovery to improved quality of life was found to be important [44]. There is no empirical evidence that guided self-help CBT (CBT-GSH), which may be helpful in BN or BED, is an effective treatment for AN [26].

No medication has regulatory approval for the treatment of AN. The World Federation of Societies of Biological Psychiatry (WFSBP) guidelines for the pharmacological treatment of eating disorders concluded that there was weak evidence from controlled studies for zinc supplementation and olanzapine for enhancing weight gain in

AN [45]. One study found olanzapine might be helpful for promotion of weight gain in outpatients with AN when given with medication management sessions [46]. Use of both agents, however, is controversial [26, 47]. Two meta-analyses of studies of newer drugs for psychosis in AN concluded that these agents were not efficacious for weight restoration or reduction of eating disorder psychopathology in patients with AN [48, 49]. Nonetheless, certain subsets of AN patients may be responsive to dopamine antagonist drugs, including those with prominent anxiety or depression, obsessive-compulsive symptoms, hyperactivity, or antipsychotic-responsive comorbid conditions such as bipolar disorder [47].

There is no evidence of efficacy for tricyclic drugs or SSRIs for enhancing weight restoration or reducing psychopathology in the refeeding phase of AN treatment [50], while evidence for fluoxetine for relapse prevention after weight restoration is mixed [51, 52]. Drugs for depression might improve co-occurring depressive or obsessive-compulsive symptoms that persist despite successful weight restoration. Results from randomized controlled trials of alprazolam, cyproheptadine, D-cycloserine, dehydroepiandrosterone, growth hormone, lithium, naltrexone, physiologic oestrogen replacement, oxytocin, and tetrahydrocannabinol in patients with AN have been mostly negative [47]. In a small randomized controlled trial, the ghrelin agonist retamorelin improved gastric emptying ($P = 0.03$) and body weight ($P = 0.12$) more than placebo [53]. A randomized controlled trial of the synthetic cannabinoid dronabinol in

patients with severe and enduring AN found small weight gain, with no side effects [54]. Different types of neuromodulation treatments (for example, deep brain stimulation, repetitive transcranial current stimulation, and transcranial direct current stimulation) have shown promise in severe and enduring AN, but systematic studies are needed before recommendations can be made [30].

Another area that has received some study is the medical treatment of AN-associated low bone mineral density. Available evidence suggests that the safest and most effective strategy for improving bone density in AN is to restore weight and, in females, menstrual function. However, even with resolution of AN, bone mineral density is not always restored. Pharmacotherapies that show promise include physiologic oestradiol replacement (that is, with a transdermal oestradiol patch) and, in adults, bisphosphonates [32].

A final important consideration is the not infrequent need for coercion in the treatment of AN [28]. Compulsory refeeding has short-term benefits, but long-term outcome is unknown [55]. More research on the potential long-term benefits and harms of compulsory refeeding in AN is needed.

Bulimia nervosa

BN is characterized by recurrent binge eating episodes, recurrent inappropriate compensatory behaviours to prevent weight gain, and self-evaluation that is unduly influenced by body weight or shape [1, 2]. The lifetime prevalence of BN is estimated to be 1.5% in women and 0.5% in men. BN occurs in people of all ages, with the most common onset occurring in late adolescence to early adulthood. BN is associated with substantial medical and psychiatric comorbidity [31, 33, 34, 56]. Co-occurring medical conditions include complications of binge eating and inappropriate weight loss behaviours, obesity, and obesity-related disorders [26, 56]. Psychiatric comorbidity includes mood, anxiety, substance use, and impulse control disorders.

The management of BN begins with a careful medical and psychiatric evaluation, with special attention to the frequency of binge eating episodes, the types and frequencies of inappropriate compensatory behaviours, potential medical complications, and co-occurring psychiatric disorders. Physical examination and laboratory evaluation should be conducted with attention to height and weight (to determine BMI), blood pressure and pulse, electrolytes, acid–base status, and complete blood cell counts. A cardiac evaluation with an electrocardiogram may be indicated if there is hypokalaemia, postural hypertension, bradycardia, or tachycardia. If vomiting has been a prominent symptom, a dental evaluation should be done. Most patients with BN can be treated on an outpatient basis, but high frequency of binge eating and/or compensatory behaviours, medical complications, psychiatric comorbidity, such as mood disorder or suicidal ideation/behaviour, or failure to respond to outpatient treatment, may necessitate hospitalization (Table 106.1). Particularly important among medical complications of purging is pseudo-Bartter syndrome, an upregulation of aldosterone that causes hypokalaemic metabolic acidosis and, upon cessation of purging, can lead to severe oedema [31]. This syndrome may be worsened by vigorous hydration with normal saline; it can be treated by gentle rehydration with a potassium-rich fluid and with spironolactone.

Many authorities believe the first-line treatment of BN in adults is individual psychotherapy, with the strongest evidence for CBT-E [26, 28, 29, 57]. CBT-E has been found superior to both IPT (at end of treatment, but not at 1-year follow-up) and psychoanalytic psychotherapy [58–60]. A more complex form of CBT-E may be preferable for patients with affect intolerance, low self-esteem, perfectionism, or interpersonal difficulties. In a comparison trial in adolescents with BN, family-based treatment was superior to CBT at end of treatment and 6-month follow-up, but the two therapies were not statistically significantly different at 12-month follow-up [61]. Dialectical behaviour therapy (DBT) and self-help modalities, especially CBT-GSH, also hold promise in BN. Self-help modalities are probably less effective than therapist-led psychotherapies but are appropriate first-step options when such therapies are not available or affordable. This includes self-help treatments administered via the Internet.

Pharmacotherapy also has a role in the treatment of BN. The WFSBP guidelines concluded there was evidence of efficacy for tricyclics, SSRIs, and topiramate for reducing binge eating and purging in BN [45]. Indeed, fluoxetine has regulatory approval for the treatment of BN, and 60 mg/day is more efficacious than 20 mg/day [62]. Fluoxetine is also efficacious for maintenance of response, but the dropout rate is high [63]. Many other types of drugs for depression are efficacious in BN, but the weak dopamine and noradrenaline reuptake inhibitor bupropion is contraindicated due to an increased risk of seizures. There is no clear evidence that these drugs enhance the effectiveness of psychotherapy for BN. In other randomized controlled trials, ondansetron was superior to placebo for reducing binge eating and purging, methylamphetamine was superior to placebo for decreasing the amount of food eaten, lithium and the prokinetic erythromycin were not efficacious, and results for opioid antagonists were mixed [45, 64, 65].

Binge eating disorder

BED is characterized by recurrent binge eating episodes that are accompanied by distress, but not the inappropriate compensatory weight loss behaviours of BN [1, 2]. BED is the most common eating disorder, occurring as a lifetime diagnosis in 1.9% of adults worldwide and 1.3% of adolescents in the United States [33, 34, 56]. It is associated with obesity and obesity-related medical conditions (for example, diabetes, hypertension, dyslipidaemia, and possibly metabolic syndrome) and with mood, anxiety, substance use, and impulse control disorders.

Management of BED involves a thorough psychological and medical evaluation to determine the severity of binge eating behaviour, identify comorbid medical and psychiatric disorders, and ensure that BN is ruled out (that is, that there are no surreptitious inappropriate compensatory weight loss behaviours). At a minimum, physical and laboratory examinations should include height and weight (to determine BMI), blood pressure and pulse, and fasting glucose and lipids. When surreptitious purging is a concern, serum electrolytes and amylase may be checked. Most BED patients can be treated on an outpatient basis, but psychiatric hospitalization should be considered for extremely frequent and distressing binge eating, a co-occurring mood disorder, or suicidal ideation and/or behaviour.

Psychological treatments that may be useful in patients with BED include psychoeducation, mindfulness techniques, self-help treatments (including CBT-GSH and those delivered via the Internet), behavioural weight loss therapy (BWLTL), CBT, IPT, and DBT [66, 67]. The strongest evidence of efficacy is for CBT and IPT, which can work over the long term and in adolescents as well as adults [66–69]. Though CBT and IPT both reduce binge eating behaviour and associated psychopathology in BED, they are less effective for weight loss in obese patients. Patients who completely stop binge eating with these treatments, however, may lose a small amount of weight. CBT and IPT are both more effective than BWLTL for reducing binge eating [69]. Though BWLTL may produce greater weight loss initially, this weight loss is not maintained after 2 years.

Physical activity may also be effective for reducing binge eating behaviour and excessive body weight in BED. In a review of three randomized controlled trials of physical activity in patients with BED, aerobic and yoga exercises reduced binge eating and BMI [70]. Additionally, aerobic exercise reduced depressive symptoms; CBT with aerobic exercise, but not CBT alone, reduced BMI; and CBT with aerobic exercise was more effective for reducing depression than CBT alone.

Pharmacotherapy may be helpful for some patients with BED [45, 66, 67]. Lisdexamfetamine dimesylate (LDX), a prodrug of d-amphetamine marketed for treatment of children and adults with ADHD, is approved for the treatment of moderate to severe BED in adults in the United States. This approval was based in part on two phase 3 studies of LDX in BED, both of which found that LDX, titrated to 50 mg/day or 70 mg/day, was efficacious for reducing binge eating episodes and obsessive–compulsive features of binge eating and for inducing 4-week binge eating cessation rates [71]. An earlier phase 2 study found that LDX at 50 mg/day and 70 mg/day, but not 30 mg/day, was efficacious for reducing binge eating [72]. LDX also caused significant weight loss in these trials (most participants were obese) but is not approved for weight loss or treatment of obesity. A long-term randomized withdrawal study of LDX in BED found that LDX was superior to placebo for maintenance of response [73]. No novel safety or tolerability issues were found.

There is evidence from randomized controlled trials to support the efficacy of the anticonvulsant agents topiramate and zonisamide in BED [45, 66]. Both drugs reduce binge eating behaviour and obsessive–compulsive features of binge eating and cause clinically significant weight loss. Additionally, topiramate has been shown to augment the efficacy of CBT in obese patients with BED, enhancing weight loss and cessation of binge eating rates. However, the use of both drugs is limited by their adverse event profiles, which include cognitive dysfunction, paraesthesiae, and renal stones.

Drugs for depression are modestly effective for reducing binge eating in BED, at least over the short term. The WFSBP eating disorder pharmacotherapy guidelines concluded there was evidence of efficacy for sertraline in particular [45]. They are also effective for depressive symptoms associated with BED. In a study of patients with BED and a co-occurring depressive disorder, the serotonin/noradrenaline reuptake inhibitor duloxetine was superior to placebo in reducing binge eating behaviour, global severity of BED symptoms, global severity of depressive symptoms, and body weight [74]. In another study, bupropion (300 mg/day) was similar to placebo in reducing binge eating frequency but produced greater weight loss [75]. Also, it was well tolerated and there were no seizures. Data on

the efficacy of the combination of antidepressant drugs with CBT are mixed.

Other medications have been studied in BED. The weight loss agents orlistat (a pancreatic lipase inhibitor) and liraglutide (a glucagon-like peptide 1 analogue) may reduce body weight in obese patients with BED, but their effects on binge eating behaviour are unclear [66, 76]. Limited mixed data also exist for baclofen and chromium [66].

Treating patients with BED involves educating the patient about all treatment options, their degree of efficacy, and potential adverse effects. Determination of initial therapy often depends on patient choice and availability. As there has been virtually no research into managing treatment-resistant BED, specific recommendations cannot be made, but there is preliminary evidence that combination therapy may be helpful.

Other eating disorders

Other eating disorders that come to clinical attention are NES and purging disorder [1]. NES is broadly defined as morning anorexia, evening hyperphagia, and insomnia. A core feature is nocturnal eating episodes, characterized by the sense that, after awakening at night, one has to eat something in order to get back to sleep. The prevalence of NES has been estimated to be 1.1–1.5% in the general population [77]. NES often co-occurs with obesity, mood disorders, and BN or BED. If possible, NES should be distinguished from the parasomnia sleep-related eating disorder, which is characterized by recurrent episodes of involuntary eating or drinking during sleep.

Study of the treatment of NES is in its infancy, and empirically based guidelines are not available. The only two randomized controlled trials were with SSRIs and had inconsistent results—sertraline was superior to placebo, but citalopram was not [77]. Preliminary data suggest CBT, progressive muscle relaxation, and topiramate may be helpful, but these treatments need study in randomized controlled trials.

Purging disorder is recurrent use of inappropriate weight loss behaviours for the purpose of influencing shape or weight, but without the binge eating episodes characteristic of BN or BED [1]. A newly recognized condition, it may be more common than realized. Though not accompanied by binge eating episodes, purging disorder may be characterized by loss of control of eating where small or normal amounts of food are ingested with a sense of loss of control.

No randomized controlled trials have yet been conducted for purging disorder, and empirically based treatment guidelines are not available. In a tertiary care treatment-seeking sample, patients with purging disorder had similar post-treatment remission or completion rates, as compared to those with AN or BN [78].

Conclusions

Substantial advances in the management and treatment of feeding and eating disorders have been achieved, but this field lags behind that for other psychiatric disorders. The cornerstone of managing AN is refeeding, nutritional rehabilitation, and weight restoration. There is strong evidence of efficacy for family-based psychotherapy

for adolescents with AN, while other forms of psychotherapy for adolescents and adults have less evidence for efficacy. No medication is approved for the treatments of AN, and the only agents with possible evidence of efficacy are zinc, olanzapine, and dronabinol. For BN, there is evidence of efficacy for CBT, IPT, drugs for depression, and topiramate. For BED, there is evidence of efficacy for CBT, IPT, LDX, topiramate, and drugs for depression. Antidepressant drugs reduce comorbid depressive symptoms, and LDX and topiramate produce clinically significant weight loss in overweight or obese patients. Less is known about the management and treatment of pica, rumination disorder, ARFID, and other specified feeding or eating disorders such as purging disorder and NES. As feeding and eating disorders often co-occur with medical and other psychiatric disorders, the management and treatment of these conditions must also be addressed.

Aetiology and management of obesity

Jamie Hartmann-Boyce, Nerys M. Astbury, and Susan A. Jebb

Epidemiology

The World Health Organization (WHO) estimated that in 2014, more than 1.9 billion adults (18+) had overweight, of whom 600 million had obesity, representing 39% and 13% of the world's adult population, respectively. Globally, 41 million children under the age of 5 were estimated to have overweight or obesity [1]. Obesity has more than doubled since 1980 and is projected to increase still; if current rates continue, almost half of the world's population will have overweight or obesity by 2030 [2]. Though once considered only a problem in high-income countries, recent years have seen dramatic rises in obesity rates in low- and middle-income countries, particularly in urban areas [1].

The prevalence of obesity varies by age, gender, and socio-economic status. Globally, obesity is more prevalent in women than in men and increases with age until old age when rates again decline. In middle- and high-income countries, the socially disadvantaged appear to be more vulnerable to overweight and obesity [3, 4]. The reasons for this association are not fully explained but may include greater exposure to environmental drivers of excess weight gain (for example, limited access to healthy food and safe and affordable recreation spaces) [5], lower levels of executive functioning (a theorized control network regulating behaviours, which has been linked with poverty in childhood) [6], and a lack of cultural capital which may diminish motivation for health-related behaviour change [7].

Obesity has been formally recognized as a global epidemic by the WHO since 1997. In 2013, the American Medical Association recognized obesity as a disease.

Definition and measurement

Overweight and obesity are defined as abnormal or excessive fat accumulation that may impair health. There are a number of ways to measure and define overweight and obesity, which are described briefly here.

Body mass index (BMI), weight in kilograms divided by the square of height in metres, is the most commonly used index for defining weight status in adults. The WHO defines adult overweight as a BMI ≥ 25 kg/m² and adult obesity as a BMI ≥ 30 kg/m² [1]. Some organizations use a lower BMI cut-off point for defining overweight

and obesity in Asian populations due to increased susceptibility to obesity-related illnesses at lower BMI levels than in people of other ethnicities. Typically, this cut-off is BMI ≥ 23 kg/m² for overweight and ≥ 27.5 kg/m² for obesity.

For children under 5 years of age, the WHO defines overweight as weight-for-height greater than two standard deviations above the WHO Child Growth Standards median, and obesity as greater than three standard deviations above the median. In children aged 5–19, the WHO defines overweight as BMI-for-age greater than one standard deviation above the WHO Growth Reference median, and obesity as greater than two standard deviations above the median [1].

Waist circumference and waist-to-hip circumference are also used as indices of excess fatness and specifically of visceral adiposity. Although some evidence points to stronger associations with metabolic health outcomes [8], the measurements are less precise than weight and height and subject to considerable inter-observer error.

Body composition measures, which aim to assess the proportion of body constituents, especially fat, are also available. Reference methods, such as whole body densitometry, dual-energy X-ray absorptiometry (DXA), and magnetic resonance imaging (MRI), are not practical in many clinical contexts. Simpler techniques, such as measurements of skinfold thickness or bioelectric impedance (measuring impedance of the body to a small electric current), are sometimes used in large surveys and cohorts, but changes in fat mass in an individual are highly correlated with changes in weight and these additional measures are unlikely to change management decisions.

Other diagnostic tools may be used to take into account obesity-related comorbidity and functional status [9].

Aetiology

The fundamental cause of obesity is an imbalance between energy intake and expenditure (calories consumed in food and drinks vs calories expended in basal metabolism and physical activity), but the determinants of intake and expenditure are complex. Rapid increases in overweight and obesity around the world, even in places where levels were historically low, illustrate the role of environmental changes in the rise in prevalence of obesity, including readily

Table 107.1 Drugs used to treat common mental health disorders which may predispose to weight gain

Drug	Treatment
Sodium valproate	Epilepsy, bipolar disorder and mania, migraine prophylaxis
Lithium	Bipolar disorder and mania, recurrent depression, aggressive and self-harming behaviour
Clozapine	Schizophrenia and related psychoses
Olanzapine, risperidone, and almost all first- and second-generation antipsychotics	Schizophrenia and related psychoses, bipolar disorder, mania, agitated and disturbed behaviour
Amitriptyline, nortriptyline, and doxepin	Depression, neuropathic pain, migraine prophylaxis
Fluoxetine	Depression, bulimia nervosa, obsessive-compulsive disorder
Mirtazapine	Depression

available energy-dense food and fewer imperatives for physical activity. These changes directly impact human behaviour, and urbanization serves as a clear example of this phenomenon. Numerous studies and reviews have highlighted the process by which urbanization in developing countries has led to concomitant increases in obesity prevalence [10–12]. Urbanization is characterized by marked increases in the consumption of animal fat and protein, refined grains, and added sugar—a phenomenon referred to as ‘the nutrition transition’ [11]. Simultaneously, the need for physical activity is reduced through decreases in active transport and increases in mechanized work where previously livelihoods were made in more manual occupations [10]. Such environmental and societal changes have been occurring worldwide and are outpacing human evolution. Humans evolved in conditions of relative food scarcity, in which high levels of physical activity were required to maintain livelihoods and lives. We evolved to conserve energy, and as a species, this leaves us genetically ill-equipped to deal with the environmental changes that have occurred over recent decades [13].

Nonetheless, within any given environment, there are marked differences in weight status between individuals, reflecting fundamental genetic differences, especially in appetite control systems (see Chapter 104) [14]. These interact with environmental drivers and behavioural differences, whether based in nature or nurture, to convey individual-level susceptibility to excess weight gain. Children are subject to the same environmental drivers as adults but are especially vulnerable. Young children lack the cognitive capacity to understand the consequences of poor dietary choices or the ability to understand the persuasive intent of food marketing, and they have limited control over their opportunities for physical activity [15]. Thus, the home environment and prevailing behaviours exert a powerful influence on a child’s weight.

The systems mapping approach employed in the 2007 UK Government Foresight report on obesity concluded that energy imbalance was caused by a complex and multi-faceted system of determinants, in which no single influence dominated [16]. However, within a complex systems map, they identified primary appetite control in the brain, the force of dietary habits, physical activity levels, and ambivalence experienced by individuals in making lifestyle changes as key determinants. Psychological factors, including self-efficacy, autonomy, and the ability to cope with stress, have also been found to be associated with obesity (for more information, see Mental health, p. 1098).

Additionally, some pharmacotherapies also cause weight gain—these include sedatives and a number of medications used to treat mental health conditions (Table 107.1).

Relationships between obesity, morbidity, and mortality

The rising prevalence of obesity presents a challenge to health care systems because elevated BMI is a major cause of morbidity and mortality [17]. The latest Global Burden of Disease study estimates that worldwide overweight and obesity caused 3.9 million deaths in 2015 and in excess of 120 million disability-adjusted life years lost in 2015, making it the fourth largest contributor to ill health [18].

Physical health

The morbidity and premature mortality attributable to raised BMI is linearly associated with increased risk factors for a wide range of diseases, especially high blood pressure, raised low-density lipoprotein (LDL) cholesterol, insulin resistance, and non-alcoholic fatty liver disease. Together these explain much of the increased risk of coronary artery disease, stroke, and type 2 diabetes [17]. Excess weight is the most important cause of preventable cancer after smoking. Overweight and obesity are significantly associated with at least 13 types of cancer, including common (colorectal and post-menopausal breast) and hard-to-treat (pancreatic and renal) cancers [19]. The underlying mechanisms are not fully understood but include changes in hormone production, particularly oestrogen, which increases the risk of breast cancer and uterine cancer. Excess fat is also associated with over-production of insulin and other growth factors which encourage cells to divide more rapidly. Finally, as adipose tissue depots increase, macrophages within the fat secrete cytokines as part of a low-grade, chronic inflammatory response, which may increase the risk of cancer [20].

Obesity is also associated with an increased risk of musculoskeletal disorders (especially osteoarthritis and lower back pain), reproductive and urological problems (including stress incontinence, infertility, polycystic ovarian syndrome, and erectile dysfunction), and respiratory problems (including sleep apnoea and asthma) [21].

Children with overweight or obesity exhibit elevated risk factors for metabolic diseases, including raised blood pressure and insulin resistance. Moreover, they are significantly more likely to have

overweight as adults, and the longer duration of excess weight further increases their risks for developing heart disease and diabetes in later life [22].

Mental health

A high prevalence of psychological comorbidities has been reported in patients with obesity, and mood disorders, anxiety, and low self-esteem are more common in individuals with obesity than their lean counterparts [23]. However, the relationship between obesity and psychological comorbidities is complex. In some cases, the relationship may be causal (for example, obesity leads to psychological comorbidities and/or psychological comorbidities lead to obesity), and in others, the two may arise together because of common risk factors, which include lower socio-economic class, poor diet, and lower levels of physical activity [24]. A recent systematic review reported that, although obese individuals were at increased risk of developing common mental health conditions, the magnitude of the association was similar to the risk of individuals with mental health conditions developing obesity, suggesting that there is a bidirectional relationship [25].

Obesity is linked to poor self-image, low self-esteem, and social isolation, all contributors to depression [26]. People with obesity can also find themselves ostracized, stereotyped, and discriminated against, which may exacerbate the development of low mood and depressive symptoms [27]. Furthermore, individuals with obesity are more likely to develop diseases such as diabetes, osteoarthritis, and other conditions which cause disability (see Physical health, p. 1097), and many of these comorbidities independently increase the risk of depression [28, 29].

The relationship between obesity and mental health can be further complicated by the fact that some drugs used to treat mental health disorders may predispose to weight gain (Table 107.1).

Benefits of weight loss

Many of the health risks of overweight and obesity can be mitigated by weight loss. A recent review evaluating the impact of weight loss interventions on cardiovascular risk factors found that even losses in the region of 0–2.5% of initial body weight led to statistically significant reductions in systolic and diastolic blood pressure, total cholesterol, low-density lipoprotein (LDL) cholesterol, HbA1c, and fasting plasma glucose [30].

The strongest long-term data come from the large diabetes prevention trials [31, 32]. Here, intensive lifestyle interventions, including changes to diet and physical activity to achieve weight loss, led to significant reductions in the cumulative incidence of type 2 diabetes [33]. In the 4-year diabetes prevention programme trial in the United States, the incidence of type 2 diabetes in the intensive lifestyle intervention 10 years after baseline was 4.8 cases per 100 person years (95% CI 4.1–5.7), compared to 11.0 (95% CI 9.8–12.3) in the control group [34]. Similarly, in the Finnish diabetes prevention programme trial, at 13-year follow-up, the group randomized to the intensive lifestyle intervention sustained a significantly lower incidence of diabetes, compared to a minimal control group (adjusted hazard ratio 0.61, 95% CI 0.48–0.79) [32].

Reductions in body weight are associated with a roughly linear improvement in other cardiometabolic risk factors, with every 10 kg

weight loss associated with a reduction of 0.23 mmol/L in total cholesterol [35] and a decrease in blood pressure of 4.6 mmHg diastolic and 6.0 mmHg systolic [36]. In clinical practice, it may be more useful to consider the degree of weight loss which an individual needs to achieve to observe clinically measurable improvements in health. These are summarized in Table 107.2 [37].

The relationship between weight change and mental health outcomes is less well established. In cohort studies, weight loss is sometimes associated with adverse effects. However, this may be attributable to unintentional weight loss associated with disease, which adversely affects mental health, or a common antecedent such as bereavement or other life events. In contrast, randomized controlled trials of weight loss interventions tend to show improvements in mental health, in particular reductions in depression and improvements in self-esteem and general mood [38, 39]. However, it is difficult to disentangle whether these improvements are due to the weight loss or to the support provided for weight loss. Most randomized controlled trials of weight loss interventions exclude participants with serious mental illness, but those which have tested weight loss interventions in this group have not reported exacerbations of mental illness, and in some cases, there has been clinically significant weight loss and improvements to overall health [40, 41].

Evidence from randomized controlled trials largely suggests that the improvements in health outcomes are independent of the method of weight loss. However, some special considerations may apply in relation to bariatric surgery and mental health outcomes (see Bariatric surgery, p. 1100).

Treating obesity

The rise in obesity and evidence of the health benefits of weight loss point to the need for effective interventions. Many people seeking to lose weight do so without professional support, and there is relatively limited evidence on the content or effectiveness of these efforts.

In recent years, there has been a significant expansion in the provision of weight management services within health care systems and such interventions are associated with greater weight loss than self-guided weight loss attempts. Interventions range from various forms of bariatric surgery to behavioural interventions, including individual counselling, group support, and total or partial meal replacements. There has been extensive investment by the pharmaceutical industry to develop novel anti-obesity agents, but progress has proved to be challenging.

Behavioural interventions

Structured behavioural weight management programmes should be considered the first port of call and mainstay of treatment for people with overweight or obesity. By focusing on improvements in diet quality and increases in physical activity, these interventions can support weight loss and bring weight-independent health benefits. They can also include interventions without person-to-person contact, that is, 'self-help' interventions. A recent systematic review found that provision of self-help resources could lead to an additional 1.85 kg of weight loss at 6 months [42]. However, most behavioural weight management programmes offered in health care settings include person-to-person contact to provide support to follow a hypoenergetic diet, together with recommendations for

Table 107.2 Therapeutic benefits of weight loss in patients with overweight or obesity

Condition	Amount of weight loss required	Notes on possible lifestyle interventions
Asthma/reactive airway disease	7–8%	No specific recommendation
Depression	None defined	'Should be offered a structured lifestyle intervention'
Dyslipidaemia (elevated triglycerides and reduced high-density lipoprotein cholesterol)	5–10%, as needed, to achieve therapeutic targets	Should include a physical activity programme and reduced-calorie healthy meal plan that minimizes sugars and refined carbohydrates, avoids trans fats, limits alcohol use, and emphasizes fibre
Female infertility	≥10%	No specific recommendation
Gastro-oesophageal reflux disease	≥10%	No specific recommendation
Hypertension	>5% to 15%	Should include caloric reduction and physical activity
Male hypogonadism	5–10%	No specific recommendation
Non-alcoholic fatty liver disease	4–10%	Caloric restriction and moderate to vigorous physical activity
Obstructive sleep apnoea	7–11%	No specific recommendation
Osteoarthritis	≥10%	Must include physical activity programme
Polycystic ovarian syndrome	5–15%	No specific recommendation
Type 2 diabetes (established)	5–15%, as needed, to lower HbA1c	Should be considered, regardless of duration or severity of disease
Type 2 diabetes (risk of developing) (people with 'prediabetes', metabolic syndrome, or 'high risk' based on validated paradigms)	10%	Should include caloric reduction and physical activity
Urinary stress incontinence in women	5–10%	No specific recommendation

Source: data from *Endocr Pract.*, 22(Suppl 3), Garvey WT, Mechanick JL, Brett EM, *et al.*, American Association of Clinical Endocrinologists and American College of Endocrinology comprehensive clinical practice guidelines for medical care of patients with obesity, pp. 1–2013, Copyright (2016), American Association of Clinical Endocrinologists.

increased physical activity. A comprehensive systematic review conducted in 2014 to inform British guidelines for weight management found that, on average, participants randomized to behavioural weight management programmes, typically lasting 12–24 weeks, lost 3.7 kg after 1 year, approximately 2.8 kg more than those randomized to usual care or minimal control conditions. No adverse effects were detected. Findings from this review suggested that most, but not all, behavioural weight management programmes were effective, but the reasons behind variations in programme effectiveness remain largely unknown [43]. After many years of intense focus on the macronutrient content of the diet (for example, low fat, low carbohydrate, high protein), there is little evidence that diet composition leads to differences in weight change over a year or more and growing recognition of the importance of adherence to the programme as a predictor of weight loss [44, 45]. For example, in a 2009 trial published in *New England Journal of Medicine*, participants were randomly assigned to one of four diets which varied based on the recommended percentages of energy derived from fat, protein, and carbohydrate. Weight loss was not significantly different between treatment groups, but adherence-related measures were strongly associated with weight loss, regardless of group [45]. Accordingly, interest has grown in understanding the techniques which may help an individual change his or her behaviour, including self-monitoring, goal setting, and planning behaviours. In a 2014 systematic review to inform British guidelines, programmes which encouraged calorie counting and comparison of an individual's behaviour with that of others were associated with greater weight loss [43].

Behavioural weight management programmes may also include provision of meal replacement products to substitute for one or two usual meals or a programme involving total diet replacement with

specifically formulated shakes, soups, or other basic foods which are nutritionally complete with respect to micronutrients but usually contain 800 kcal per day or less, sometimes referred to as very low-energy diets. Results from a systematic review suggest a mean weight loss of 10.3 kg at 1 year after being offered a very low-energy diet with behavioural support, 3.9 kg greater weight loss than the control groups offered a behavioural programme alone [46]. Results from a recent systematic review of partial meal replacements as part of diets involving more than 800 kcal per day found weight losses midway between those reported from behavioural programmes alone and those from very low-energy diets [47]. Together, these data suggest that tight control over the type and amount of food through the use of a highly structured dietary programme can bring additional weight loss, compared to dietary advice alone, when delivered as part of behavioural weight management programmes.

Pharmacological interventions

The physiological control systems regulating both energy intake and expenditure provide a series of logical targets for pharmacological intervention to reduce intake or increase expenditure. However, the search for safe and effective drugs to treat obesity has been difficult. Though numerous drugs have been developed which lead to successful weight loss, their side effects have frequently led to drugs being withdrawn during development or soon after coming to the market. In other cases, non-severe side effects or insufficient weight loss limit adherence and mitigate against long-term use, with weight typically regained once the medication is stopped. A new generation of treatments are now coming to market, particularly linked to the treatment of people with diabetes with overweight or obesity, though the cost is likely to be prohibitive for many health care systems.

Generally, obesity pharmacotherapies fall under three categories: those which aim to decrease energy intake; those which aim to increase energy expenditure; and those which aim to decrease energy absorption. Each of these is discussed briefly later in this chapter.

By far, the simplest are compounds that reduce absorption. The most common of these is orlistat, which is available both over-the-counter or by prescription. Orlistat prevents the absorption of a proportion of dietary fat which is instead excreted. However, unless the patient also adheres to a low-fat diet, this malabsorption will lead to oily, loose stools, which discourages patients continuing with medication. A 2011 review for the US Preventive Services Task Force found that orlistat led to an additional 3 kg weight loss at 1 year, compared to a behavioural weight management programme alone [48]. A longer-term trial in which patients were randomized to receive orlistat or placebo for 4 years found 2.8 kg greater weight loss and a 37% reduction in the incidence of diabetes [49]. For patients who are able to make the necessary dietary changes to minimize the side effects (and which also enhance weight loss), orlistat can be a useful and safe aid for weight loss.

Substances such as caffeine are known to act as metabolic stimulants and are associated with modest increases in weight loss, but are not recommended as weight loss aids [50]. Drugs which have greater metabolic effects also tend to be associated with a greater incidence and severity of adverse effects, especially increases in heart rate or blood pressure. The most well-known metabolic stimulant used to treat obesity is phentermine, today often combined with topiramate. Though clinical trials of this combination have shown greater weight loss than previously seen with orlistat, there are concerns about its long-term psychiatric and circulatory system effects, which led to its rejection by the European Medicines Agency (EMA). It is, however, available in the United States after approval by the Food and Drug Administration (FDA) in 2012 [51].

To date, the overwhelming bulk of work relating to pharmacotherapies for obesity has been focused on drugs to reduce energy intake. These include centrally acting treatments which act on neural pathways or those that work on gut mechanisms to boost gut signals and enhance appetite control. The former includes lorcaserin, which works via serotonergic mechanisms. Though phase 3 trials have demonstrated effectiveness for weight loss, use is again limited by concerns over adverse events; similar to phentermine, lorcaserin is licensed for use in the United States, but not in Europe [51]. Liraglutide, an injectable long-acting glucagon-like peptide-1 receptor agonist initially developed for the treatment of type 2 diabetes, is an example of the latter. A recent systematic review found liraglutide consistently resulted in a 4–6 kg weight loss (studies ranged from 20 weeks to 2 years), with comparative data suggesting weight loss was greater than that seen with orlistat or phentermine/topiramate [52]. Some studies also observed improvements in blood pressure and glucose. Both the FDA and EMA have licensed the use of liraglutide for weight loss, but long-term data are lacking and the high cost means this treatment is likely to be reserved for patients in whom other treatment options have failed.

Bariatric surgery

Surgical interventions for the primary purpose of weight loss have become increasingly popular in recent years, with an estimated 10-fold increase in the number of procedures since 2000 [53]. In

most countries, bariatric surgery is only recommended for people with severe obesity (BMI >35 kg/m²) or for those with significant obesity-related comorbidities. Unlike behavioural interventions that rely on an individual's motivation to adhere to a hypoenergetic diet, bariatric surgery leads to weight loss either by physically restricting food intake (restriction) and/or by limiting nutrient absorption from the gastrointestinal tract (malabsorption), leading to reduced energy availability and weight loss.

There are numerous surgical procedures available, the most common being the laparoscopic adjustable gastric band (Lap-band) and Roux-En-Y gastric bypass (RYGB), the latter being associated with larger weight losses. One of the largest and longest studies of outcomes following bariatric surgery is the Swedish Obesity Study in which a cohort of 2010 patients receiving bariatric surgery were matched to a control population and followed up over 20 years [54]. The mean changes in body weight after 2, 10, 15, and 20 years were –23%, –17%, –16%, and –18% in the surgery group. Compared with control, bariatric surgery was associated with a long-term reduction in overall mortality, as well as significantly decreased incidences of diabetes, myocardial infarction, stroke, and cancer. The remission rate of type 2 diabetes was also significantly greater in the surgery group at 2 and 10 years. Though bariatric surgery clearly represents an invasive procedure, risks are low when conducted by experienced surgeons; however, patients do require long-term follow-up, especially after bypass operations where nutrient absorption is permanently impaired [55].

It is estimated that at least 40% of patients presenting for surgery have at least one psychiatric diagnosis [56], with depression, anxiety, and eating disorders being the most common conditions [57, 58]. Overall, bariatric surgery is associated with post-operative improvement in depressive symptoms, self-esteem, health-related quality of life, and body image in patients with obesity [59, 60]. However, it is of concern that there are reports that surgery may predispose to more serious psychological side effects. A systematic review reported that the rate of suicide among those who have undergone bariatric procedures is more than five times that of the general population [61]. Additionally, patients who undergo bariatric surgery may be more likely to develop alcohol and drug dependencies [62]. In light of this, careful consideration should be made as to the suitability of those presenting for surgery and ongoing provision of appropriate support to enhance physical and mental health outcomes.

Other therapies

Though the use of other therapies for self-management of weight loss—including liposuction, food supplements, hypnotherapy, and acupuncture—is thought to be relatively common, there is very limited evidence to support their use. Where these therapies have been tested in randomized controlled trials, trials have been typically been small, short term, and limited by methodological issues, hampering the ability to draw conclusions about the effects of these therapies [63, 64].

Treating obesity in children and adolescents

Although there has been considerable progress in developing weight management programmes for adults, there has been less success in developing effective programmes to treat obesity in children. A 2009 Cochrane review found limited quality data to recommend that one treatment programme be favoured over another but found that behavioural interventions aiming to change

diet and physical activity could reduce the level of obesity in children and adolescents at 6 and 12 months after programme start. Some studies in adolescents with moderate to severe obesity found a reduction in weight with the use of medication (orlistat or sibutramine), in addition to a behavioural programme, but side effects were frequent [65].

As well as uncertainty over which types of programmes might be most effective, the provision of treatment for obesity in children and adolescents is also limited by a paucity of services in many countries. A systematic review of interventions for obesity in children and adolescents suitable for use in generalist primary care found only marginal reductions in BMI Z-score [66]. Children with severe obesity should be referred to a specialist centre able to conduct a thorough investigation of the genetic and metabolic status of the child and to offer appropriate interventions, with access to ongoing multi-disciplinary support for the child and their family [67]. On occasions, and for older children, this may include the use of pharmacotherapy or surgery; however, behavioural interventions are the mainstay of obesity treatment for children [65].

Early intervention is preferable because young children are rapidly growing and less weight change is needed to achieve a healthy weight [68]. A US task force has suggested that interventions should be of moderate to high intensity (>75 hours over 6–12 months) and include dietary, physical activity, and behavioural counselling components [69]. Some programmes focus the intervention on parents, especially for very young children, teaching an authoritative parenting style and emphasizing the importance of the family environment as a key determinant of a child's weight [70, 71]. Others, modelled on adult community weight management services, aim to equip children with practical skills relating to diet and physical activity. These interventions have shown some short-term success [72]. However, family-based programmes which take a comprehensive approach to family behaviour change appear to be more effective for older children than treating parent or child alone [73].

Weight loss maintenance

Behavioural, pharmacological, and surgical interventions have all been shown to lead to clinically significant weight loss. However, post-intervention weight regain is very common, particularly in the case of behavioural and pharmacological treatments, as many people find it hard to maintain the cognitive control necessary to restrain their appetite and adhere to a hypoenergetic diet.

Research is ongoing into effective weight loss maintenance treatments, but to date, there is no specific intervention which has shown convincing and reproducible improvements in long-term weight control. A systematic review of non-surgical interventions for weight loss maintenance found that behavioural interventions focusing on both diet and physical activity resulted in an average difference of –1.56 kg (95% confidence interval –2.27 to –0.86 kg) in weight regain, compared with controls, at 12 months. In the same review, orlistat combined with behavioural interventions resulted in a –1.80 kg (–2.54 to –1.06) difference in regain, compared with placebo, at 12 months [74]. Data from cohort studies have identified a number of characteristics associated with long-term weight loss maintenance, including dietary restraint, frequent self-weighing, and engagement in leisure time physical activity [75]. Increases in physical activity also appear to be important in randomized controlled trials, perhaps in offsetting small excesses in energy intake;

systematic reviews have shown better long-term weight loss from interventions combining diet and physical activity than those aiming to change diet alone [76].

However, weight regain is common, and at present, many patients may need to accept the need for repeated intermittent weight loss interventions for long-term weight control. Evidence from large trials with long-term follow-up suggest some residual health benefits from initial weight loss [32, 34, 77].

Preventing weight gain

The high and increasing prevalence of obesity makes interventions to prevent weight gain a public health priority. Such interventions offer the potential for benefit to the whole population, regardless of weight status, by preventing primary weight gain among lean individuals, reducing the risk of further weight gain among those with overweight or obesity, and reducing weight regain post-weight loss.

A 2014 systematic review found that in adults, weight gain prevention interventions such as individual counselling and exercise programmes were associated with reductions in weight and improvements in health outcomes, but it was uncertain as to whether benefits were clinically meaningful and could be maintained over time [78]. In children, a recent systematic review found moderate-quality evidence for school-based obesity prevention interventions but concluded more research was needed to evaluate programmes in other settings and of other designs [79]. Overall, progress to constrain weight gain has been limited. Though isolated areas and interventions have shown improvements, no country to date has managed to reverse the rising prevalence of obesity, suggesting that individual-level interventions or actions in specific settings may be insufficient to offset wider environmental drivers and emphasizing the need for concerted actions by the whole of society to prevent obesity across the life course [80].

Conclusions

Obesity is a chronic, relapsing condition that is associated with significant morbidity and leads to premature death. The health risks of obesity can be offset by effective interventions, which may need to be offered on repeated occasions. As the range of effective interventions increases, attention is focusing on the personalization of care and the optimal combination of interventions to achieve weight loss and to potentially improve specific clinical conditions. Though drugs and surgery can modify an individual's internal physical environment, these treatments may be enhanced when combined with behavioural strategies to help individuals manage the external, obesogenic environment. Moreover, stronger public health interventions to prevent obesity have the potential to enhance individuals' weight loss efforts and to disproportionately benefit people with the greatest susceptibility to weight gain.

Elimination disorders in children and adolescents

Alexander von Gontard

Introduction

Elimination disorders (EDs) comprise the three broad categories of faecal incontinence (FI), daytime urinary incontinence (DUI), and nocturnal enuresis (NE). They are very common and distressing disorders in children. Thus, 1–3% of typically developing 7-year-old children are affected by FI, 2–3% by DUI, and up to 10% by NE [1]. These rates are even higher in children with special needs, for example those with intellectual disability [2]. Untreated, they can persist into adolescence and even adulthood. In addition, the rate of comorbid child psychiatric disturbances is markedly increased in children with EDs—30–50% of children with FI, 20–40% of those with DUI, and 20–30% of those with NE are affected by clinically relevant behavioural or emotional disorders [3].

EDs are a heterogeneous group of disorders with specific signs, symptoms, aetiologies, and treatment approaches. Although the ICD-10 [4] and DSM-5 [5] classification systems provide a general framework, they do not reflect the current state of research [6]. Most of the expanding research on EDs in the past decades has been conducted by paediatricians (especially nephrologists and gastroenterologists), as well as by paediatric urologists, epidemiologists, and basic scientists. Unfortunately, few contributions have come from the field of child psychiatry, despite the high comorbidity rate of psychiatric disorders and the preponderance and effectivity of cognitive behavioural treatment approaches. This output has resulted in two important classification systems, which have superseded those of the ICD-10 [4] and the DSM-5 [5] in clinical practice and research:

- The International Children's Continence Society (ICCS) for DUI and NE [7].
- The Rome IV classification system for FI and constipation [8].

The aim of this chapter is to provide an overview of the current state of knowledge on EDs, as well as to outline practical approaches in assessment and treatment. As EDs can coexist, the chapter will follow the treatment sequence recommended for these combined forms of incontinence—starting with FI, followed by DUI and NE.

Faecal incontinence

FI (or encopresis) is a common disorder, which is associated with stigmatization, distress, and associated comorbid disorders despite good treatment approaches. Two main different subtypes can be differentiated: FI with and without constipation.

Classification

According to the DSM-5 classification system, encopresis occurs either voluntarily or involuntarily and is defined by defecation in inappropriate places [5]. A duration of at least 3 months, a frequency of once per month, and a minimum age of 4 years are also required for diagnosis. This is important, because soiling is still so common in 3-year-old children that it is considered to be part of typical development. Finally, organic causes have to be ruled out. Two subtypes are differentiated, that is, encopresis 'with constipation and overflow incontinence' and 'without constipation and overflow incontinence'. As primary and secondary forms (defined by continent intervals) are identical, this differentiation is not important in encopresis.

The international Rome IV classification system avoids the term encopresis altogether and recommends the neutral term of faecal incontinence [8]. Two basic conditions are differentiated: functional constipation and non-retentive FI. The second change is that constipation is defined as the main disorder, which can coincide, but not necessarily, with soiling. Constipation is more common than FI, and the Rome IV stresses that it is aetiologically the overriding disorder. The second condition is non-retentive FI, denoting soiling without any signs of constipation. The Rome IV diagnostic criteria are listed in [Box 108.1](#) [8]. The criteria are stricter than those of DSM-5, more specific, and based on empirical research, and the duration has been reduced to 1 month.

Prevalence

Encopresis is a common disorder, affecting 1–3% of children from 4 years of age (the definitional age) throughout school years and can persist into adolescence and even adulthood [9, 10]. The prevalence depends on the definitions used; thus, 5.4% of 7-year-old children

Box 108.1 Rome IV diagnostic criteria for functional constipation and non-retentive stool incontinence**I** Diagnostic criteria for functional constipation

Must include two or more of the following, occurring at least once per week for a minimum of 1 month, with insufficient criteria for a diagnosis of irritable bowel syndrome:

- 1 Two or fewer defecations in the toilet per week in a child of a developmental age of at least 4 years.
- 2 At least one episode of faecal incontinence per week.
- 3 History of retentive posturing or excessive volitional stool retention.
- 4 History of painful or hard bowel movements.
- 5 Presence of a large faecal mass in the rectum.
- 6 History of large-diameter stools that may obstruct the toilet.

After appropriate evaluation, the symptoms cannot be fully explained by another medical condition.

II Diagnostic criteria for non-retentive faecal incontinence

At least a 1-month history of the following symptoms in a child with a developmental age older than 4 years:

- 1 Defecation into places inappropriate to the sociocultural context.
- 2 No evidence of faecal retention.
- 3 After appropriate medical evaluation, the faecal incontinence cannot be explained by another medical condition.

Reproduced from *Gastroenterology*, 150(6), Hyams JS, Di Lorenzo C, Saps M, et al., Childhood functional gastrointestinal disorders: child/adolescent, pp. 1456–1468, Copyright (2016), with permission from the AGA Institute.

soiled in total, but only 1.4% once or more per week [11]. Boys are more commonly affected by encopresis than girls (rates: 3–4 times higher in boys). Encopresis occurs almost exclusively during the day. The rare occurrence of nocturnal encopresis is often associated with

Table 108.1 Differences between encopresis with constipation and non-retentive faecal incontinence

	Functional constipation	Non-retentive faecal incontinence
Bowel movements	Seldom	Daily
Large amounts of stools	Yes	No
Normal stools (consistency)	Half	Nearly all
Pain during defecation	Half	Seldom
Abdominal pain	Often	Seldom
Appetite	Reduced	Good
Colon transit time	Long	Normal
Palpable abdominal mass	Often	None
Palpable rectal mass	Often	Never
Rectal diameter (sonography)	Increased	Normal
Daytime urinary incontinence	Tenth	Seldom
Nocturnal enuresis	Third	Tenth
Comorbidity of behavioural and emotional disorders	30–50%	30–50%
Laxative therapy	Helpful	Not helpful, even worsening

Source: data from *Arch Dis Child*, 71(3), Benninga MA, Buller HA, Heymans HS, et al., Is encopresis always the result of constipation?, pp. 186–193, Copyright (1994), BMJ Publishing Group Ltd and the Royal College of Paediatrics and Child Health; *Arch Dis Child*, 89(1), Benninga MA, Voskuil WP, Akkerhuis GW, et al., Colonic transit times and behaviour profiles in children with defecation disorders, pp. 13–16, Copyright (2004), BMJ Publishing Group Ltd and the Royal College of Paediatrics and Child Health.

organic causes. Constipation is more common than encopresis, with a median prevalence of 9% worldwide [12].

Clinical signs

The two subtypes do present with different spectrum of signs and symptoms (**Table 108.1**) [13, 14]. Children with functional constipation have a reduced number of bowel movements with large stools of altered consistency (too soft or too hard). Defecation is often painful. Abdominal pains and reduced appetite are typical. The colon transit time is increased, and abdominal and rectal masses are palpable. The rectal diameter is increased on ultrasound (>30 mm). DUI, and even NE, can coexist. Thirty to 50% have additional emotional and behavioural disorders. Finally, laxative therapy is helpful.

Children with non-retentive FI have daily bowel movements of normal size and consistency. Pains are not typical, and appetite is good. Colon transit time is normal, and no stool masses can be palpated. Enuresis and urinary incontinence are less common, while comorbidity with psychological disturbances is also 30–50%. Finally, laxatives have no effect—and can even worsen the soiling.

Aetiology

Genetic factors do play a role in constipation, as shown in a large twin study—less in FI [15]. Constipation often develops from acute constipation, which can be triggered by both somatic (such as painful defecation due to anal fissures) or psychological factors, including stressful life events (such as separation of parents) [16]. As a consequence, chronic stool retention can follow, characterized by painful defecation, avoidance of defecation, and contraction of the external anal sphincter. Faeces are accumulated in the colon and rectum and colon transit times increase, while peristalsis and sensation decrease. Fluid withdrawal induces large, hard faecal masses. Soiling occurs because of interference with rectal function—and by fresh stools bypassing these faecal masses.

The aetiology of non-retentive FI is not known [9]. It is not due to psychological factors alone, as the comorbidity rate of clinically relevant psychological symptoms is comparable to that of functional constipation [3, 13, 14].

Overall, 30–50% of all children with FI are affected by a comorbid emotional or behavioural disorder. In a large population-based study of children aged 7.5 years, children with encopresis had significantly increased rates of separation anxiety (4.3%), specific phobias (4.3%), generalized anxiety (3.4%), attention-deficit/hyperactivity disorder (ADHD) (9.2%), and oppositional defiant disorder (ODD) (11.9%) [11]. This means that children with FI show a heterogenous pattern of both internalizing and externalizing disorders.

Assessment

The basic steps of assessment are shown in **Table 108.2**. The standard diagnostic procedures are non-invasive, are sufficient for most children, and can be performed in an outpatient setting.

The history is the most important aspect of assessment. Questionnaires can be very helpful to gain additional information. A very useful chart is the Bristol Stool Form, which depicts seven types of stool, depending on consistency and form.

A physical paediatric and neurological examination is recommended to rule out organic causes. Medical causes account for 5% in constipation and for 1% in non-retentive FI. These include anal fissures, abscesses, skin tags, dermatitis, anal stenosis, anorectal

Table 108.2 Assessment of elimination disorders

Faecal incontinence and constipation	Daytime urinary incontinence and nocturnal enuresis
Standard Assessment	
Sufficient for most cases	
History	History
Questionnaires and charts	48-hour frequency/volume chart
Bristol Stool Form Scale	Questionnaires and charts
Physical examination	Physical examination
Sonography	Sonography
Screening for behavioural disorders or full child psychiatric assessment	Screening for behavioural disorders or full child psychiatric assessment
	Urinalysis
Extended Assessment	
Only if indicated	
	Uroflowmetry and pelvic floor EMG
Stool bacteriology	Urine bacteriology
Other diagnostic procedures: plain abdominal X-ray, colon contrast X-ray, MRI of colon, manometry, endoscopy and biopsy	Other diagnostic procedures: radiological examinations, invasive urodynamics, cystoscopy, etc.

malformations, cystic fibrosis, Hirschsprung's disease, coeliac disease, cow milk intolerance/allergy, cerebral palsy, spina bifida, myelomeningocele, and side effects of medication.

Ultrasound is very helpful, as an enlarged rectal diameter of >30 mm is indicative of constipation [17]. Also, by sonography, a rectal examination can be avoided. Due to high comorbidity rates, a clinical child psychiatric assessment, or at least screening with validated parental behavioural questionnaires, is recommended. If many problem scores are checked, assessment and counselling or, if necessary, treatment are recommended [3]. All other examinations are not indicated routinely, but only if an organic type of FI is suspected (such as in Hirschsprung's disease).

Treatment

The first step comprises counselling, provision of information, and psychoeducation. Unspecific measures, such as enhancing motivation and alleviating guilt feelings, are also helpful. Only if the child's food intake is restricted to low-fibre foods is a change in diet recommended. Much more important is to increase fluid intake, as many children do not drink sufficient amounts of liquids.

For both types, toilet training is the basic treatment approach. Children are asked to go to the bathroom three times a day after mealtimes and to sit on the toilet 5–10 minutes in a relaxed way. Children should be given a footstool if their feet do not reach the ground and are allowed to play or read, as they like. They do not need to pass urine or stools every time. These toilet sessions are documented in charts. The toilet training procedures have the effect of regulating defecation habits over the day, as the postprandial defecation reflexes are most active after mealtimes.

In non-retentive FI, this toilet training is the main treatment. Laxatives are not indicated. In children with constipation, toilet training is combined with laxative treatment—first disimpaction, then maintenance treatment.

Disimpaction is necessary to evacuate faecal masses at the beginning of treatment. The preferred way is orally with high doses of polyethyleneglycol (PEG—macrogol), for example up to 1.5 g/kg body weight per day, until disimpaction is successful. If not sufficient, rectal disimpaction with enemas are a good alternative—containing either phosphate or sorbite. Recommended doses are 30 mL per 10 kg body weight or half an enema for preschool children, and 3/4 to one enema in schoolchildren. Often, these have to be repeated several times. Both forms of disimpaction are effective [18].

After successful disimpaction, long-term maintenance treatment over a minimum of 6–24 months is recommended to avoid reaccumulation of stool masses. In addition to toilet training three times a day after mealtimes, oral laxatives are given. The preferred and most effective laxative is PEG (macrogol), a long, linear osmotic polymer that binds water [19, 20]. Side effects, such as abdominal pain, are rare. The initial dose is 0.4 g/kg body weight per day in two doses. If stools are too hard, the dose is increased—if too soft, reduced. The therapeutic range varies from 0.2 to 1.4 g/kg body weight per day [21]. Lactulose, a disaccharide, is less effective and has more side effects. The dosage of liquid lactulose ranges from 1 to 3 mL/kg body weight per day in 1–3 doses.

The long-term course of both types of FI is not favourable. Constipation and non-retentive FI can persist into adolescence and even young adulthood [9, 10]. Therefore, constipation and non-retentive FI needs to be treated actively, with regular follow-up visits.

In children with a combination of EDs, treatment of functional constipation and non-retentive FI should always be the first step for two reasons; on the one hand, both DUI and NE can remit by successful treatment; on the other hand, the outcomes of DUI and NE are much worse if constipation and FI are not addressed.

Daytime urinary incontinence

DUI and NE are even more common disorders than FI. They are lumped together in the ICD-10 [4] and DSM-5 [5] classification systems under the term enuresis. DSM-5 defines enuresis as an involuntary or intentional wetting of children 5 years of age or older after organic causes have been ruled out. The wetting must have persisted for 3 months or longer and must occur at least twice per week or else must cause clinically significant distress or impairment. Only nocturnal, diurnal, or combined enuresis are differentiated—no other subtypes. As DSM-5 is not up-to-date with the current state of research, newer classification systems are needed [6].

The standard classification is provided by the ICCS [7]. It is based on international, multiprofessional consensus, including paediatricians, paediatric urologists, and child psychiatrists. The criteria have become mandatory at international meetings and for publication in journals.

According to the ICCS terminology, urinary incontinence is a general umbrella term for the symptom of any 'uncontrollable leakage of urine', which can be continuous (which is rare and usually caused by organic conditions) or intermittent (which is common and usually functional). An overview is provided in Table 108.3.

Any daytime wetting is termed daytime urinary incontinence, which can be organic (structural, neurogenic, or due to other paediatric causes) or, in most cases, functional. The term 'diurnal enuresis' is obsolete and should be avoided. If a child wets during sleep and

during the day, he or she would receive two diagnoses: one for the NE and one for the DUI.

Further specifications of the ICCS criteria are shown in [Table 108.3](#). The lower chronological age limit is 5 years, and a duration of 3 months and a frequency of once per month are required. Frequent and infrequent wetting can be differentiated. Rare wetting of less than once a month is considered to be a symptom, but not a condition. Organic causes have to be ruled out. These encompass structural causes (such as epi- and hypospadias, urethral valves and stenosis, other malformations of the urogenital tract), neurological causes (such as spina bifida, tethered cord syndrome and others), and medical causes (diabetes, urinary tract infections). Finally, many different subtypes of DUI can be differentiated.

The three main syndromes of DUI are urge incontinence, voiding postponement, and dysfunctional voiding. Each types of DUI has typical symptoms, which are summarized in [Table 108.4](#). *Urge incontinence (or overactive bladder)* is characterized by urge symptoms, increased micturition frequency, and small voided volumes. In contrast, in *voiding postponement*, low micturition frequency and postponement of micturition are typical. In both cases, children employ holding manoeuvres to avoid wetting. *Dysfunctional voiding* is a disorder of the emptying phase; instead of relaxing the sphincter muscle, it is contracted paradoxically. Straining and an interrupted urine stream are indicative of this disorder. *Stress incontinence* is rare in children—in contrast to adults. Wetting during coughing, sneezing (that is, any increase of intra-abdominal pressure), and small volumes are typical. *Giggle incontinence* is characterized by wetting during laughing and large volumes with apparently complete emptying. *Detrusor underactivity*, a decompensation of the detrusor muscle, is marked by an interrupted stream; emptying of the bladder is possible only by straining. Wetting exclusively 5–10 minutes after normal micturition is typical of a *vaginal reflux*. *Functional obstruction* can impede urine flow, and *diurnal urinary frequency of childhood* is a

benign, self-limiting condition with typical signs of frequency and urgency (often without incontinence).

Prevalence and clinical presentation

One and a half times more girls than boys are affected by DUI. Two to 3% of 7-year olds and <1% of adolescents wet during the day. Urge incontinence and voiding postponement are the two most prevalent types. The clinical signs of the three common disorders will be presented in more detail.

Children with *urge incontinence* are characterized by a high micturition frequency of >7 times per day, with short intervals in between. Children typically have urge symptoms—sometimes with sudden, intensive (imperative) urge. They wet small volumes, especially during the afternoons, increasing with tiredness. They try to stop the urge by initiating holding manoeuvres such as contracting pelvic floor muscles, pressing the thighs together, holding the abdomen, jumping from one leg to the next, sitting on the heels, and squatting with the heels pressed against the perineum (curtsey sign). Vulvovaginitis, perigenital dermatitis, and urinary tract infections are common.

Typical signs of *voiding postponement* are a low micturition frequency (<5 times per day) and the habitual postponement of micturition in certain situations (school, play, reading, television). With increasing deferral and fullness of the bladder, holding manoeuvres are instituted (as in urge incontinence) until wetting cannot be avoided. Constipation and encopresis are common. Children have a high rate of psychological disorders such as ODD [22].

Dysfunctional voiding is characterized by repeated straining at the beginning and during micturition, intermittent and fractioned urine flow, incomplete bladder emptying with residual urine, urinary tract infections, stool retention, constipation, FI, and vesico-ureteral refluxes.

The comorbidity rate of psychological symptoms and disorders among children with DUI (30–40%) is higher, compared to children with enuresis (20–40%) [3]. In a population-based study of 8242 children at 7.5 years of age, externalizing disorders were prominent, with significantly increased rates of ADHD (24.8%), ODD (10.9%), and conduct disorders (11.8%) [23].

Aetiology

Genetic factors play a role in DUI as well. In a large population-based study, the odds ratio for daytime incontinence was increased by 3.28 if the mother, and by 10.1 if the father, was affected [24]. Linkage studies demonstrated a positive linkage to chromosome 17 in urge incontinence [25]. Urge incontinence is caused by spontaneous contractions of the detrusor during the filling phase of the bladder, which are not sufficiently inhibited by the central nervous system [26]. Genetic factors also play a major role in giggle incontinence—but not in the other types of incontinence.

Psychosocial factors do, however, play a major role in the aetiology of subtypes of daytime incontinence. Voiding postponement can be due to an acquired habit—or as one of many oppositional symptoms as part of ODD [22].

Assessment

Assessment and a detailed diagnosis is the core of successful treatment—as each subtype of DUI responds best to their specific treatment. The steps are outlined in [Table 108.1](#) and are quite

Table 108.3 Basic definitions of the ICCS for daytime urinary incontinence (DUI) and nocturnal enuresis (NE)

DUI	NE (or enuresis)
Intermittent incontinence	Intermittent incontinence
Wetting during day (wake state)	Any wetting during sleep
Minimum chronological age of 5 years	Minimum chronological age of 5 years
Duration of 3 months	Duration of 3 months
Minimum frequency of once per month	Minimum frequency of once per month
Symptom, not disorder: less than once per month:	Symptom, not disorder: less than once per month:
Frequent incontinence: ≥4 times/week	Frequent incontinence: ≥4 times/week
Infrequent incontinence: <4 times/week	Infrequent incontinence: <4 times/week
Exclusion of organic causes	Exclusion of organic causes
Many different subtypes	Four different subtypes

Table 108.4 Classification of daytime urinary incontinence (DUI) with main distinguishing symptoms according to the ICCS

Type of daytime wetting	Main symptoms and features
Common types	
Overactive bladder (OAB) and urge incontinence	Urge symptoms, increased daytime voiding frequency, and small voided volumes
Voiding postponement	Infrequent micturitions <5 times per day, postponement
Dysfunctional voiding	Straining to initiate and during micturition, interrupted stream of urine
Rare types	
Giggle incontinence	Wetting during laughing, large volumes with apparently complete emptying
Stress incontinence	Wetting during coughing and sneezing, small volumes
Underactive bladder	Interrupted stream, emptying of bladder possible only by straining
Vaginal reflux	Wetting exclusively 5–10 minutes after normal micturition due to vaginal reflux
Obstruction	Impediment (can be functional) to urine outflow, decreased urine flow
Diurnal urinary frequency of childhood	Benign, self-limiting condition with typical signs of frequency and urgency

Source: data from *Neurourol Urodyn*, 35(4), Austin PF, Bauer S, Bower W, *et al.*, The Standardization of Terminology of Bladder Function in Children and Adolescents: Update Report from the Standardization Committee of the International Children's Continence Society (ICCS), pp. 471–81, Copyright (2016), John Wiley and Sons.

comparable to those of FI. Very important is the registration of micturition volumes and times, fluid intake, and other observations in a 48-hour micturition chart. Sonography of the bladder and kidney is a valuable instrument to detect malformations and measure the bladder wall thickness (which is often increased in DUI) and residual urine after micturition. Urinalysis is recommended, and a dipstick is usually sufficient. Uroflowmetry is also non-invasive and is performed routinely in many centres, but is mandatory only in dysfunctional voiding.

Treatment

The basic approaches include provision of information, increasing fluid intake, counselling regarding micturition habits, and registering incontinence episodes [27]. This non-pharmacological, non-surgical treatment of incontinence has been named 'urotherapy' and contains many elements of cognitive behavioural therapy (CBT). Treatment is always symptom-oriented, with the aim of achieving complete dryness. Comorbid psychiatric disorders are addressed separately and will increase motivation and outcomes.

The main focus in the treatment of *urge incontinence* is a symptom-oriented cognitive behavioural approach aimed at conscious control of the urge without the use of the pelvic floor muscles, that is, holding manoeuvres. Children are instructed to register when they feel an urge, to go to the toilet immediately without using holding manoeuvres, and to register in a chart if their pants were dry or wet. If these simple techniques are not sufficient, pharmacotherapy with an anticholinergic medication is recommended in addition. First-line drugs are oxybutinin or propiverin. Oxybutinin is dosed

initially at 0.3 mg per kg body weight/day in three doses and can be increased to 0.6 mg per kg body weight/day (maximum of 15 mg/day). The side effects are dose-dependent and reversible. They include typical anticholinergic effects such as flushing, accommodation problems, tachycardia, hyperactivity, dryness in the mouth, residual urine, and constipation. Propiverin has fewer side effects but is not available in many countries. The dosage is a maximum of 0.8 mg per kg body weight/day in two doses (total maximum of 15 mg/day). Recently, the effects of percutaneous electrostimulation [transcutaneous electrical nerve stimulation (TENS)] have been very promising.

Timed voiding is indicated in all cases of *voiding postponement*. Children and parents are instructed to increase the micturition frequency up to seven times per day in regular intervals and to register the course in a chart. Medication is not indicated.

Treatment of *dysfunctional voiding* includes increasing motivation, cognitive behavioural elements, relaxation and general drinking, and toileting advice [28]. The most specific and effective treatment is biofeedback—either with uroflowmetry or pelvic floor electromyography (EMG). Medication is again not indicated [28].

In therapy-resistant cases, structured group therapies have been successful [29]. These combine counselling, provision of information, relaxation techniques, and cognitive behavioural, play, and group therapy approaches.

Outlook

The outlook of DUI is quite favourable in children with DUI, provided that a specific treatment based on an exact diagnosis is provided. In children with combined EDs, the treatment of DUI should follow after that of FI and/or constipation—but before that of NE. In many children with combined DUI and NE, the NE will resolve upon successful management of the daytime problems.

Nocturnal enuresis

NE is 2–3 times more common than DUI. As presented earlier, NE and DUI are lumped together in the ICD-10 [4] and DSM-5 [5] classification systems, although they are completely different disorders. Therefore, the ICCS classification is again important for the correct diagnosis of NE and its subtypes [7]. NE denotes any wetting during sleep (at night or daytime naps). In fact, the term enuresis can be used without the addition of the adjective nocturnal, as the term of so-called 'diurnal enuresis' is discouraged. If a child wets while sleeping and while awake, two diagnoses are given: one for the type of NE and one for the type of DUI (Table 108.5).

Many diagnostic criteria are the same in DUI as in NE (Table 108.2). The classification of NE (or enuresis for short) is simple (Table 108.1), based on the longest previous dry period and on concomitant lower urinary tract symptoms (LUTS). *Primary enuresis* means that the child has been dry for <6 months; *secondary enuresis* indicates that a relapse after a dry period of at least 6 months has occurred. Children with secondary enuresis have experienced stressful life events and have higher rates of comorbid psychiatric disorders. Otherwise, assessment and treatment of primary and secondary enuresis are exactly the same.

Table 108.5 Subtypes of nocturnal enuresis according to ICCS terminology

		Maximal dry interval of <6 months	Maximal dry interval of >6 months
		Primary nocturnal enuresis (PNE)	Secondary nocturnal enuresis (SNE)
No signs of bladder dysfunction* during daytime	Monosymptomatic nocturnal enuresis (MNE)	Primary monosymptomatic nocturnal enuresis (PMNE)	Secondary monosymptomatic nocturnal enuresis (SMNE)
Signs of bladder dysfunction* during daytime present	Non-monosymptomatic nocturnal enuresis (NMNE)	Primary non-monosymptomatic nocturnal enuresis (PNMNE)	Secondary non-monosymptomatic nocturnal enuresis (SNMNE)

* Daytime incontinence, urgency, frequency, holding manoeuvres, interrupted flow, etc.

Source: data from *Neurourol Urodyn*, 35(4), Austin PF, Bauer S, Bower W, *et al.*, The Standardization of Terminology of Bladder Function in Children and Adolescents: Update Report from the Standardization Committee of the International Children's Continence Society (ICCS), pp. 471–81, Copyright (2016), John Wiley and Sons.

The second division is far more important—children with NE, but without daytime LUTS, have *monosymptomatic* enuresis. NE and LUTS is called *non-monosymptomatic* enuresis. In non-monosymptomatic NE, daytime symptoms have to be treated first before addressing the night-time wetting to achieve treatment success [30].

Prevalence

One and a half to two times more boys are affected by NE than girls. The prevalence is 10% among 7-year-old children, 1–2% among adolescents, and 0.3–1.7% among adults. The mean spontaneous remission rate is 15% per year. Primary enuresis is more common than secondary enuresis, and monosymptomatic enuresis is twice as common as non-monosymptomatic enuresis.

Signs and symptoms

Typical symptoms of *monosymptomatic NE* are deep sleep and difficult arousal and increased urine volumes at night (polyuria) with large wetted volumes. Bladder function during the day is completely normal.

Children with *non-monosymptomatic NE* have the same symptoms, but in addition, they have similar signs as those with DUI (except for wetting during the day). Also, urinary tract infections, constipation, and FI are possible.

Children with *primary* and *secondary NE* have the same symptoms, except for a higher rate of comorbid psychiatric disorders in the latter group.

Overall, 20–30% of children with enuresis, 20–40% of those with urinary incontinence, and 30–50% of those with encopresis have clinically relevant disorders [3].

Externalizing disorders predominate, but internalizing disturbances can occur as well. In a British population-based study of 8242 children at the age of 7.5 years, children with enuresis were affected by separation anxiety (8.0%), social anxiety (70%), specific phobia (14.1%), generalized anxiety (10.5%), depression (14.2%), ODD (8.8%), conduct disorders (8.5%), and ADHD (17.6%) [31]. ADHD is the most common comorbid disorder in enuresis. Enuresis in combination with ADHD is more difficult to treat due to non-compliance.

Aetiology

Enuresis is a genetically determined maturational disorder of the central nervous system [32]. Seventy to 80% of all children with enuresis have affected relatives. The concordance rates are higher among mono- than dizygotic twins. In linkage studies, several loci on chromosomes 12, 13, and 22 could be identified—irrespective of the subtypes of enuresis [32].

Three main mechanisms are responsible for the development of enuresis. Firstly, increased urine volumes (polyuria) affects some, but not all, children. This is associated with a circadian variation (but not lack) of antidiuretic hormone (ADH). Secondly, impaired arousal is another important factor, as children do not respond to signals of their full bladder to wake up. Thirdly, children have an inhibition deficit of the brainstem and do not adequately suppress the emptying reflexes of the bladder while sleeping. The same factors are responsible for the development of *non-monosymptomatic enuresis*—in addition to local bladder dysfunction. Psychosocial factors can modulate these genetic and neurobiological risks and lead to relapses or a continuation of NE.

Assessment and treatment

Assessment of NE is the same as that of DUI. Also, basic urotherapy, provision of information, and counselling are the first steps, combined with recording of dry and wet nights on a calendar over a baseline period of 4 weeks. Children are asked to draw a symbol for wet and dry nights (clouds and suns, stars, etc.) on a chart. Any daytime symptoms in *non-monosymptomatic NE* should be treated first [30]. These simple measures will achieve dryness in 15–20% without any further intervention.

If children continue to wet, the first-line treatment is alarm therapy, which requires active co-operation of the child and family [33]. If alarm treatment is not feasible, then it is advisable to start with desmopressin medication first.

Approximately 70% achieve dryness, with long-term cure rates of 50%. Two different types of alarms exist, the body-worn and bedside alarms, and both are equally effective. In case of wetting, the alarm is triggered and the child should wake up completely, go to the toilet, and void any remaining urine. Parents are asked to document the course of the treatment in a chart. To be successful, the alarm must be used consecutively every night for a maximum of 16 weeks. After 14 consecutive dry nights, the alarm is discontinued and the child is considered to be dry. Parents are advised to restart alarm treatment if a relapse occurs. If not sufficient, alarm treatment can be combined with additional CBT components. If a child does not respond to the alarm, a switch to desmopressin, the second-line treatment, is recommended.

Indications for medication are therapy resistance towards alarm treatment, lack of motivation in the children, stress in the family, lack of co-operation, and the requirement of short-term dryness, that is, for school outings, etc. Desmopressin is the medication of choice in these cases due to positive effects and few side effects. Desmopressin (or DDAVP) is a synthetic analogue of ADH. In 70%, a reduction of wet nights or even dryness can be achieved, but after discontinuing medication, most children have a relapse, so that only

18–38% of children remain dry in the long run. It has a distinctly lower curative effect than the alarm.

Desmopressin is given 30–60 minutes before going to sleep in the evenings only. The oral dosage is 0.2–0.4 mg—or 120–240 µg as a melt tablet. It is advisable to titrate the required dose over 4 weeks, starting with the low dose first and increasing the dose only if necessary. This should be documented on a chart. If a child does not respond within 4 weeks, he or she should be considered to be a non-responder and desmopressin is discontinued. Otherwise, one can continue with the required dosage for a maximum of 12 weeks, after which desmopressin should be stopped—to check if the child can remain dry without medication. If a relapse occurs, desmopressin can be given in 3-month blocks. Adverse effects are rare and not pronounced, like headache, stomach ache, lack of appetite, etc. The most dramatic, though rare, side effect is hyponatraemia and water intoxication, which can require intensive care. Therefore, it is important not to overdose—and not to drink <8 oz (250 mL) after taking the medication.

Tricyclic drugs like imipramine have a proven antienuretic effect—and similar relapse rates as desmopressin. Due to the risk of cardiac arrhythmias and intoxication in high doses, it has become a third-line treatment in therapy-resistant cases. Also, imipramine needs close clinical and laboratory surveillance.

Outlook

NE has the best treatment results of all EDs, again provided that an exact diagnosis is made and the recommended guidelines are followed. In children with combined EDs, NE is the last condition in the treatment sequence.

Summary

The aim of this chapter was to provide an overview on EDs in children and adolescents. The clinical aspects of the three major groups of FI, DUI, and NE were presented. These are heterogeneous disorders with divergent aetiologies, symptoms, and treatment approaches. Most EDs are functional, that is, non-organic. The guidelines for assessment and treatment are logical, and if followed, the outcome is quite promising. The treatment is symptom-oriented, with the goal of complete continence, and comorbid psychiatric disorders, which are common but do not affect most children with EDs, need to be addressed. A multi-disciplinary approach can be very helpful.

Circadian rhythms

Circadian rhythms are endogenous 24-hour oscillations in physiology and behaviour that enable an organism to anticipate and adapt to the changing temporal demands of the environment [1]. The term circadian is derived from the Latin for ‘around a day’. The sleep/wake cycle is the most obvious example of a circadian rhythm. Other examples include daily fluctuations in locomotor activity, core body temperature, heart rate, blood pressure, renal activity, liver metabolism, and secretion of glucocorticoids, melatonin, and testosterone [2, 3]. Circadian rhythms in physiological parameters are not unique to man; they are observed in organisms as diverse as cyanobacteria, fungi, algae, plants, *Drosophila*, and rodents [4]. Circadian rhythms confer a survival advantage to organisms that possess them, increasing their reproductive fitness. For example, ground squirrels lacking endogenous rhythms are more vulnerable to predation and show a 20% reduction in lifespan [5].

Any circadian rhythm must meet three criteria [1]. Firstly, it must persist under constant conditions (that is, in the absence of changes in temperature or light), with an endogenous (or ‘free-running’) period of approximately 24 hours. This distinguishes internally driven rhythms from responses to external cues. Secondly, it must be entrainable. To anticipate daily environmental events (for example, sunrise), the rhythm must be able to adjust to changes in the timing of these events. For example, the timing of sunrise varies between geographical locations and also changes across the seasons. This process of synchronization is known as entrainment, and an external stimulus that can synchronize a circadian rhythm is called a *zeitgeber*, German for ‘time-giver’. Finally, a circadian rhythm must be temperature-compensated, meaning that its periodicity should remain constant over a range of physiological temperatures.

Mechanistic basis of circadian rhythms

Mammals possess a circadian ‘master clock’ which resides in the suprachiasmatic nucleus (SCN), a small brain structure composed of approximately 20,000 neurons, located in the anterior

hypothalamus, just above the optic chiasm [6]. The role of the SCN was first shown by rodent lesion studies; in rats, circadian rhythms in water consumption, locomotor activity, and corticosterone secretion were all abolished by SCN ablation [7, 8]. In hamsters, transplantation of neonatal hypothalamic tissue (including the SCN) can restore circadian rhythms following SCN ablation [9]. Moreover, transplanting SCN tissue from *tau* mutant hamsters, which have a 20-hour circadian period, imposes a 20-hour period on the recipient [10]. In humans, compression of the SCN by expanding pituitary tumours causes progressive circadian disintegration [11]. In the 1970s and 1980s, *in vivo* oscillations in glucose uptake and electrical activity were first reported in the rat SCN; both were upregulated in the day [12, 13]. Analogous results were subsequently reported with *in vitro* slice preparations [14]. Rhythmic firing was later observed in isolated cultured neurons, demonstrating that circadian oscillations result from subcellular mechanisms, rather than cell–cell interactions [6].

The molecular circadian clock

Today, the molecular basis of mammalian circadian rhythms is well characterized. The basic mechanism is an autoregulatory transcriptional–translational feedback loop (TTFL), involving four core ‘clock genes’: Period (*Per1* and *Per2*), Cryptochrome (*Cry1* and *Cry2*), Brain and Muscle ARNT-Like (*Bmal1*), and Circadian Locomotor Output Cycles Kaput (*Clock*) [15]. These genes encode the proteins PER1-2, CRY1-2, BMAL1, and CLOCK, respectively [15]. The basic clock mechanism involves the binding of CLOCK and BMAL1 to E-box enhancers in the promoters of *Per1-2* and *Cry1-2*, driving their expression. In turn, PER and CRY form homo- and heterodimers and inhibit CLOCK/BMAL1 binding, providing a negative feedback loop. In addition, several other genes are known to regulate the mammalian TTFL. For example, casein kinase 1 (*Ck1*) plays an important role in setting the core clock speed by phosphorylating PER proteins, which targets them for ubiquitylation and proteasomal degradation [16].

The TTFL in the SCN is synchronized with the environment by light input from the retina. Light information is transmitted from the eye to the SCN via photosensitive retinal ganglion cells (pRGCs).

Although they also receive input from rod and cone photoreceptors, pRGCs are intrinsically photosensitive due to their expression of the photopigment melanopsin. Ablation of pRGCs impairs photic entrainment in mice but spares pattern-forming visual function [17]. The axons of pRGCs, which form the retinohypothalamic tract (RHT), synapse directly with the SCN [18, 19]. Glutamate and pituitary adenylyl cyclase-activating polypeptide (PACAP) are the principal neurotransmitters at these synapses [20]. Although light information is the primary *zeitgeber* for the entrainment of the circadian clock, the timing of other events such as feeding and exercise can also be considered *zeitgebers*, which affect the SCN via non-photoc pathways [1].

Clock outputs

How does the action of the TTFL translate into circadian rhythms in physiology and behaviour? The immediate output of the TTFL is the rhythmic expression of ‘clock-controlled genes’ within the SCN itself [11, 21]. These genes are not part of the TTFL but show rhythmic expression because they possess E-boxes. In turn, these clock-controlled genes regulate the expression of their own downstream target genes. The net result is that roughly 10% of the SCN transcriptome is rhythmically expressed. It is unclear how rhythmic patterns of electrical activity are generated in the SCN [20], but these oscillations are conveyed to other brain regions by monosynaptic or multisynaptic pathways, or via the rhythmic synthesis and secretion of peptide hormones such as vasoactive intestinal peptide (VIP) [11, 21]. The SCN’s target regions are ultimately responsible for the co-ordination of circadian physiology and behaviour. Examples include the rhythmic secretion of the hormone melatonin from the pineal gland and the rhythmic secretion of corticotropin-releasing hormone (CRH) from the hypothalamus, which leads to the release of glucocorticoids from the adrenal glands [11, 21].

Multiple body tissues show self-sustained rhythmic clock gene expression *in vitro* [21, 22]. Initially observed in rodent fibroblasts [23], these peripheral rhythms are particularly well characterized in the liver [24]. As in the SCN, around 10% of the transcriptome is rhythmically expressed in most peripheral tissues [25]. In the brain, rhythmic electrical activity, hormone output, and clock gene expression has been reported in the olfactory bulb, amygdala, lateral habenula, hippocampus, motor cortex, and cerebellum, together with a variety of nuclei in the hypothalamus [21, 22]. Taken together, it appears that the brain and body are full of localized autonomous circadian clocks. The SCN synchronizes these peripheral clocks with each other and the external environment [11, 21]. Glucocorticoids may be one synchronizing signal; the administration of the glucocorticoid dexamethasone is known to synchronize 60% of the liver’s circadian transcriptome [11, 21].

Sleep

Sleep is a recurring physiological state characterized by altered consciousness, reduced perception of environmental stimuli, and inhibition of most voluntary muscles [26]. Although we spend around a third of our lives asleep, the exact functions of sleep are not well understood. Popular theories include rejuvenation of the immune system [27] and repair and regeneration of nervous tissue, bone, and muscle [26]. From a cognitive perspective, sleep may be important

for memory consolidation [28], while according to the synaptic homeostasis hypothesis, sleep is required to reverse the net increase in synaptic strength which occurs in many brain circuits during wakefulness [29]. Whatever the functional roles of sleep, its importance is underscored by the myriad health problems that are associated with sleep disruption.

In humans, sleep consists of both rapid eye movement (REM) sleep and non-rapid eye movement (NREM) sleep, which has three stages [30–32]. During sleep, the body repeatedly cycles through these stages in a predictable and sequential manner, progressing through NREM stages 1, 2, and 3 and ending with REM sleep. Typically, the first cycle lasts 70–100 minutes, and subsequent cycles last 90–120 minutes. Four to five cycles are completed each night. REM sleep accounts for 20–25% of total sleep time, and the proportion of REM sleep increases across cycles. Conversely, the proportion of stage 3 NREM sleep (also known as slow-wave sleep) tends to decrease across cycles. Arousal threshold increases with each NREM stage, while muscle activity and eye movements decrease [30–32]. The three NREM stages are characterized by oscillatory brain activity of different frequencies. Sleep spindles and K-complexes occur at the onset of stage 2 NREM sleep. During REM sleep, there is vigorous eye movement, but most voluntary muscles are paralysed. Brain activity in REM sleep closely resembles that observed during wakefulness. REM sleep is also associated with dreaming, an association first noted in the early 1950s [33].

Mechanistic basis of sleep and wakefulness

Wakefulness is a state of alertness characterized by high forebrain and cortical activity, which is promoted by the ascending arousal system (AAS) [34]. The AAS originates in the upper brainstem [35] and can be broadly divided into two separate pathways, each innervating distinct brain regions and involving different neurotransmitters [36]. The first pathway consists of cholinergic projections from the pedunculopontine (PPT) and laterodorsal tegmental (LDT) nuclei of the brainstem, which are more active during wakefulness and REM sleep and less active during NREM sleep [37]. One of their key targets is the thalamic reticular nucleus (TRN), which inhibits thalamocortical rhythms to promote wakefulness [38]. The second pathway innervates multiple targets in the hypothalamus, forebrain, and cerebral cortex [36]. It consists of noradrenergic projections from the locus caeruleus (LC), serotonergic projections from the dorsal and medial raphe nuclei (DRN and MRN), dopaminergic projections from the ventral periaqueductal grey (VPAG), and histaminergic projections from the tuberomammillary nucleus (TMN) [34]. It also includes cholinergic and GABAergic projections from basal forebrain (BF) nuclei and peptidergic projections from lateral hypothalamic (LH) nuclei [34]. These LH neurons can be subdivided into those expressing orexin (also known as hypocretin) and those expressing melatonin-concentrating hormone (MCH). Monoaminergic and orexinergic neurons are most active during wakefulness, less active during NREM sleep, and least active during REM sleep [35]. In contrast, the MCH-releasing neurons are most active during REM sleep [39], and the cholinergic neurons are most active during REM sleep and wakefulness [40].

The AAS is inhibited by the ventrolateral preoptic nucleus, or VLPO, a small cluster of neurons in the anterior hypothalamus [34]. During sleep, a subpopulation of VLPO neurons is highly active [41] and suppresses the AAS through the release of the inhibitory

neurotransmitters GABA and galanin [42, 43]. Central VLPO lesions are known to reduce NREM sleep, while lesions to the extended VLPO decrease REM sleep [44]. In addition to the suppression of the AAS by the VLPO, neurons in the VLPO can be inhibited by the AAS. This inhibition is driven by noradrenergic projections to the VLPO from the LC, serotonergic projections from the MRN, and GABAergic and galinergic projections from the TMN [45]. As such, there is reciprocal inhibition between the AAS and the VLPO. The AAS inhibits the VLPO during wake, and the VLPO inhibits the AAS during sleep. It has been proposed that this reciprocal inhibition creates a bi-stable ‘flip-flop’ circuit—whereby sleep and wake cannot be promoted at the same time. This putative mechanism, also known as the ‘sleep switch’, may explain why sleep–wake transitions are swift [36, 37].

Sleep timing: the two-process model of sleep

Sleep timing is thought to be dependent on two hypothetical mechanisms [46, 47]. The first, known as ‘Process S’, describes a homeostatic drive for sleep, which increases progressively during wakefulness and dissipates during sleep. The biological substrate of this mechanism is unproven, although adenosine is a likely candidate. Adenosine accumulates in the brain during wakefulness [48], while the administration of adenosine or adenosine receptor agonists promotes sleep in rats and cats [49, 50]. These pharmacological effects are likely mediated by the excitation of sleep-promoting brain regions and the inhibition of wake-promoting regions [34]. Recent evidence suggests that adenosine accumulation is also responsible for the antidepressant effect of sleep deprivation [51].

The second component of the two-process model—‘Process C’—describes the contribution of the circadian clock to sleep regulation [46, 47]. More specifically, it describes a circadian drive for wakefulness, which rises during the day and falls during the evening and night. According to the two-process model, Process C counteracts Process S to keep us awake during daytime when homeostatic sleep pressure is steadily increasing. In the evening, sleep onset coincides with the opening of the ‘sleep gate’, the point at which the discrepancy between Processes S and C reaches a critical threshold. SCN lesions in primates result in increased sleep time, as well as arrhythmia [52]. This suggests that under normal conditions, signals from the SCN oppose the homeostatic drive for sleep, providing a plausible biological substrate for Process C. These signals may be carried by projections from the SCN to the ventral subparaventricular zone (SPZ) and the dorsomedial nucleus of the hypothalamus (DMH). In rats, lesions of both structures impair the circadian rhythmicity of the sleep/wake cycle [44, 53]. The DMH may be a critical relay between Processes C and S, as it receives inputs from the SCN and SPZ and innervates both the VLPO and the LH nuclei of the AAS [53].

Sleep and circadian rhythm disruption in psychiatric disorders

The relationship between severe mental illness and abnormal sleep was first described in the late nineteenth century by the German psychiatrist Emil Kraepelin [54]. Today, sleep and circadian rhythm disruption (SCRD) is reported in 30–80% of patients with schizophrenia and is increasingly recognized as one of the most common features of the disorder [55]. Moreover, recent evidence suggests that

the degree of SCRD is correlated with the severity of positive, negative, and cognitive symptoms [56–59]. Sleep disturbances in schizophrenia include increases in sleep latency and reductions in total sleep time, sleep efficiency, REM sleep latency, REM sleep density, and slow-wave sleep duration [54, 55, 60–62]. Schizophrenia is also associated with significant circadian disruption such as abnormal phasing, instability, and fragmentation of rest–activity rhythms [63–66]. Crucially, schizophrenia patients with SCRD score badly on many quality-of-life clinical subscales, highlighting the human cost of SCRD in schizophrenia [55, 67, 68]. Furthermore, patients often comment that an improvement in sleep is one of their highest therapeutic priorities [69].

SCRD is not limited to schizophrenia. Up to 90% of patients suffering from an acute depressive episode report simultaneous changes in their sleep profile that are usually described as difficulties initiating and maintaining sleep during the night. Significantly, persistent insomnia increases the risk of relapse into a new depressive episode [70]. Increased sleep disruption, as in mothers after childbirth, raises the risk of post-partum depression, with poorer sleep quality correlated with more severe depression [71]. Seasonal affective disorder (SAD), or ‘winter depression’, is clinically classified as a subtype of major depression that describes a condition of serious mood alteration associated with a change in the season towards autumn and winter. Individuals tend to show excessive daytime sleepiness, have little energy, and crave sweets and carbohydrates. SAD individuals may also feel profoundly depressed. While there is a trend suggesting an overall increase in the prevalence of SAD with increasing latitude and with the shortened daily light period during the winter season, there is considerable country-to-country variation [72, 73]. These inconsistencies in the prevalence of SAD might be because this condition is a more severe expression of the naturally occurring seasonal variation in mood experienced by a large percentage of the general population. The best evidence that there is a recurrent, seasonally influenced winter depressive condition that is a function of an interaction between light and internal circadian and/or circannual rhythms is the very high success rate of phototherapy [74]. In individuals with a diagnosis of bipolar disorder, disruption of their 24-hour sleep/wake cycle, shortened sleep, or travel across multiple time zones seems to act as an important trigger for a relapse (77% of patients) into mania [75]. By contrast, during the depressed phase, patients may become hypersomnolent, sleeping up to 12–14 hours per day [76]. Sleep in alcoholics is disturbed both on drinking nights and on nights during withdrawal. During periods of heavy drinking and up to 2 years after discontinuation of alcohol intake, sleep consists mainly of reduced NREM states, while REM sleep is suppressed and sleep duration is short, with sleep of the second half of a normal 8-hour bedtime being fragmented [77]. Rates of insomnia in this population are reported to be between 40% and 70%. Interestingly, those alcohol users who have a good prognosis for recovery are those individuals who tend to return to normal ratios of NREM/REM sleep and who overall sleep well [77]. Excessive alcohol consumption can cause depressive-like states—indeed, ethanol is classified as a depressant drug, mainly through its sedative effects via GABA facilitation and inhibition of glutamatergic NMDA function [77]. Finally, the relationship between disrupted sleep and various anxiety-related disorders is well recognized, but the cause and effect can be difficult to untangle. For example, insomnia predisposes

individuals to anxiety which, in turn, precipitates sleep disruption that then increases the likelihood of panic. Conversely, studies have shown that sleep problems may actually precede conditions such as anxiety and depression [71, 78].

It is perhaps significant that behavioural abnormalities similar to those seen in psychiatric disorders can be induced in healthy individuals by sleep deprivation [79–84] or transitory circadian desynchronization [85]. For example, SCRD may exacerbate or even contribute to the cognitive impairments of schizophrenia patients. Consistent with this, associations between cognitive performance and specific sleep or circadian parameters are present in medication-naïve [86], medicated [57, 87–92], and unmedicated schizophrenia patients [93]. For example, the severity of patients' cognitive symptoms is inversely related to slow-wave sleep duration and REM sleep density [93], and the amplitude of rest–activity rhythms is strongly associated with performance in cognitive tasks that assess distractibility, reaction time, and verbal fluency [57]. A correlation is also present between attentional set-shifting performance and REM sleep latency [94]. Similar associations are evident in healthy individuals; performance in the go/no-go task (a test of response inhibition) is associated with multiple slow-wave sleep parameters [95].

Sleep makes a crucial contribution to memory consolidation [28]. Reduced overnight consolidation of procedural learning has been demonstrated in schizophrenia patients [96], and these deficits were accompanied by reduced slow-wave sleep duration [89]. Another study with schizophrenia patients showed an association between sleep spindle activity during stage 2 NREM sleep and overnight improvements in a finger-tapping, sequence-learning task [90, 91]. Sleep spindle activity is significantly reduced in schizophrenia patients [97].

In schizophrenia, where again we have the most detailed studies, positive symptoms appear to be aggravated or even triggered by SCRD. In healthy human subjects, sleep deprivation results in increased perceptual distortions [82, 98], greater paranoia [99], and reduced prepulse inhibition [82]. Clinically, sleep disturbance is a significant risk factor for the first episode of psychosis [100], as well as for relapse in recovering patients [101]. Severe sleep disturbance often precedes the onset of psychotic episodes in schizophrenia patients [59, 102, 103], while it is also predictive of the maintenance of these symptoms [103]. In addition, the severity of sleep disruption is positively correlated with the severity of psychotic symptoms [102]. Finally, the positive symptoms of schizophrenia are associated with high-frequency EEG episodes in sleep [104]. It is also interesting to note that circadian desynchronization increases negative mood, irritability, and affective volatility in healthy volunteers [85, 105]. A total of 24 hours of sleep deprivation in healthy human subjects also leads to anhedonia [82], one of the core negative symptoms of schizophrenia. Consistent with this, improvements in sleep quality are frequently correlated with amelioration of negative symptoms in schizophrenia patients [68, 106]. Moreover, the negative symptoms of schizophrenia are associated with reduced REM sleep latency and various slow-wave sleep deficits [94, 107–109]. Likewise, in adolescents at ultra-high risk for psychosis, sleep disruption is associated with greater negative symptom severity [110]. Collectively, such associations hint at causal mechanisms, and therefore possible new therapeutic targets for improved health in psychiatric disorders.

Shared neuropathophysiology

What therefore could be the cause of SCRD in psychiatric disorders? One possibility is a shared dysfunction in common brain mechanisms (for example, specific enzymes, neuroreceptors, or neurotransmitter pathways) that contribute to the observed abnormalities [111]. According to this hypothesis, SCRD is not a consequence of the psychiatric disorder but is a core symptom intrinsically rooted in its underlying neuropathophysiology. This is plausible, given that psychiatric disorder implicates distributed brain circuits, affecting multiple neurotransmitter systems [112], many of which overlap with those involved in sleep regulation [113]. Dopamine, glutamate, and serotonin are all implicated in psychiatric disorder, while all three neurotransmitters are involved in sleep and circadian function. Moreover, multiple candidate genes for psychiatric disorder have a credible biological connection with sleep and circadian function within the brain. If these genes are the substrates of the comorbidity, their manipulation should result in both SCRD and disorder-relevant behavioural abnormalities (for example, impaired memory or reduced prepulse inhibition). Although this prediction is very difficult to address in humans, it can be tested using animal models. Indeed, there is a new, but rapidly growing, literature which speaks to this question [111].

Studies in rodents

Just as sleep deprivation can trigger psychiatric symptoms in healthy humans, the same is true in wildtype rodents. NMDA receptor (NMDAR) antagonist-induced hyperlocomotion, a schizophrenia-relevant behaviour, is heightened by sleep deprivation in male Wistar rats [114]. Sleep deprivation is also known to cause cognitive deficits; it impairs object recognition memory [115, 116], spatial recognition memory [117, 118], long-term spatial memory in the Morris water maze [119–123] and radial arm maze [124], and attentional performance in the 5-choice serial reaction time task [125]. These findings appear to reflect genuine memory deficits, as partial sleep deprivation (by gentle handling) has little effect on exploratory locomotor activity or on indices of stress such as plasma corticosterone or adrenocorticotrophic hormone levels [116]. In rats, sleep deprivation impairs prepulse inhibition [126–128], which may be relevant to the cognitive symptoms of psychiatric disorder.

Disrupted circadian rhythms and complete arrhythmia can be induced in healthy hamsters by a single light treatment—a combination of a nocturnal light pulse and a phase delay in the light/dark (LD) cycle. Crucially, this also impairs object recognition memory performance [129, 130]. In mice, circadian rhythms can be disrupted with T7 cycles, ultradian LD cycles consisting of a 3.5-hour light phase followed by a 3.5-hour dark phase [131]. This leads to lengthening of the body temperature and rest–activity rhythms, but no change in total sleep time, REM sleep time, or the rhythmic expression of *Per2* in the SCN [132]. T7 cycles impair object recognition memory performance, although it is unclear whether this impairment reflects a genuine memory deficit or a reduction in object exploration, as locomotor activity data were not reported [131].

Clock gene transgenic mice

Genetic manipulation of core clock genes can induce SCRD. Under 12:12 LD, circadian rhythmicity is unaffected in *Cry* single-knockout (*Cry1^{-/-}* and *Cry2^{-/-}*) and *Cry* double-knockout (*Cry1/*

$2^{-/-}$) mice [133, 134]. However, *Cry1^{-/-}* mice have a shortened endogenous period and *Cry2^{-/-}* have a lengthened endogenous period, while *Cry1/2^{-/-}* mice become completely arrhythmic in constant darkness [133, 134]. Significantly, object recognition memory performance is impaired in *Cry1^{-/-}*, *Cry2^{-/-}*, and *Cry1/2^{-/-}* mice. These deficits cannot be explained in terms of altered activity, since total object exploration does not differ between knockouts and wildtypes. They may be related to altered anxiety, however, as all three models exhibit heightened anxiety in the elevated plus maze [135].

Moving from correlation to causality and new treatment targets

SCRD is rarely targeted for treatment in psychiatric patients, but when it is, individuals report improvements in both sleep quality and psychiatric symptoms. Treating insomnia with the GABA_B receptor agonist sodium oxybate leads to an improvement in both the sleep quality and the negative symptoms of schizophrenia patients [136]. In another study, insomnia was treated with cognitive behavioural therapy (CBT) in 15 patients with persistent persecutory delusions and schizophrenia [58]. At least two-thirds of participants showed a substantial (>25%) improvement in insomnia, while approximately half showed a substantial (>25%) reduction in persecutory delusions. There were also reductions in hallucinations, anxiety, and depression. These studies represent an important advance, as they are the first to demonstrate that the targeted treatment of sleep disruption in schizophrenia patients can yield improvements in their ‘classical’ behavioural symptoms. This suggests that SCRD can make a causal contribution to the behavioural symptoms of psychiatric patients. However, both studies should be interpreted with caution, due to a number of methodological limitations; the sample sizes were small, the studies did not include control groups, and patients received medication throughout the studies. However, such issues were addressed in a very recent study where 3755 university students across the UK were randomized into two groups. One group received online CBT for insomnia; the other group did not but had access to standard treatments. The aims of the study were to explore whether sleep disruption is a driving factor in the occurrence of paranoia, hallucinatory experiences, and other mental health problems in young adults (average age of 25 years). Individuals who received the CBT interventions showed large reductions in insomnia, as well as significant reductions in paranoia and hallucinatory experiences. The treatment also led to improvements in depression, anxiety, nightmares, psychological well-being, and daytime work and home functioning [137]. These studies support the proposal that treating disrupted sleep could provide a key route for improving mental health.

SCRD in psychiatric illness such as schizophrenia has often been attributed to the side effects of medication. Although intuitively plausible, drug effects cannot be the only cause of SCRD in schizophrenia, since SCRD affects both medication-naïve [70] and medicated patients [71]. Indeed, SCRD often precedes the diagnosis of schizophrenia, prior to any medication [70, 72]. Recent and potentially exciting results have shown that dopamine antagonist drugs might actually improve sleep quality in schizophrenia [55, 71, 73], possibly due to their strong sedative effects [74]. So-called typical antipsychotics improve sleep efficiency and total sleep time [55], while atypical drugs for psychosis are even more effective

at improving sleep quality in schizophrenia patients [75] (also see Chapter 64). It is also possible that antipsychotic medication might also act directly upon clock gene expression. Such actions are currently being explored by researchers at the University of Oxford.

More evidence from rodent models

SCRD can also be targeted in rodent models that demonstrate simultaneous SCRD and psychiatric-relevant behavioural abnormalities. If SCRD makes a causal contribution to the behavioural symptoms of psychiatric disorders, then such interventions should ameliorate their behavioural impairments. Proof-of-principle for this approach is provided by the targeted ‘treatment’ of SCRD in the R6/2 transgenic mouse model of Huntington’s disease, which displays a progressive disintegration of sleep and circadian rhythmicity across its lifespan [138]. Interventions employed include bright light therapy [139], temporally scheduled feeding [140, 141], temporally scheduled exercise [139], and pharmacological imposition of a daily sleep/wake cycle with the sedative drug alprazolam [142, 143] and/or the vigilance-promoting drug modafinil [143]. Bright light therapy and scheduled exercise delayed the disintegration of rest–activity rhythms [139], while scheduled feeding also restored behavioural rhythmicity [140, 141] but had no impact on cognitive performance [141]. Strikingly, however, alprazolam administration improved behavioural rhythmicity and slowed cognitive decline in the R6/2 model [140, 141]. This suggests that SCRD causally contributes to cognitive dysfunction in Huntington’s disease. The same experimental approach could easily be applied to a psychiatric-relevant mouse model, or indeed any neuropsychiatrically relevant animal model. Temporally scheduled exercise has already been shown to improve behavioural rhythmicity in the schizophrenia-relevant *Vipr2^{-/-}* mouse model [144], although cognitive performance was not assessed.

Treatments on the horizon?

Despite our growing knowledge of the molecular mechanisms underlying the 24-hour circadian clock and its role in the development of psychiatric disease, there are very limited therapeutic options that have been developed to act on the clock directly to reduce SCRD. As light is the primary entraining agent for the SCN, bright light therapies and CBTs that strengthen natural *zeitgebers* such as scheduled outdoor exercise [145, 146] have been shown to have some success. However, potent pharmacological interventions are still lacking. Melatonin has long been characterized as an output of the circadian clock and can be used to modify the phase of the clock, presumably by acting via melatonin receptors that are expressed within the neurons of the SCN and widely across the multiple other cell populations throughout the body. Melatonin has therefore been studied as a possible chronotherapeutic drug and shows promise in certain circadian-related conditions [147, 148]. Prolonged-release melatonin (tradename Circadin™) is used to treat primary insomnia [149] in the aged, and the agonist agomelatine in the treatment of major depressive disorder [150]. Most recently, tasimelteon was approved in the United States for the orphan circadian disorder non-24-hour sleep–wake disorder in the totally blind [151]. Targeting the melatonin system, however, has limited efficacy; for example, tasimelteon showed a beneficial effect on stabilizing sleep–wake in 20% of the patient population after 1 month of treatment [151]. As a consequence, recent efforts have focused on developing alternatives, mainly targeting the core clock. Solt *et al.* reported a novel

REV-ERBa receptor agonist was effective at regulating both sleep as well as metabolism in mice [152, 153], and Hirota *et al.* have developed a small-molecule cryptochrome activator [154]. An alternative strategy that is yet to be employed is the development of molecules that act on the light input pathway to the clock, providing a pharmacological replacement for light for the treatment of SCRD. Such an approach could yield an exciting alternative.

Future perspectives

In conclusion, there are clear links between SCRD and the behavioural symptoms of psychiatric illness, although the mechanistic bases of these associations remain to be clearly defined. Rather than considering SCRD to be a by-product of medication or social isolation in psychiatric disease, it might be better conceptualized as a central feature of the condition. While SCRD is unlikely to be a primary cause of psychiatric disease, the treatment of sleep disturbances can yield improvements in the disorder's core symptoms and has the potential to significantly improve the quality of life of patients and their carers.

Diagnosis of sleep and circadian rhythm disorder

Kirstie Anderson

Introduction

In 400 BC, Hippocrates wrote ‘sleep and watchfulness, both of them when immoderate, constitute disease’. Unfortunately modern doctors in training receive little or no training in sleep medicine [1]. Disrupted sleep has immediate and long-term consequences on physical and mental health. Sleep fulfils many functions, but arguably the most important is regulation of normal affect and cognition, including a vital role in memory consolidation and new learning [2–4].

As explained at the molecular level in Chapter 109 and the systems level in Chapter 111, sleep is controlled by two neuronal circuits. The homeostat drives an increasing pressure to sleep after every hour awake and the circadian rhythm drives alertness in the day and sleep at night, with light intensity as the strongest external timekeeper [5]. Both total sleep time and the circadian rhythm change over the course of our lives [6]. As teenagers and young adults, typical sleep need is 8–9 hours for the majority, with a tendency for a delay in the sleep phase such that many comfortably fall asleep after, rather than before, midnight [7]. There is a tendency to phase-advance (that is, fall asleep earlier) with ageing. Adults fall asleep by 30 minutes earlier every decade from the third decade onwards [8]. There is greater sleep fragmentation and increased time to fall asleep in healthy older adults with and without sleep complaints [9]. At least 30% of adults in the United States regularly sleep <6 hours a night [10]. Over 7 hours of sleep at night is the adult norm, and over 9 hours is necessary for many teenagers, as well as those repaying sleep debt [11].

The physiological definition of sleep shows us to be either awake or alternating between non-rapid eye movement (NREM) or rapid eye movement (REM) sleep at approximately 90- to 120-minute cycles (Fig. 110.1).

Current classification of sleep disorders

Sleep disorders fall into one or more of four categories: hypersomnia, insomnia, circadian rhythm disorder, and parasomnia. Common

night-time disorders also include restless legs syndrome and associated periodic limb movements of sleep. The 2014 International Classification of Sleep Disorder, third edition (ICSD-3) has been used for the diagnostic criteria [13]. In addition, the most recent diagnostic criteria for restless legs syndrome (<http://www.irlssg.org>) improved specificity of the diagnosis and highlighted both episodic and chronic symptoms [14].

Taking a sleep history

A sleep history should be a short, but routine, part of all psychiatry consultations. Many sleep disorders can be accurately diagnosed by clinical history alone. A limited number of things go wrong with sleep—patients complain of sleeping too much or too little, of sleeping at the wrong time of the day, and less commonly of ‘things that go bump in the night’ (or the complaint will come from the bed partner).

Simple screening questions are suggested in [Box 110.1](#). A collateral history from the bed partner, where possible, is helpful to determine the presence of any snoring, periodic limb movements of sleep, sleepwalking, or other parasomnia. It is important to ask about the duration of symptoms (typically young onset for narcolepsy and NREM parasomnia) and whether they are progressive or relapse and remit. Some conditions disturb the bed partner far more than the patient, and establishing who is more concerned is important.

Discussing the patient’s concerns about sleep and expectations of normal sleep is not only worthwhile, but also part of treatment in insomnia disorder. For those with significant daytime sleepiness, driving safety should be discussed when relevant. The American Academy of Sleep Medicine recommends, ‘Have you had crashes, near misses, or claims on insurance in the last year?’. Those who are aware of nodding at the wheel or have modified driving are at most risk [15].

One of the most simple and cost-effective tests is a sleep diary kept for at least 2 weeks. Alongside a typical history, this may be the only diagnostic test needed for insomnia disorder, circadian rhythm disorder, or daytime sleepiness caused by sleep restriction or shift work.

Fig. 110.1 The sleep hypnogram. Sleep stages over a typical night as determined by polysomnography. During adult life, at night, we cycle between non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep approximately every 90–120 minutes. REM sleep typically occurs >90 minutes into the night, and NREM sleep is divided into three stages: N1, N2, and N3. N3 is often known as slow-wave sleep (SWS). Young adults will wake 2–4 times during the night, although they may not be aware of this. Most adults will have 4–5 cycles of REM sleep, although dream recall is highly variable and few patients recall 4–5 distinct cycles of dreaming.

Box 110.1 Recommended questions for a sleep history

Key sleep questions

- 1 Do you snore heavily? Has anyone witnessed prolonged pauses in breathing (apnoeas)?

For typical obstructive sleep apnoea, snoring is very loud, heard outside the bedroom door; the pauses are typically 20–30 seconds, rather than brief (<5–10 seconds); and a snort or a start at the end of apnoea is characteristic.

- 2 Do you have unpleasant tingling or discomfort in the legs which makes you need to kick or to move? Is it worse in the evenings? Is it helped by moving (restless in the body, rather than a racing mind)?

Everybody needs to be asked specifically about restless legs; people can find it hard to describe the dysaesthesia—‘wiggly’, ‘itchy’, ‘worms under the skin’. Bed partners can be asked about the infuriatingly regular kicks that may wake them, but not the patient—every 20–30 seconds is typical.

- 3 What drugs do you take, and when do you take them, including the dose and timing of caffeine/alcohol and nicotine?

Consider over-the-counter medication that might affect sleep, so short-acting painkillers, sedative opiates, and adrenergic drugs such as inhalers or some nasal sprays; counting the cups of coffee or tea is important.

- 4 ‘Take me through your typical 24 hours’—describing the sleep/wake pattern over a day.

Particularly helpful for those with sleep restriction, circadian rhythm disorder, and insomnia.

- 5 Do you nap during the day—if so when and for how long? Can you get through the day without sleeping?

Examples of when they might sleep can help to distinguish fatigue from true hypersomnia; few of us would sleep in the middle of a conversation or with food in our mouths.

- 6 Do you have any history of nightmares, acting out of dreams, sleep-walking out of the bedroom? If so, what time of night do things tend to happen?

Typically, the first cycle of REM sleep starts 90 minutes into the night, so REM parasomnias are more likely in the second half of the night. NREM parasomnias can occur within the first hour of sleep.

This should include: lights out, time in bed, estimated time asleep, any daytime napping, and ideally daily intake of caffeine, alcohol, meals, and exercise. There is debate about the time needed for diagnosis, but ICSD-3 highlights that certain circadian rhythm disorders will be missed with a single week of diaries. Weekends are different to weekdays, even in those who are unemployed or on work shifts. Some diaries rate satisfaction with sleep on a nightly basis, but this does not have diagnostic sensitivity and the author does not do this—generally, if they were satisfied with sleep, they would not be completing a sleep diary. Patients should complete the diary once a day, but not at night. Commercial accelerometers within smart phones and other gadgets tend to overestimate movement as wake and should not be used [16]; they can, in themselves, exacerbate insomnia. If patients awake refreshed and do not perceive a problem falling asleep, then they should largely avoid looking at movement-based data. Typical diaries are shown from normal and abnormal sleepers (Fig. 110.2).

Screening questionnaires—which scales to use?

The Epworth Sleepiness Scale (ESS) is the most widely used questionnaire to assess daytime sleepiness as self-rated over the prior month [17] (Box 110.2). Advantages include speed and simplicity for the patient and validation within psychiatry populations. However, it correlates poorly with more objective measures of sleep in the laboratory [18]. Many typical insomniacs score 0–1; >10 is taken as daytime sleepiness, and >17 as very sleepy. Change in ESS score is often used to assess interventions for sleepiness such as stimulants [19, 20]. Added value is often obtained from asking a spouse or partner to also complete the questionnaire.

The other widely used questionnaire to separate good and bad sleepers is the Pittsburgh Sleep Quality Inventory [21]. Seven questions give a single score, with >5 indicating some form of sleep disturbance and those scoring >10 having more severe sleep disturbance. This is widely used in research but is more complex to complete.

The insomnia severity index is validated for insomnia severity and improvement after therapy, with scores ranging from 0 to 24 [22]. It is quick and easy to complete but will not distinguish between primary or secondary causes of insomnia.

(a)

Diary 1

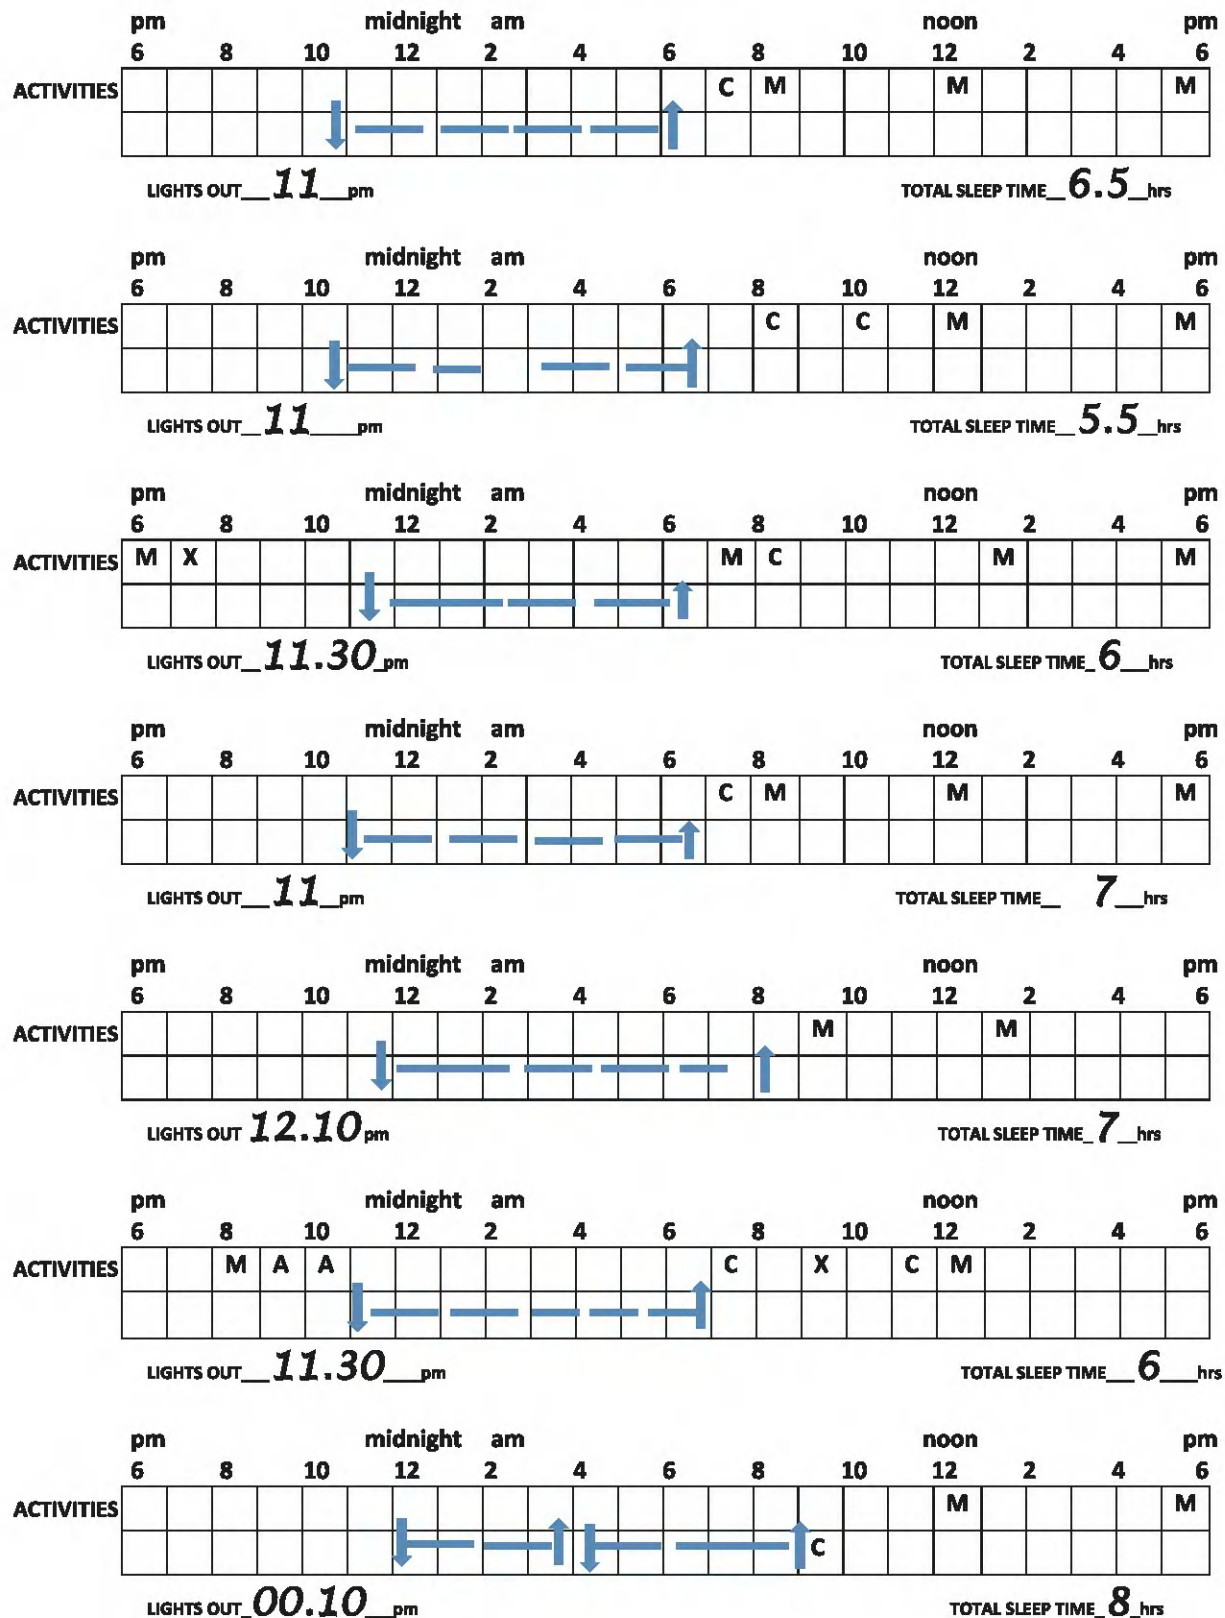

Fig. 110.2 Sleep diaries.

(a) Diary 1. A normal (albeit slightly introspective) 45-year old with occasional brief awakenings and rapid returns to sleep. Taking up to 30 minutes to fall asleep is normal, and increased sleep time at weekends and non-work days are within current societal norms. Treatment was a clear explanation about normal sleep and advising him to avoid using his phone to record his sleep.

(b) Diary 2. Insomnia disorder where time in bed is far longer than time perceived asleep, and both difficulty initiating and maintaining sleep are seen without daytime naps. Variability among nights is seen, with occasional good nights of prolonged sleep.

(c) Diary 3. Delayed sleep phase syndrome in a 23-year-old male who has had this sleep pattern since the age of 15. The pattern is of falling asleep typically between 2.30 a.m. and 4 a.m., but waking well after 11 a.m. with a few night awakenings. The estimated total sleep time is far greater than in the patient with insomnia.

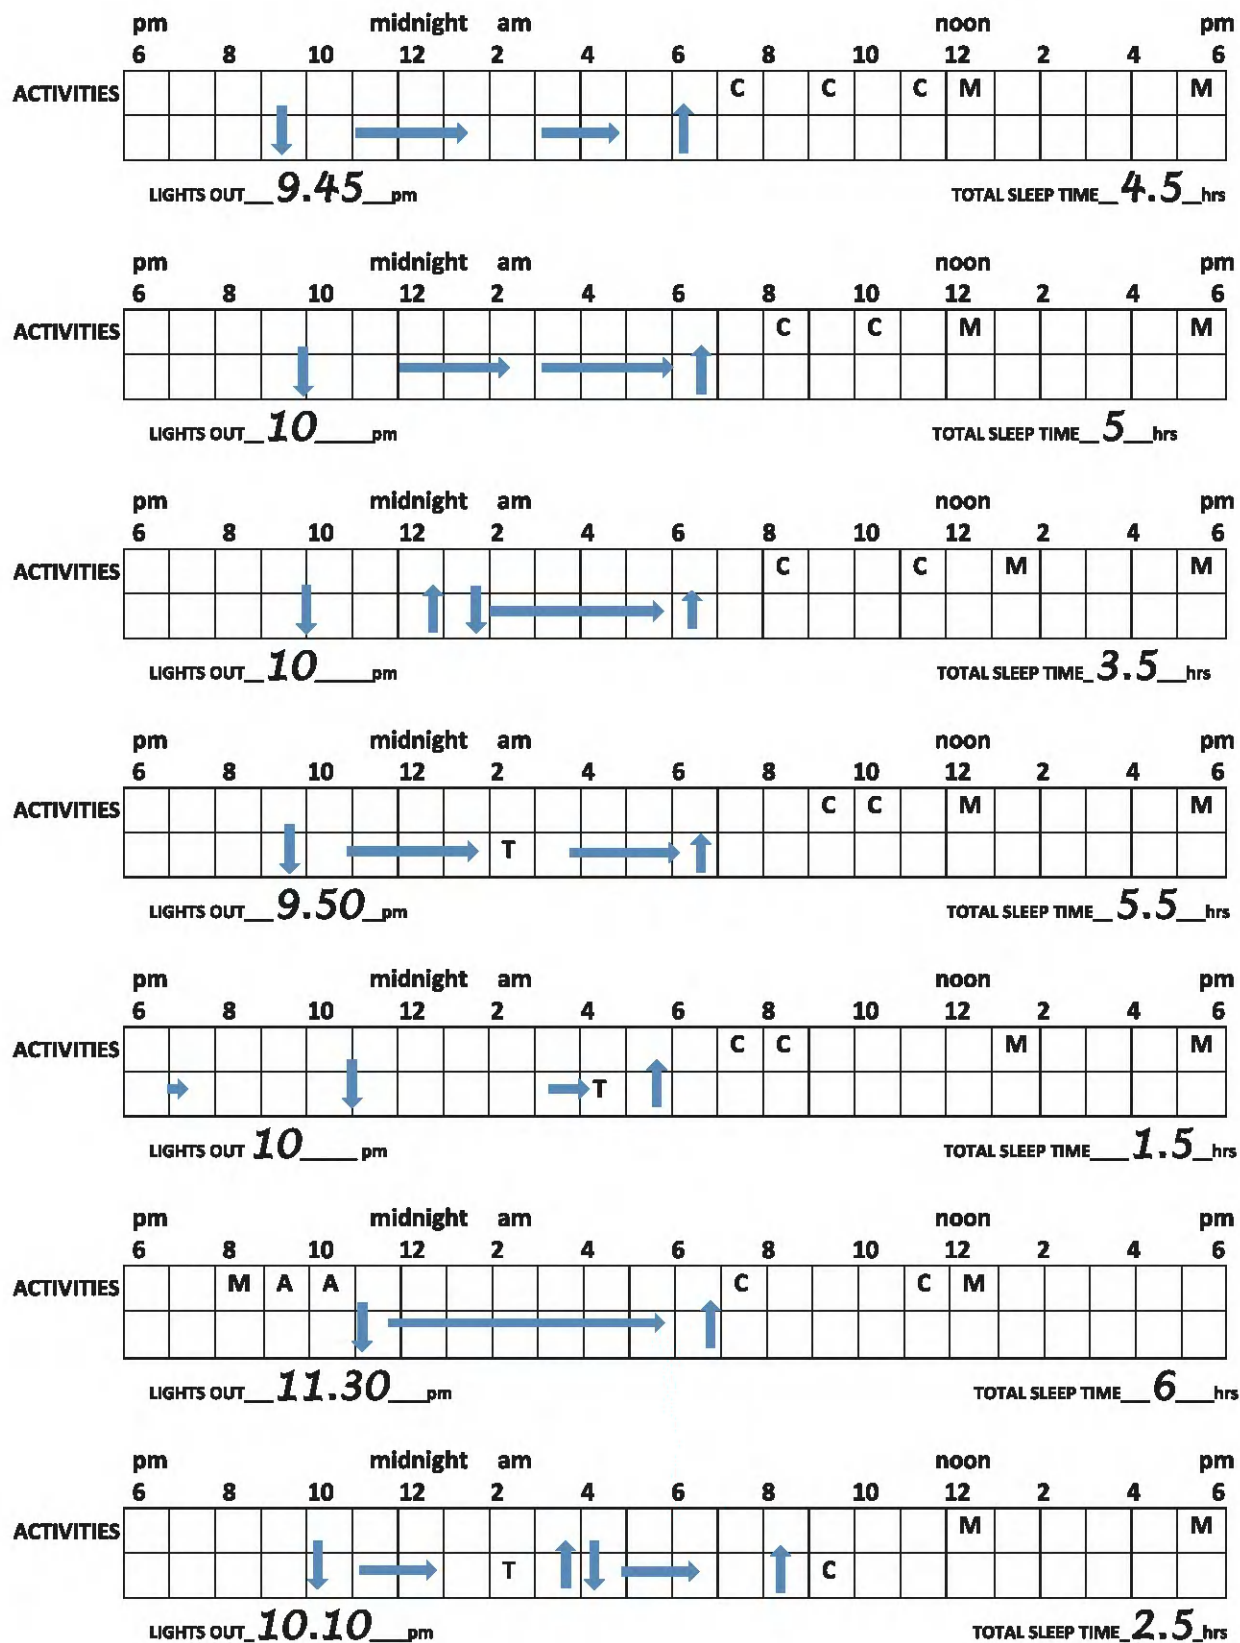

Fig. 110.2 Continued

Box 110.2 Epworth Sleepiness Scale

Name: _____ Today's date: _____

Your age (Yrs): _____ Your sex (Male = M, Female = F): _____

How likely are you to doze off or fall asleep in the following situations, in contrast to feeling just tired? This refers to your usual way of life in recent times.

Even if you haven't done some of these things recently try to work out how they would have affected you.

Use the following scale to choose the most appropriate number for each situation:

0 = would never doze

1 = slight chance of dozing

2 = moderate chance of dozing

3 = high chance of dozing

It is important that you answer each question as best you can.

Situation	Chance of dozing (0–3)
-----------	------------------------

Sitting and reading

Watching TV

Sitting, inactive in a public place (e.g. a theatre or a meeting)

As a passenger in a car for an hour without a break

Lying down to rest in the afternoon when circumstances permit

Sitting and talking to someone

Sitting quietly after a lunch without alcohol

In a car, while stopped for a few minutes in the traffic

THANK YOU FOR YOUR COOPERATION

Hypersomnia

Hypersomnia affects up to 15% of the adult population, with 5% severely affected [23]. Differential diagnoses include obstructive sleep apnoea (OSA), sleep restriction with insufficient hours in bed for the needs of the individual, sedative medication, narcolepsy with or without associated cataplexy (transient loss of skeletal muscle tone typically triggered by strong emotion), and idiopathic hypersomnia. Excessive daytime sleepiness can be caused by head trauma (usually transient for the first 3–6 months; if it persists, other causes should be screened for) [24]. Troublesome daytime sleepiness is common in both early and more advanced neurodegenerative conditions such as Parkinson's disease where it is typically multifactorial. Louter and colleagues produced a useful diagnostic algorithm [25].

Circadian rhythm disorders can masquerade as hypersomnia, in particular in shift workers over 40 or young adults with delayed sleep phase syndrome.

Behaviourally induced insufficient sleep syndrome (sleep restriction)

Those who are sleep-restricted for sleep will have daytime sleepiness. There are few true short sleepers, and most of the adult population

sleeping <5 hours will have symptoms of poor concentration and sleepiness. 'Social jet lag' describes increased sleep over weekends to repay sleep debt. Variability over days and completion of a sleep diary, alongside a careful history, may be sufficient to make the diagnosis. Occasionally, wrist actigraphy can record sleep–wake patterns where there is diagnostic doubt.

Napoleon, Margaret Thatcher, and Thomas Edison are often acclaimed as short sleepers of only 4 hours a night. Further analysis reveals them all to be efficient power nappers. Edison, who dismissed sleep as a 'waste of time and throwback to our cave days', was once furious to be caught napping in a cupboard during the day.

Obstructive sleep apnoea

The most common cause of significant daytime sleepiness in those over the age of 50 is OSA. It remains underdiagnosed despite having an excellent, cost-effective, symptomatic therapy—continuous positive airways pressure [26]. Risk factors include male sex, increasing age (in particular over 50), obesity, increased neck circumference (>17 inches), and retrognathic jaw. Increasing obesity means that at least 10% of men over 40 and 5% of women now have moderate or severe sleep apnoea [27]. In children, OSA is seen with adenotonsillar hypertrophy and certain dysmorphic conditions such as Down's syndrome.

Psychiatry patients have particular risk factors for sleep apnoea, and studies across a range of psychiatric disorders have reported rates of up to 66% [28, 29]. There is most evidence for increased rates in major depressive disorder and in those with elevated BMI [30]. This is a particular problem with those established on drugs for psychosis with metabolic syndrome [31, 32].

The history includes very loud snoring, progressively troublesome sleepiness, awaking unrefreshed, and often progressive over months and years. Spouses often reposition the patient onto their side, and the pauses in breathing are often long enough (>30 seconds) to cause concern. It is rare for the patient themselves to have a perception of choking, although people can wake themselves with their own snoring. Morning headache is common, often due to exacerbation of primary headache such as migraine, rather than associated respiratory failure. Clues for those who live alone include a dry, sore throat in the morning, nocturia, awaking unrefreshed, vivid dreams, and night-time sweating, alongside daytime sleepiness. Untreated OSA can cause treatment-resistant hypertension.

At least 20% of patients are not overweight, and those over 65 years of age can be slim with atypical presentations, including cognitive impairment. The STOP-Bang is a validated screening tool for OSA to assess those who may need further investigations [33] (<http://www.stopbang.ca>).

Those with suspected OSA should be referred for a respiratory sleep study. This detects pauses in breathing—either partial (hypopnea) or complete (apnoea)—alongside oximetry and gives an apnoea–hypopnea index (AHI). AHI of >5/hour is abnormal, but AHI of >15 (moderate) and >30 (severe) is far more likely to cause symptoms and to respond to treatment. Those with untreated OSA report more symptoms of depression and anxiety than the background population [34, 35].

Symptomatic OSA is notifiable to the driving licence authorities, but treated patients can restart driving.

It is also worth mentioning chronic fatigue syndrome. Sleep disorders must be excluded, and OSA is a common mimic. Recent polysomnography studies in those with an established diagnosis of chronic fatigue syndrome showed 21–49% had an undiagnosed sleep disorder, most commonly OSA [36, 37].

Central sleep apnoea

Those taking sedative medication and, in particular, opiates, as well as those with heart failure, can have prolonged apnoeas without snoring as a central phenomenon. Increased opiate prescribing over the past 20 years has led to a belated recognition of their harmful effects, including sleep apnoea [38]. Those with chronic pain often complain of bad sleep, but this is mostly attributed to the pain itself. Within pain clinics, rates as high as 25–50% are reported, often with secondary respiratory failure [39, 40]. Those at highest risk are those taking >200 mg of equivalent dose of morphine, in combination with benzodiazepines. Recent changes in the Center for Disease Control prescribing guidelines in the United States have recognized the dangers and may influence prescribing in other countries [41].

Narcolepsy

Narcolepsy, meaning ‘seized by somnolence’, was described by Gelineau in 1880 to include sleep attacks and falls triggered by strong emotion (cataplexy). The most recent diagnostic criteria (Box 110.3) reflect an increasing understanding of the neuropathology [42]. Narcolepsy is now characterized as type 1 or type 2, with the diagnosis made on a typical history plus supportive investigations [either polysomnography plus daytime multiple sleep latency tests or, more recently, reduced cerebrospinal fluid (CSF) hypocretin]. Its prevalence is 0.05–0.1%, but often with significant delay to diagnosis [43].

It typically develops in adolescence with excessive daytime sleepiness evolving over weeks to months and then remaining relatively fixed and unremitting over time. It is best thought of as a sleep switch problem where patients transition between sleep/wake states more frequently than normal. The classical tetrad of excessive daytime sleepiness, hypnagogic and hypnapompic hallucinations, cataplexy, and sleep paralysis is only seen in 20% of patients at first presentation. One-third of patients will never develop cataplexy or have only very subtle symptoms. The majority will have disabling sleepiness and will not be able to get through the day without napping. Many describe naps as difficult to resist at times, but classical sleep attacks without any recollection of the event are, in fact, uncommon. The description from a relative or witness is often of a conversation stopped halfway and restarted as if no time has passed.

Key diagnostic features include the need for brief and typically refreshing naps, of sometimes just a few minutes. Adult patients will typically have a fragmented night, and some feel that this should be part of the diagnostic criteria. Certainly if an adult is very sleepy, but with a long, deep, and unbroken night, then another cause of sleepiness is more likely. Dream recall is strikingly vivid, often after even short daytime naps. The description of hypnagogic hallucinations

Box 110.3 Diagnostic criteria for narcolepsy with and without cataplexy

Narcolepsy type 1—narcolepsy with cataplexy

Criteria A and B must be met:

- A** The patient has daily periods of an irrepressible need to sleep or daytime lapses into sleep occurring for ≥ 3 months.
- B** The presence of one or both of the following:
 - 1** Cataplexy and a mean sleep latency of ≤ 8 minutes and ≥ 2 sleep-onset REM periods (SOREMPs) on a multiple sleep latency test (MSLT) performed according to standard techniques. A SOREMP (within 15 minutes of sleep onset) on the preceding nocturnal polysomnogram may replace one of the SOREMPs on the MSLT.
 - 2** CSF hypocretin-1 concentration, measured by immunoreactivity, is either ≤ 110 pg/mL or $< 1/3$ of mean values obtained in normal subjects with the same standardized assay.

Narcolepsy type 2—narcolepsy without cataplexy

Criteria A–E must be met:

- A** The patient has daily periods of an irrepressible need to sleep or daytime lapses into sleep occurring for ≥ 3 months.
- B** A mean sleep latency of ≤ 8 minutes and ≥ 2 SOREMPs are found on an MSLT performed according to standard techniques. A SOREMP (within 15 minutes of sleep onset) on the preceding nocturnal polysomnogram may replace one of the SOREMPs on the MSLT.
- C** Cataplexy is absent.*
- D** Either CSF hypocretin-1 concentration has not been measured or CSF hypocretin-1 concentration measured by immunoreactivity is either > 110 pg/mL or $> 1/3$ of mean values obtained in normal subjects with the same standardized assay.
- E** Hypersomnolence and/or MSLT findings are not better explained by other causes such as insufficient sleep, obstructive sleep apnoea, delayed sleep phase disorder, or the effect of medication or substances or their withdrawal.

* If cataplexy develops later, reclassify as type 1.

can vary, but unlike those with psychotic disorders, the hallucinations occur within sleep and are typically visual.

Cataplexy is typically an axial loss of posture affecting the head, face, and neck, and patients can describe their face becoming loose or their jaw dropping. Bigger attacks cause falls, but with retained consciousness; eyes close, and patients look as if they are asleep. Recovery is typically quick within a minute or so. Cataplexy is worse at times of emotional arousal. Younger children can find it harder to describe emotional triggers and may have a near permanent decrease in muscle tone, giving a tongue that lolls and a pseudomyopathic appearance with a clumsy, waddling gait [44]. Those presenting later in life have a milder phenotype, but sleepiness that is definitely new in onset over the age of 40 is rarely due to narcolepsy.

Narcolepsy is now known to be caused by a loss of hypocretin neurons within the hypothalamus [45]. Since hypocretin also has a key role in metabolism, patients typically gain weight as the condition evolves with a craving for carbohydrate-rich foods. Children, in particular, can have significant weight gain and precocious puberty as a consequence [46]. Many have parasomnia and a mild REM sleep behaviour disorder (RBD); the dream enactment rarely causes injury but can lead to diagnostic confusion and can occasionally be the presenting complaint [47].

Specific diagnostic tests include haplotyping for the commonly associated HLA-DQB1*0602 allele. This is seen in 95% of those with narcolepsy and cataplexy, but also in 25% of the background population and only in 60% of those without cataplexy, so it is of limited use.

It is strongly associated with low CSF hypocretin. The author does not use it, unless planning CSF testing. Polysomnography plus multiple sleep latency tests have for years been the gold standard objective test of both sleepiness and abnormally early-onset REM sleep (4–5 timed nap opportunities with patients given a 20-minute period and the instruction to ‘try to fall asleep’). Those with a mean sleep latency of <8 minutes are said to be pathologically sleepy; many patients with narcolepsy have far shorter sleep latencies of <5 minutes [48], and the presence of REM sleep within 15 minutes on two or more occasions has 70% sensitivity and 97% specificity [49, 50]. There is no value for routine EEG to assess for the presence of sleepiness.

Differential diagnosis includes sleep restriction, and careful assessment of the average time in bed should be measured, ideally with sleep diaries. Comorbid sleep apnoea should be excluded in those with increased BMI who also snore.

Idiopathic hypersomnia

A less well-defined condition, patients typically complain of prolonged and unrefreshing sleep, typically answering the question of ‘how long do you nap?’ with the answer ‘until I am woken’. Naps are much more likely to last over an hour, and for these patients, there is little dream recall and no cataplexy [51, 52]. In one-third of patients, symptoms have been present since childhood. Unlike narcolepsy, there is a family history in at least a third. Typically, patients describe the phenomenon of a prolonged night sleep of often 9 or 10 hours and then marked difficulty waking (sleep drunkenness), with repeated returns to sleep. Being late into work or school is common. Diagnostic criteria again require polysomnography plus multiple sleep latency tests confirming a mean sleep latency of <8 minutes, but without sudden-onset REM sleep. Polysomnography often shows prolonged slow-wave sleep and high sleep efficiency. Unlike narcolepsy, about 10% spontaneously remit. The differential diagnosis includes hypersomnia associated with depression, but this more commonly causes more variable symptoms over weeks and months, with periods of remission [53].

Parasomnias—‘things that go bump in the night’

Described as ‘undesirable physical and/or experiential phenomena accompanying sleep’, parasomnias can involve complex motor acts, including walking, eating, texting, and even driving. Rarely, this can be misdiagnosed as a primary psychiatric problem or, more commonly, as possible nocturnal seizures. At least 20% of all children have some form of parasomnia, although most do not present to doctors. At least 2–3% of the adult population have some form of parasomnia, and this is increased to 4–9% in psychiatric patients [54].

Parasomnias are divided into those occurring in NREM or REM sleep.

Non-rapid eye movement parasomnias

Confusional arousals, sleepwalking (somnambulism), sleep-related eating disorder, and sexsomnia are all NREM parasomnias. They are disorders of arousal [55], with incomplete waking from slow-wave sleep (N3). These disorders are common in childhood,

and there is often a family history. Events can occur within the first 30–60 minutes of sleep, which is less common for REM-related events. Occasional sleep *talking* is also an NREM parasomnia, but so common as to be near universal.

Typically, there is a lack of awareness for at least some, if not all, of the events or if there is recall, it is patchy. Partners almost always describe more night-time events than the patients, and events last minutes, rather than seconds (5–15 minutes would be the average). There is variability to events, but clustering is common, with several events over a week and then periods of relative remission. Patients who are out of the bed and out of the bedroom are more likely to have NREM, rather than REM, parasomnia. Patients can be both argumentative and combative, but directed violence is rare. Hallucinatory phenomena can occur within NREM sleep.

NREM parasomnia typically decreases moving into adulthood; however, those who are predisposed can then have further symptoms with acute psychiatric illness, shift work, or irregular sleep patterns [56]. The other well-recognized trigger is another sleep disorder such as OSA or restless legs [57, 58].

Specific additional investigations include sleep diaries to look for triggers and scheduling issues and a witness history, wherever possible. The value of inpatient video polysomnography is debated, as it rarely changes the diagnosis but may detect additional sleep apnoea or restless legs [59]. If events are captured, they arise from slow-wave sleep (N3 sleep stage). If the differential diagnosis does include nocturnal seizures, then MRI brain and EEG should also be performed. However, the main value of a sleep study is to look for other sleep disorders in adults that might be triggering the event or an alternative diagnosis if no witness history is available. The current ICSD-3 criteria do not require polysomnography to make the diagnosis with a typical history.

Rapid eye movement parasomnias

These disorders are typically brief, memorable, and dream-filled, and unlike NREM parasomnias, patients are far more likely to have recall of events. REM parasomnias include nightmare disorder, isolated sleep paralysis, and RBD.

In normal sleep, a powerful, descending glutaminergic signal inhibits the spinal motor neurons during REM sleep with reduced skeletal muscle activity or REM atonia [60]. Only the diaphragm and the extraocular muscles are active (giving the rapid, jerky eye movements on the electro-oculogram within polysomnography). In RBD, an insidious and progressive degeneration of this brainstem control causes increasingly troublesome dream enactment, alongside vivid and often violent dream content. Affected patients shout and act out dreams, and up to 70% will injure themselves or their bed partner and this is often the prompt for referral. This is typically in the second half of the night. The condition predominantly affects older men, with a reported prevalence of at least 1%. RBD was first described by Carlos Schenck in 1986 in a small series of elderly men [61]. In fact, selective brainstem lesions in animals were shown to cause dream-like behaviours many years earlier [62]. Over recent years, there has been increasing recognition of the strong association between RBD and other neurodegenerations, and in particular Parkinson’s disease, dementia with Lewy bodies, and multiple system atrophy. Over 80% of those with RBD will develop one of these conditions over 15 years of follow-up [63]. Studies show subtle cognitive, olfactory, and gait disturbance in RBD patients, compared to controls

Fig. 110.3 Inpatient video polysomnography in a patient with REM sleep behaviour disorder. A 30-second epoch of polysomnography showing EEG, EOG, and EMG, with loss of normal REM atonia (bottom line) highlighted with black arrows. This patient had a clinical history typical for REM sleep behaviour disorder (RBD).

[64]. In the Parkinson's disease clinic, at least 50% of patients will have some symptomatic RBD with a range of validated screening questionnaires primarily developed for research [65].

The ICSD-3 criteria specify the need for polysomnography in the context of a typical history, unlike other parasomnias where history alone is sufficient. This shows loss of REM atonia and occasionally abnormal behaviour on video (Fig. 110.3).

RBD is rare in children, but there is a recognized association with narcolepsy. Loss of REM atonia is seen with SSRI and SNRI antidepressants, with occasional dream enactment [66, 67].

Screening for RBD should therefore be a routine part of history taking in the memory clinic, and RBD can mimic some of the features of post-traumatic stress disorder. Key differences include a variety of different dreams, with not all of them being violent, and a lack of daytime distress. Occasionally, severe OSA can cause strikingly vivid dreams and mimics RBD. Screening for sleep apnoea should be considered in those who are sleepy or have other features to suggest OSA.

Other REM parasomnias

Isolated sleep paralysis where someone awakes but for a minute or so cannot move. This occurs with associated dream-like imagery and occasionally with a feeling of heaviness in the chest or shortness of breath, and it is more common in the second half of the night or on waking from sleep. Touch relieves symptoms, and patients can describe trying to shout or to move. The diagnosis is made on history alone, and there are no specific tests routinely used. This is a common parasomnia experienced by at least 20% of the population

on occasion and up to 2–3% regularly [68], but it can be distressing when it first occurs. It is due to a dissociation between reactivation of skeletal muscle tone and return to wakefulness and is often seen with abrupt awakenings from REM sleep. For those with other psychopathology, the dreams can be more intrusive and involve themes of abuse. Typical triggers include irregular sleep/wake cycles for any reason. It can also be seen as a rebound phenomenon when stopping REM-suppressing antidepressants such as venlafaxine. It is seen frequently in those with narcolepsy, but alongside other features such as daytime sleepiness [69].

Nightmares are a universal phenomenon, but those with frequent and distressing nightmares have nightmare disorder. There is an association with depressive symptomatology [70]. An almost endless list of medications are said to be associated with nightmares or vivid dreams, but in practice, the common culprits are beta blockers, opiates, or cessation of REM-suppressing antidepressant medications.

Benign hypnagogic hallucinations

There is debate about which sleep state these strikingly real, but exclusively nocturnal, and typically visual phenomena arise from. Typically occurring in the early part of the night, insects are commonly described themes, with rapid resolution of symptoms when lights come on. Insight is retained or rapidly returns with wakefulness. They seem more frequent in young women, but there are limited prevalence data.

Box 110.4 Circadian rhythm disorders

- Advance sleep phase syndrome
- Delayed sleep phase syndrome
- Shift work disorder
- Jet lag circadian rhythm disorder
- Irregular sleep/wake syndrome
- Non-24-hour sleep/wake syndrome

Circadian rhythm disorders

There are six distinct circadian rhythm disorders currently defined by ICSD-3 (**Box 110.4**) and increasing recognition of the relatively high frequency of these conditions in psychiatric patients [71]. All are caused by misalignment of the period of sleep, and many are characterized by the length of sleep time and often the quality of sleep remaining relatively normal, but simply out of sync with societal norms.

Delayed sleep phase syndrome

This presents in teenage years with patients who typically fall asleep and wake far later than the societal norm, causing associated daytime dysfunction. The diagnosis can be made on history alone, alongside well-completed sleep diaries (**Fig. 110.2**). For many, the key question is 'if you were allowed to sleep when you wanted, would you sleep well?'. The quality of sleep is often good if uninterrupted, but patients simply do not feel sleepy in the first half of the night, falling asleep between 3 and 4 a.m. and then struggling to wake in the morning. Those who have sleep restriction when woken early may have daytime sleepiness; there is also evidence that the total sleep period (tau) is longer in this group. Males are more commonly affected [72].

The diagnostic criteria include either sleep diaries or actigraphy for at least 2 weeks, with a typical sleep diary shown from a teenager subsequently well treated with melatonin and light therapy (**Fig. 110.2c**). There are two groups: those with a lifelong tendency, often with a family history; and those that drift during teenage years. Many report symptoms persisting over years, once established. It can be misdiagnosed as insomnia or chronic fatigue syndrome.

Shift work disorder

At least 20% of the western world do shift work, and for at least 20%, this significantly disrupts sleep. This decreases total sleep time and disrupts the circadian rhythm, with substantial evidence for increased mortality, obesity, cancer rates, and affective disorders in those who do shift work, compared to non-shift workers [73–75].

Shift work disorder occurs at greater rates in women, those over 40, and those who work rotating or back-to-back night to day shifts. Patients typically present with both insomnia when trying to sleep during the day and sleepiness during their shift, although many do not attribute either sleepiness or fatigue to their work patterns. This is often because sleep debt can accumulate over time, and shifts that may have been tolerable in the third or fourth decade become harder if there is added sleep disturbance with a young family, a longer

commute, or an additional sleep disorder such as sleep apnoea. ESS may well be increased, but the key test remains sleep diaries.

Restless legs syndrome and periodic limb movements of sleep

This common sleep-related movement disorder is seen in at least 5% of the population at all ages [76], and diagnosis can be made on a typical clinical history for many. However, it is often missed by both patient and doctor as a cause of a disturbed night and a sleepy day. The diagnostic features, as described by the most recent International Restless Legs Syndrome Study Group (IRLSS) criteria, are an unpleasant dysaesthesia deep within the legs that causes the desire to move and is at least partially relieved by movement [14]. Twenty-five per cent of patients have daytime symptoms, but there is a clear circadian pattern, with symptoms worst in the evening and first half of the night. Patients can find it surprisingly difficult to describe the sensations; 'creeping', 'itchy', 'fidgety', and 'crawling' are all words used. Thighs and calves are affected more than the soles of the feet, and patients are restless in bed, seeking cool surfaces upon which to rest their feet. Pacing and walking during the night is seen in more severe cases. Symptoms can be asymmetric and include the low back, and less commonly the arms can be affected. Unlike arthritis pain or peripheral neuropathy, people are better or symptom-free when walking.

Symptoms can be episodic, and not all have sleep disturbance, but for those with moderate or severe symptoms, they can have considerable sleep fragmentation and subsequently a sleepy day. At least 50% will have a family history, and those with other affected family members typically present at a younger age. About 5% have had symptoms starting under the age of 16, often mislabelled as growing pains. There is an association with restless legs and high caffeine intake, smoking, and excess alcohol. Exercise close to bedtime exacerbates symptoms.

Approximately 80% of those with restless legs can describe (or a frustrated bed partner can) strikingly periodic limb movements of sleep and occasionally of wakefulness. There is a brief judder of the toe, foot, and ankle, and 20–30 seconds pass before the next. The impressive response to dopamine agonists is often both diagnostic and therapeutic.

There is an association with low ferritin levels for some and blood levels should be checked, and many psychotropic medications exacerbate symptoms, particularly those that are dopa-depleting, as well as some antidepressants and melatonin.

Polysomnography can record the periodic limb movements with both limb EMG and video. This also helps to exclude other/additional causes of sleep disturbance such as OSA. Lower limb/foot actigraphy can be used over 2–3 nights at home to measure the periodic limb movement index.

The differential diagnosis includes drug-related akathisia and hypnic jerks, but both lack the striking circadian pattern to symptoms and periodicity to night-time myoclonus.

Insomnia disorder

Insomnia remains the most common sleep disorder in primary care, with at least 10% of the population affected [77]. Now simplified as a

diagnostic entity in its own right, it is defined as difficulty initiating sleep, difficulty maintaining sleep, and associated daytime distress persisting for >3 months. It is commonly comorbid with other mental and physical health problems [78, 79]. At least 40% will have anxiety disorder. Typically, ESS will be low at 0–2, and those with high ESS should be screened for secondary causes of insomnia.

At least 10% have restless legs syndrome as the cause of their insomnia; 20% of those with sleep apnoea will perceive an unrefreshing night, although the other clues of snoring and daytime sleepiness should prompt further investigations. Gastro-oesophageal reflux can be surprisingly toxic to sleep as another secondary cause. It can be surprisingly hard to distinguish insomnia alone from insomnia with comorbid OSA in those over 65 [80].

The other common mimic is circadian rhythm disorder where patients perceive difficulty initiating sleep with delayed sleep phase, but in fact, they then stay asleep well, and sleep diaries and an accurate history should distinguish the two. There are a small number of truly short sleepers who, in fact, awake refreshed after just 5 hours but feel this is not enough. For insomnia disorder, there has to be associated daytime functional impairment.

The cornerstone of both diagnosis and therapy is sleep diaries where a typical pattern of more time in bed than being asleep is usually seen. Sleep efficiency (total sleep time/time in bed) can be calculated. Normal sleep is typically >85% sleep efficiency, and those with severe insomnia often have sleep efficiency of <50%. A typical diary is shown in Fig. 110.2. Most will have occasional nights of more normal sleep. Fatigue, rather than daytime sleepiness, is described, and documented daytime naps should be infrequent. A hypervigilant phenotype is typical, with 'My mind is racing' and 'As soon as I climb the stairs, the lights go on' as typical statements heard in clinic. Women are more affected than men, and increasing age is also a risk factor. A widely accepted model is that of predisposing factors, a precipitating trigger, and then perpetuating maladaptive behaviours that disrupt both the normal homeostatic and circadian drivers to sleep [81].

The history should include questions about the typical 24-hour pattern and the bedroom itself. Review of the prescription list for any stimulant medications is required, alongside an assessment of mood. There is often a mismatch between perceived daytime performance and more objective assessments. This is very different to the sleep apnoea or narcolepsy story where daytime function has usually been objectively affected. Use of sleeping tablets, including over-the-counter preparations, needs to be documented, as these may cause some of the daytime fatigue.

A sleep study is not indicated unless another sleep disorder is suspected, and actigraphy is rarely used outside of research. Polysomnography when performed typically shows reduced sleep efficiency, prolonged sleep latency, and early REM latency, but these changes are also seen in depressive disorder. There is often sleep misperception, with patients estimating less time asleep in the laboratory, but explaining this rarely helps the patient.

Miscellaneous sleep disorders

Hypnic jerks

A single shock-like jerk at sleep/wake transition is a near-universal phenomenon diagnosed by history alone, but it can be

non-specifically increased by any condition that delays sleep onset or increases night awakenings.

Exploding head syndrome

This dramatically named, but benign, phenomenon is diagnosed by history alone and is thought to be the sensory equivalent of hypnic jerks. At sleep/wake transitions, a patient will hear a single loud bang or an explosion, or occasionally there is a flash of light that can briefly seem entirely external; symptoms can cluster and be worsened by anxiety, and this tends to increase sleep latency and increase night awakenings.

Bruxism

Those who grind their teeth at night, such that bed partners can hear, risk damage to the enamel and often disturb their partners, and some, but not all, have jaw pain. Night-time grinders tend to be daytime clenchers, with tenderness around the temporomandibular region, and there is some evidence for daytime jaw relaxation. There is some limited evidence for an association with increased anxiety and low mood [82].

Conclusions

Unfortunately, sleep disorders remain underdiagnosed and undertreated [1, 12]. In addition, sleep disturbance in those with mental health problems is often attributed to the psychiatric diagnosis or psychotropic medication, rather than considering a distinct and treatable set of disorders. This chapter has provided the tools to identify specific sleep problems, how to take a sleep history, and how to then investigate and diagnose common sleep disorders. Their treatment is described in Chapter 114—it should assume a greater priority.

Epidemiology of sleep–wake and primary prevention of its disorders

Lena Katharina Keller, Eva C. Winnebeck, and Till Roenneberg

Introduction

A recent study [1] estimated the economic costs of insufficient sleep to be roughly between 1% and 3% of the gross domestic product (GDP) in the industrialized world. To understand the mechanisms and causes behind this expensive modern sleep ‘experiment’, we need to strengthen sleep research both in the laboratory and in the field.

Sleep research is almost 100 years old. By studying sleep predominantly in laboratories, the physiology underlying sleep was systematically elucidated, describing, for example, the neuronal circuits and brain regions that initiate and maintain sleep [2] and how the timing of sleep and wakefulness are controlled by an internal 24-hour clock—the circadian clock [3]. Sleep research outside the laboratory in the real world, that is, the epidemiology of sleep, is even younger, looking back about only 30 years [4].

Sleep and its functions can only be understood in the context of the whole 24-hour day, which includes wake. We therefore base this review on formal considerations of the four main (albeit inter-related) aspects of sleep (and wake): duration, timing, structure, and quality (Fig. 111.1). The molecular underpinnings of the system have been described in Chapter 109.

Duration

Wake and sleep are not identical with, but closely related to, activity and rest, which together make up the circadian day. Internal days can deviate from 24 hours, but in the long term, the duration of activity–rest (sleep–wake) averages up to 24 hours. If, on average, longer sleep was not followed by shorter wake, and vice versa, we would gradually advance or delay our sleep timing and other daily behaviours.

Timing

The *timing* of sleep and wake, is similarly interdependent as the duration of sleep and wake. The timing is often defined by the onset and offset of the respective episodes; however, this measure is highly dependent on the episodes’ durations. The timing of sleep or wake is therefore more reliably defined by the mid-points of either sleep

or wake, rather than by their transitions. As will be described later, the mid-point of sleep on work-free days is used as a surrogate for chronotype. The concept of *chronotype* refers to how the circadian clock of an individual embeds itself into the 24-hour light–dark cycle—earlier or later.

Both sleep timing and duration are regulated by at least two processes [5, 6]—one homeostatic, and the other circadian. The former works like an hourglass; sleep pressure builds up during wake and dissipates during sleep (with non-linear characteristics). Sleep pressure can be estimated from the EEG, specifically the spectral power of slow-wave sleep (SWS) [7]. Yet, if sleep was solely controlled by the homeostat, sleep timing would be quite labile. Let us presume someone regularly slept 8 hours from 10 p.m. to 6 a.m. and was awake for 16 hours from 6 a.m. to 10 p.m. If this person stayed up one day until 6 a.m., he/she might sleep as long as 12 hours due to the prior sleep loss and would wake up at 6 p.m. with minimal sleep pressure. From that moment on, the homeostat would let this person sleep from 6 p.m. to 2 a.m. and be awake from 2 a.m. to 6 p.m.

But sleep—like most functions in our body—is also regulated by the circadian clock, which makes being asleep and being awake more likely to occur at certain times in the 24-hour cycle than at others. The model proposed by Borbély and Daan [5, 6] implements the circadian involvement in sleep regulation in making the thresholds that trigger falling asleep and waking up oscillate in a circadian manner. The circadian clock’s influence on sleep becomes evident in jet lag situations. When we travel fast over many time zones, the resynchronization of our circadian clock lags behind (as a rule of thumb, the circadian clock adapts by no more than about 1 hour per day). As a result, we have difficulties adjusting to the new light–dark regime at our destination, cannot sleep for several days during the local night, and can hardly be awake during the local day.

Our lifestyle has drastically changed with industrialization. While we used to expose ourselves to bright natural light outdoors during the day and actual darkness during the night, we now spend most of the day inside (with light up to a 1000-fold dimmer than outside) and simply switch on artificial light from sunset to bedtime. We have thereby drastically weakened the synchronizing signals (zeitgeber) [8] that our circadian clocks use to synchronize (i.e. entrain) to the

Fig. 111.1 Key aspects of sleep–wake behaviour can be assessed separately but are highly interrelated.

24-hour cycle. In adapting to this new situation, most people's circadian clocks have become later [9]. This delayed circadian phase is quickly reversible, as Ken Wright has shown in elegant experiments where he took urban students camping for 1 week and exposed them to the strong zeitgeber of natural light and dark [10]. Especially the late chronotypes advanced, and the chronotype differences between individuals became much smaller.

Structure

Both wake and sleep—albeit in very different ways—are also characterized by temporal structures that depend on many parameters—in our society, most importantly, on whether they occur on work-free days or workdays. This is illustrated in Fig. 111.2 where the physical activity averaged over several days rarely reaches zero in any of the subjects; this has at least two reasons: (1) sleep times can vary greatly between days (thereby 'spilling' activity into the average rest-or sleep-window); and (2) some activity can still be recorded during

sleep. Workday sleep timing is usually more regular, so that activity troughs are often more pronounced than on weekends. Although activity levels during sleep are by many factors smaller than during wake, the residual levels can still be analysed. The resulting activity structure during sleep shows a clear rhythmicity with a period of around 90–150 minutes, a property it shares with the sleep stages recorded by polysomnography (PSG) in sleep laboratories (see Activity monitoring for sleep–wake epidemiology, p. 1140).

Quality

The fourth aspect is quality (Fig. 111.1). Although we intuitively know that sleep and wake quality are strongly interdependent, we need an objective measure for sleep quality before we can quantify the respective qualities and their interdependence scientifically. Since sleep fulfils many biological functions, which we still need to fully understand, a universal definition of sleep quality may be difficult.

Sleep science commonly distinguishes between *subjective* and *objective* sleep quality. *Subjective sleep quality* refers to how well the sleeper reports to have slept after the sleep episode or to sleep in general. This self-report is likely influenced by the sleeper's individual and cultural preconception about how sleep should be or how one should feel after waking up. It is also influenced by the sleeper's individual psychological state such as their affect [11]. *Objective sleep quality*, by contrast, compares certain objective sleep measures of an individual with normative values. These normative values may, in themselves, harbour a bias just by how they were obtained and who served as reference population—often young, healthy university students in controlled sleep laboratory environments. The most common measures for objective sleep quality are: how long people take to fall asleep (sleep latency); how often they wake and how long they are awake (wake after sleep onset); how much of their time in bed people actually sleep (sleep efficiency); the sleep architecture (shuttling between sleep stages); time in certain sleep stages; and the intensity of the slow brain waves during deep sleep (delta power).

Fig. 111.2 Activity profiles can vary in their timing, shape, and amplitude. In general, they differ greatly between workdays (top row) and work-free days (bottom row). Profiles were taken from our large actimetry database and represent averages over 23–60 days (work or work-free, respectively).

Some of these sleep measures and objective quality indicators can be subjectively assessed by questionnaires such as the Pittsburgh Sleep Quality Index (PSQI) [12], but most must be measured via PSG in the sleep laboratory.

Importantly, both objective and subjective sleep quality are biased by the modern notion of what sleep should ‘look’ like, namely efficient, consolidated, and, if possible, initiated 6–8 hours before one has to get up (for work). The more we find out about sleep in non-industrialized societies, that is, before the use of electrical light [13–17] or in people who have to live according to the natural photoperiod [18], the more we may have to challenge our notions and current methods of measuring sleep quality. The fact that subjective and objective sleep quality are only poorly associated with each other [11, 19, 20] indicates how difficult and highly flawed our current definition of sleep quality is.

Epidemiology of sleep in the real world

Since 2000, we have been building a database on daily sleep behaviour using the Munich ChronoType Questionnaire (MCTQ) [21]. By now, it contains more than a quarter million entries. The MCTQ asks participants to give the times when they go to bed, prepare for sleep, fall asleep, wake up, and get up [21]. Most importantly, these questions are asked separately for workdays and work-free days. The growing database allowed us to quantify the key aspects of human sleep–wake behaviour. We assessed the amount of sleep people get and when they get it, and how different aspects of sleep change with age [22], season [23, 24], and geographical location [25], even with daylight-saving time [23]. Our results suggest that, although people sleep just as long on work-free days as they did 10 years ago, they get continuously less sleep on workdays [26]. Also, throughout their school and work life, most people alternate between under-sleeping on workdays and over-sleeping on work-free days. One factor leading to this difference in sleep duration is a change in sleep timing from workdays to work-free days. This so-called *social jetlag* [27] is quantified as the difference between the social and the biological ‘time zone’. The fact that >80% of the working population in our database needs an alarm clock to wake up on workdays [26] indicates that almost the entire working population experiences a strain on their circadian clock and sleep.

Sleep timing

Sleep times on workdays are predictably more synchronized among individuals than on work-free days, that is, they have a narrower distribution [mid-sleep on workdays (MSW); see Fig. 111.3] than on free days [mid-sleep on free day (MSF); see Fig. 111.3] (for day-specific differences in sleep timing, see also Fig. 111.5a).

The internal circadian clocks of most of us have continuously delayed during industrialization (due to decreasing zeitgeber strengths), while social times, for example work or school start times, have remained relatively stable. We fall asleep much later than our rural ancestors and use alarm clocks to wake up, thereby accumulating a sleep debt over the work week, for which we try to compensate on weekends.

For chronotype assessment, that is, how late or early one’s circadian clock is embedded into the light–dark cycle, sleep timing on work-free days is a better basis than sleep timing on workdays. However,

Fig. 111.3 Distribution of mid-sleep times in the MCTQ database. The narrower distribution shows the mid-sleep times on workdays (MSW; $n = 197,829$; mean = $3:19 \pm 1.13$), and the later wider distribution represents mid-sleep times on free days (MSF; $n = 200,260$; mean = $4:47 \pm 1.34$; excluding people who use alarm clocks on work-free days). The assessment of chronotype involves correcting MSF for oversleep (see text for details), resulting in the distribution in the middle (MSF_{sc}; $n = 181,600$; mean = $4:19 \pm 1.27$).

since work-free days are still influenced by workdays in the form of catch-up-sleep, we correct MSF for ‘over-sleep’ (MSF_{sc}; see <https://www.thewep.org/documentations/mctq> for a comprehensive list of variables assessed or computed from the MCTQ). Note that MSF_{sc}-based chronotype should only be calculated for people who do not use alarm clocks on work-free days.

The MCTQ-assessed chronotype is not a scaled preference for doing things at specific times of day (as is the aim of the morningness–eveningness questionnaire developed in the 1970s) [28]. The MSF_{sc}-time should be regarded as a surrogate for the entrained phase of an individual’s circadian clock. Validations with more objective measures of phase of entrainment, such as sleep-logs, actimetry, or measurements of the rise of melatonin in the evening, show good accordance [29–31] with the one-time assessment of chronotype (MSF_{sc}).

Sleep duration

Most people accumulate a sleep debt on workdays. As outlined in the introduction, this is most probably due to the effects of our modern light environments on the circadian clock and fixed work schedules. Fig. 111.4 shows the distributions of sleep duration on work- and work-free days, with the former being over 1 hour shorter and just slightly narrower than its counterpart on work-free days. Fig. 111.5b shows that the day-specific sleep durations can, in some individuals, differ by >5 hours.

Sleep quality

As discussed, we still need an objective measure for sleep quality. However, apart from pathologies that are not directly sleep-related

Fig. 111.4 Distributions of sleep duration on workdays ($n = 197,829$; mean = $7.06 \text{ hours} \pm 1.08 \text{ hours}$) and on work-free days ($n = 200,260$; mean = $8.12 \text{ hours} \pm 1.22 \text{ hours}$).

(apnoea, restless legs, chronic pain, etc.), chronic accumulation of sleep debt, the habitual use of alarm clocks, and constant attempts to sleep at the wrong circadian times must greatly reduce sleep quality. All these scenarios are aspects of social jet lag (Fig. 111.5a). This modern syndrome could turn out to be the most prevalent and costly high-risk behaviour of our times. With every hour of social jet lag, the chances of being overweight or obese increase by 33% [26], substantiating an association found already much earlier between

sleep duration and metabolic problems [32]. Social jet lag is also associated with higher odds of being a smoker and correlates with alcohol and caffeine consumption [27], as well as with signs of depression such as appetite loss and feelings of sadness [33].

Sleep structure

So far, there are no epidemiological data on the structure of sleep, since it is currently only accessible via measuring brain waves and other parameters in sleep laboratories using PSG. PSG recordings are subsequently analysed and 'scored' into different sleep stages. Sleep's 'architecture' cycles through these different sleep stages approximately every 90–150 minutes. This sleep-inherent 'ultradian' rhythmicity was first described by Dement and Kleitman [34]. To obtain epidemiological data on sleep structure, we recently explored how to extract this ultradian structure from activity.

Activity monitoring for sleep-wake epidemiology

The methods used in sleep laboratories (for example, PSG) usually obtain detailed information on individuals in clinical settings and are less suited for large-scale studies (too costly, time-consuming, and labour-intensive). Epidemiological sleep studies require simple and cost-effective methods to assess and monitor the desired variables. They therefore often rely on self-reporting—either as one-off questionnaires (for example, the MCTQ; see Epidemiology of sleep in the real world, p. 1139) or by keeping sleep-logs.

Another method for sleep monitoring that is becoming increasingly popular is the continuous measurement of physical activity or body movement via actimetry (or 'actigraphy'). Body movements are recorded mostly with watch-like, wrist-worn devices. Since people move much more during their wake-time than during their

Fig. 111.5 Differences in sleep-wake behaviour between workdays and work-free days. (a) Social jetlag is defined by the differences in sleep timing between the two day types [27]; frequencies on the right of the stippled zero line concern people who sleep later on work-free days than on workdays, while those on the left of this line sleep later on workdays. (b) Similar differences exist between sleep duration on workdays and work-free days, with the majority sleeping longer on work-free days (right of the stippled zero line).

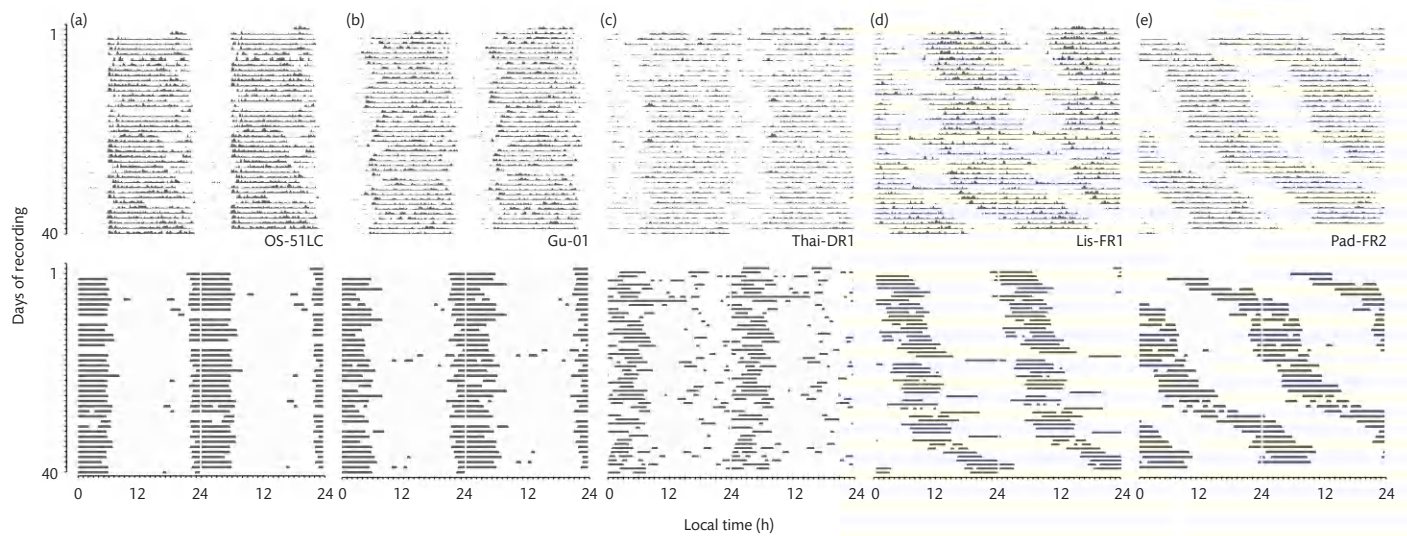

Fig. 111.6 Activity records can be used to infer on sleep–wake times. The top row shows five 40-day activity recordings from different individuals, and the bottom row shows the respective sleep times as bars [27]. The pale backgrounds indicate photoperiods, which were calculated based on the individuals' locations (latitude and longitude) and recording dates. We selected these five examples to demonstrate how different the sleep–wake behaviour can be. The example in (a) shows a female with strict regularity in her relatively early sleep–wake schedules. The next pair of graphs in (b) is again a female and early chronotype whose schedules are far less regular (possibly because her partner is a late chronotype). The central pair of graphs in (c) shows a male whose nocturnal sleep episodes are late, short, and irregular and who takes naps in the early evening. The next two examples in (d) and (e) show a male and a female, respectively, whose clocks—despite being visually unimpaired individuals—have difficulties to stably synchronize to the 24-hour rhythm of the environment.

sleep (Fig. 111.2), one can estimate when and how long they sleep by the episodes of relatively low activity [35, 36], that is, rest–activity is used to assess sleep–wake (Fig. 111.6).

Sleep timing and duration from actimetry

The many different methods to assess sleep via actimetry are either published or remain black boxes built into proprietary software. Overall, their concordance with the gold standard in sleep monitoring (PSG) is reasonably high—at least in healthy sleepers [35, 36]—but they have also been validated in sleepers suffering from common sleep pathologies such as sleep apnoea (for example, [37–39]). Most methods perform well but tend to underestimate short awakenings within a sleep episode [wake after sleep onset (WASO)]. Detection generally becomes less reliable when the difference between wake-time and sleep-time activity is low, that is, when people are bedridden or suffer from motor disorders or highly interrupted sleep.

For studies outside of laboratories and clinics, sleep detection via actimetry has many advantages despite providing much less information than PSG. Unlike self-reports, it is an objective measure of sleep timing and duration and produces—without burden—a detailed longitudinal record (over days and weeks) of an individual's rest–activity or sleep–wake behaviour. Long-term actimetry puts sleep into the context of the previous and following wake and sleep episode and thus allows, for example, teasing apart homeostatic and circadian influences on sleep (see Introduction, p. 1137). As such, long-term actimetry is superior to a single night in the sleep laboratory; it allows analysing the regularity of the sleep–wake pattern, identifying the daily phase and amplitude of general activity [for example, by a 24-hour cosine fit providing the *centre of gravity* (COG)], calculating the mid-points of sleep, or characterizing weekly patterns (for example, differences between work- and work-free days).

Long-term actimetry also allows detecting more complex sleep–wake problems, disorders or pathologies that are only apparent in long-term recordings. A good example is the N24 disorder [40] where sighted individuals cannot synchronize (i.e. entrain) to the normal light–dark cycle and therefore drift through societal time (Fig. 111.6d and e). Shift-workers have a similar problem, but the influences are inverted; societal time (for example, work schedules) make these individuals drift through their own circadian time (Fig. 111.7). Note how similar the rest–activity/sleep–wake patterns are in the individuals shown in Fig. 111.6d and e to those shown in Fig. 111.7d and e.

To make use of this strength of actimetry, its recordings need to be long enough to reveal the important patterns and be representative of an individual's sleeping habits. Since the pattern and variability in people's sleeping habits are often not known beforehand, any initial actimetry recording should cover at least 14 days (including three weekends) and ideally aim for 6 weeks. With complex disorders and sleep schedules, these initial recordings need to be complemented by even longer recordings over months.

Sleep structure from actimetry

So far, research has usually used actimetry only to obtain information about the timing and duration of sleep episodes. However, new efforts are under way that allow extracting more information about the sleep episode itself, that is, its structure and ultradian cyclicity. This effort is based on the observation that body movements are part of sleep physiology and vary with sleep stages or sleep stage transitions (for example, [34, 41–43]). Many current commercial actimeters (notably not for use in clinical or research settings!) claim to inform consumers about their sleep depth based on their movements during sleep. Whereas these consumer products are currently not scientifically validated and their output needs to be treated with absolute

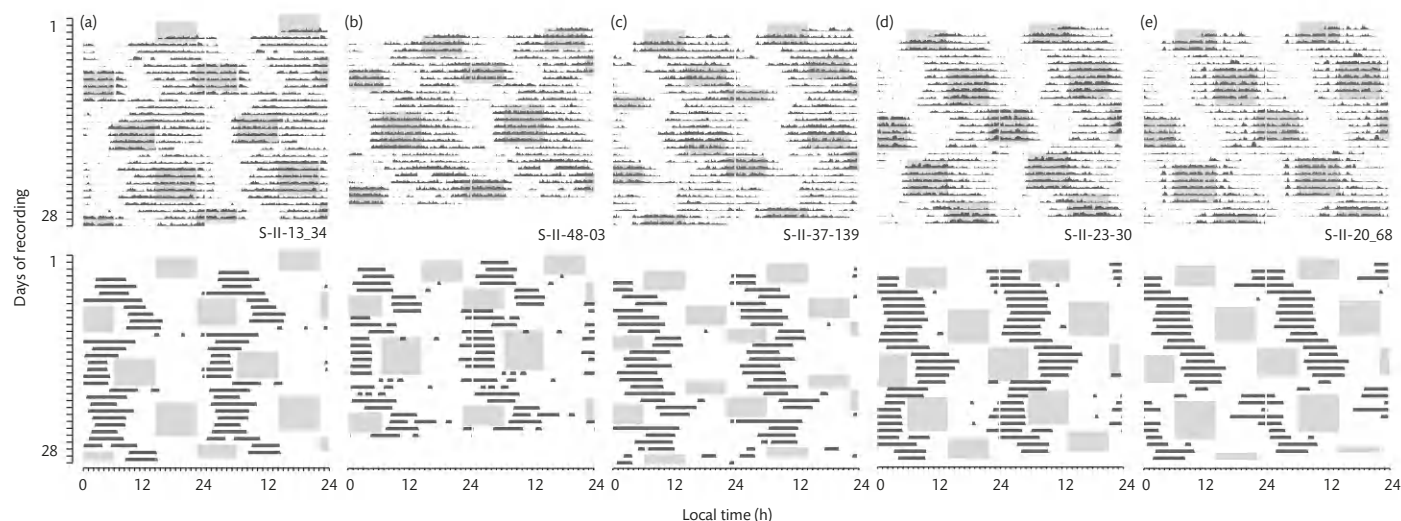

Fig. 111.7 Actimetry and the derived sleep times in five examples of shift-workers. As in Fig. 111.6, the top row shows the activity, and the bottom row the calculated sleep times. The grey squares indicate work times.

caution [44–46], the principle on which they are based may well work. We ourselves have developed a method that reveals the rhythms in body movement during sleep in actimetry recordings—rhythms that are highly reflective of sleep cycles, as determined by clinical PSG [47]. These extended applications of actimetry in large epidemiological studies will provide valuable new insights into the structure of sleep and its relation to sleep timing, sleep duration, and sleep quality.

Sleep–wake in psychiatric patients

The association between sleep–wake behaviour and mental disorders is apparent in the standard criteria for the diagnosis of psychiatric disorders in DSM-5 and ICD-10 [48]. Sleep problems are commonly seen as symptoms or comorbidities of the psychiatric disorder itself. For example, one of the diagnostic criteria for a depressive episode are changes in sleep (hypersomnia or insomnia); for a manic episode, a decreased need for sleep; and the criteria for post-traumatic stress disorder include nightmares and difficulty sleeping. However, the association between sleep and psychiatric pathologies is highly complex with numerous feedbacks. The causal links in this network are still not well understood but are certainly not unidirectional. While psychiatric patients frequently develop sleep problems [49], sleep problems may trigger psychiatric disorders in the general population [50]. Furthermore, psychopharmacological treatments influence sleep both by improving [51] and by creating/increasing sleep problems [51, 52]. Sleep—or rather its deprivation—is even used as therapy in major depression [53]. But again, the role of sleep deprivation in depression is complex; on the one hand, isolated sleep deprivation may acutely reduce depression [54], possibly via changing the synaptic rearrangements that occur during sleep [55]; on the other hand, chronic sleep deprivation may increase the risk for developing a variety of psychiatric (and somatic) disorders [56].

Similar to the concept of *sleep quality*, the term *sleep problems* is used for many different symptoms. Here, we try to put some order into the different aspects of sleep in the context of psychiatry

by separating the individual—though interdependent—aspects of sleep, namely timing, duration, structure, and quality (see also Introduction, p. 1137 and Fig. 111.1).

Sleep timing

Sleep timing, or chronotype, has often been associated with psychiatric syndromes (for review, see [57]). Notably, many studies ask for sleep preferences, for example for morningness (MEQ; [28]), instead of actual sleep timing (for a discussion about different chronotyping methods, see [58]). Two studies using actual sleep timing found that the later people sleep, the more depressed they are [33, 59]. In addition, Levandovski and co-workers [33] showed an association with social jet lag, indicating that the clash between chronotype and social schedules, rather than chronotype/sleep timing per se, can lead to depressive symptoms. Whether a later chronotype predisposes to depression or depression goes along with a change in chronotype still has to be worked out (for an in-depth discussion, see [60]). The fact that advancing circadian phase (chronotype) is being used as a therapeutic approach in patients suffering from depression indicates that sleep timing is being regarded as a cause—at least in part—for developing depressive symptoms [61].

Other psychiatric syndromes, such as seasonal affective disorder (SAD) [62], schizophrenia [63, 64], obsessive–compulsive disorder [65, 66], and attention-deficit/hyperactivity disorder (ADHD) [67], have also been found to be associated with delayed sleep timing. It seems that most psychiatric, as well as neurodegenerative, disorders go along with changes in sleep timing [68–71].

Sleep duration

The most obvious example of the relationship between psychiatric syndromes and sleep duration is bipolar disorder; during depressive episodes, most patients sleep longer, whereas during manic episodes, sleep is usually shortened [49]. Notably, shortened sleep during mania is not to be confused with insomnia, the inability to initiate or maintain sleep, but is due to an apparent reduction in sleep need, that is, patients feel awake and refreshed after as little as 3 hours of sleep [49].

Other mood disorders have also been associated with changes in sleep duration; patients suffering from SAD show a prolonged sleep duration during winter [72]—as, to some extent, is also true for the general population [23]; patients with non-seasonal unipolar depression either sleep significantly longer (hypersomnia [73]) or shorter (hyposomnia [74]) than healthy controls. These changes in sleep duration are usually caused by the inability to initiate sleep and/or early morning awakenings. Another explanation for this condition is that patients adhere to habitual sleep times, even when their circadian timing changes. Some studies failed to show hypersomnia (or hyposomnia) in depressed patients in the sleep laboratory and concluded that these symptoms must be rather a subjective sleep complaint [75], but sleep measured in a one-night PSG in an artificial environment does not capture the actual sleep of patients at home.

Our own research showed that adolescent patients with remitted depressive disorder still sleep longer, compared to healthy controls [60]. Schizophrenia is also associated with hyper- [64] or hyposomnia [76]. The latter was also found in post-traumatic stress disorder [77], alcoholism [78], autism [79], and generalized anxiety disorder [80].

The relationships between psychiatric syndromes and sleep duration are all but straightforward. On the one hand, studies in the general population found sleep durations of under 5 hours increased the odds for a variety of psychiatric conditions: mood disorders such as depression [56, 81, 82]; anxiety disorders [56, 81]; obsessive-compulsive disorder [81]; and nicotine and alcohol dependence [56, 81]. On the other hand, sleep over 9 hours was associated with depression [82], anxiety disorders, social phobia, and alcohol dependence [81]. In children, both shortened and prolonged sleep increased the likelihood for ADHD [83, 84]. Although sleep duration differs significantly between workdays and work-free days [85], Park and colleagues [81] analysed the relationship of sleep duration and various psychiatric disorders only on weekdays, which predominantly reflects external (that is, social) time constraints.

Sleep quality

Reduced subjective sleep quality can include a variety of symptoms—from trouble initiating and maintaining sleep (insomnia) to early morning awakenings, excessive daytime tiredness, and the feeling of not being refreshed despite a sufficient sleep duration. All of these symptoms have been associated with a variety of psychiatric disorders [86], both as preceding symptoms and as comorbidities. Reduced subjective sleep quality is, for example, often associated with acute depression [87, 88] and is even found in patients with remitted depression [60] either as a residual symptom or as a predictor of relapse. Sleep disturbances can be predictors for the onset of major depression [89], and subjects complaining about insomnia have a 4-fold higher chance of developing major depressive disorder [50].

Sleep structure

The concept of sleep structure has been described (see Structure, p.1138). Due to the limited number of publications, we focus here on the main characteristics of PSG in psychiatric patients. The most obvious changes in PSG could be found in depressed patients. Many studies show a disturbed sleep consolidation, as well as changes in sleep depth and REM sleep pressure [90, 91]. Additionally, two meta-analyses found a reduced duration of SWS [90, 91], which remained

unconfirmed in another study [92], which also found none of these symptoms in SAD.

A recent meta-analysis on PSG and psychiatric disorders by Baglioni *et al.* [92] showed that beyond ADHD and SAD, almost every psychiatric disorder (including personality disorders, schizophrenia, and eating disorders) is associated with sleep alterations. Specific psychiatric disorders were not characterized by single PSG parameters, but rather a specific combination or profile of altered parameters.

Primary prevention of sleep–wake disorders

Sleep disorders, according to ICD-10, refer to hyposomnia, hypersomnia, delayed or advanced sleep timing, irregular sleep, and non-24-hour sleep. The aetiology of these may be as complex as sleep itself. This complexity includes the neuronal circuits and switches that initiate, maintain, and terminate sleep [2], as well as the circadian [3] and homeostatic control [6, 93]; it also pertains to the many different functions that our brain performs during sleep such as synaptic reorganization [94], clearing of accumulated metabolites [95], consolidating memory [96], or immune functions [97]. This is a far from complete list of sleep's mechanistic gearbox that constitutes a breeding ground for sleep–wake disorders. But sleep can only be understood in context, which again constitutes a complex network of different levels. Many everyday life factors influence when, for how long, and how we sleep. Many of them are related to how we expose ourselves to light or what genetic chronotype we are: light exposure during the day—office worker vs farmer, commuting by bike or by tube; light exposure during the night—using intense, blue-rich light after sunset, sleeping in a darkened room; light exposure across the year—affected by season, longitude, timezone and 'time-meddling' like daylight saving time; being a victim of societal time—late-chronotype teenagers learning at 8 in the morning, late chronotypes working early shifts or early chronotypes working at night. Again, this is an incomplete list of context factors, which are fertile soil for developing sleep–wake disorders. While the mechanistic complexity of sleep control does not readily lend itself to primary prevention, the contextual influences on sleep do. Here, we keep to the structure of this chapter and address this issue separately for timing, duration, structure, and quality.

Sleep timing

Sleep timing is by far the most important and amenable threshold for preventive and therapeutic sleep medicine. Most sleep disturbances—apart from the comorbidities of psychiatric or other pathologies (pain, apnoea, etc.)—are due to living against one's internal circadian clock. This modern, highly prevalent syndrome [26] has many names: circadian disruption, circadian misalignment, circadian stress, circadian strain, or social jet lag (for details, see [98]). Its most extreme version is called shift-work. Sleeping and waking at the wrong circadian times has numerous health consequences, many of which are probably directly or indirectly related to sleep disturbances. Realigning sleep times with the temporal window provided by the circadian clock will therefore ameliorate sleep disturbances and thereby decrease health deficits. A recent epidemiological study has shown that late chronotypes have higher odds for developing

type 2 diabetes if they work 'normal' day jobs, compared to working permanent night shifts [99]. Other studies have shown how sleep and health in shift-workers profit by realigning sleep and circadian time [100] or by assigning shifts according to chronotype [101].

In a majority of the population in urban/industrialized regions, circadian clocks are delayed while work schedules have hardly changed. Most people are therefore, figuratively speaking, 'permanent shift-workers'. Thus, any measure that decreases the resulting social jet lag is sleep problem-preventive. Such measures can change either the internal or the external time. The internal phase can be advanced by strengthening the zeitgeber [more light during the day and less (blue-containing) light during the night] or by ensuring an asymmetry in light exposure (more light before internal midday and less thereafter). Another point of action is delaying work and school start times or making them flexible.

Sleep duration

Circadian misalignment and social jet lag always also affect sleep duration. Using an alarm clock and being unable to fall asleep early enough (due to the wake maintenance zone [102]) lead to chronic sleep deprivation during the work week and to over-sleep on weekends. This is also, though of a very different nature, a problem in shift-workers; shift-specific sleep problems are commonly due to forced awakenings. While late chronotypes are awoken by the external alarm clock before early shifts, early chronotypes are awoken too early by their internal (circadian) clocks when they try to get an extended sleep after night shifts [103]. Thus, changing sleep timing—as described—can, in most cases, also prevent insufficient sleep in terms of sleep duration.

Sleep quality

Although we argued that fully consolidated sleep episodes are a modern concept, frequent interruptions are certainly a sign of poor sleep. Sleep quality and sleep interruptions change with age [104]. Alzheimer's patients often wake up during the night and are sleepy during the day. This is partly due to drastically reduced light-dark cycles in these patients, and again this syndrome is treatable with increased zeitgeber strength [105].

Low subjective sleep quality often is due to a wrong conception of what sleep should look like. For example, early chronotypes living in a predominantly late society often perceive their early tiredness and awakening as signs of a sleep disturbance, but only because they are not aware of their chronotype and the large inter-individual variability in circadian sleep timing. Once educated, society still challenges compliance with their own rhythms, but this then becomes a matter of choice, rather than a perceived illness. In other cases, simply by advising 'patients' to keep sleep diaries, which they can visualize, rectifies their misconceptions about sleep.

Sleep structure

Abnormalities in sleep structure can be used in diagnosis and treatment of sleep disorders arising from both the mechanistic and the contextual levels. So far, sleep structure is best detected by PSG in the sleep laboratory or at home, but we are confident that actimetry can be used in future to derive the ultradian structure of sleep and thereby contribute to detection and prevention of sleep disorders. Sleep stages and structure depend on the time of day [3], so that attempts to sleep within the temporal window provided by the

circadian programme should be part of sleep hygiene and preventive sleep medicine.

Conclusions

While we begin to understand the link between sleep timing and somatic problems (for example, metabolic syndrome), we need much more research to understand the association between sleep and psychiatric disorders. We will have to resolve several chicken-and-egg problems, and we have to look into the contexts of light, activity, food, and sleep within our weekly structures. We are optimistic that a combination of long-term activity recordings and the increasing possibilities to extract sleep information from activity will be a rich source for elucidating the different aetiologies of sleep pathologies, as well as the relationships between sleep and pathologies per se.

Genetics of sleep–wake disorders

Diego R. Mazzotti, Allan I. Pack, and Philip R. Gehrman

Introduction

As with the vast majority of biological traits in humans, sleep has an important genetic component. Sleep-related traits and sleep disorders can be considered complex or multifactorial conditions, that is, the aetiology and the biological basis are a combined effect of genetic factors, environmental non-genetic components, and their interaction. Since the stimulus of the Human Genome Project, biomedical research has made real progress in characterizing the genetic architecture and molecular pathways underlying human complex diseases [1]. Establishing that a given trait is heritable implies that underlying genetic factors play a role in determining the phenotype. Despite the established genetic heritability of many sleep-related phenotypes, only a small number of validated genetic variants have been discovered so far. Thus, compared to some other fields, understanding the genetic architecture of sleep-related phenotypes through genome-wide association studies (GWAS) is in a relatively nascent stage. As methodologies for analysing these data continue to develop, research in these emerging genetic areas will improve our current knowledge. Given the known heritability of many traits of sleep and circadian rhythm in humans and also of specific sleep disorders, this is currently a major opportunity for the sleep research community.

In addition to the characterization of genetic factors underlying sleep disorders, a number of neuropsychiatric conditions have been extensively studied in regard to their genetic architecture [2]. It is also well described how sleep disorders are associated with many neuropsychiatric illnesses, and this relationship suggests that there are shared genetic components explaining this association. Only recently have advances in genomic technologies supported the development of knowledge to interpret these relationships biologically. Therefore, it is expected that a better understanding of the genetic contributions to sleep disorders and psychiatric conditions will reveal both common shared and unique molecular pathways to these traits that will help to inform the aetiology of these morbidities, thereby supporting the development of new diagnostic and therapeutic approaches.

Genetics of sleep duration

The duration of sleep varies in individuals in the general population, and a number of studies have shown that the prevalence of

self-reported short sleep duration (<6 hours per night) ranges from 14% to 35% worldwide [3]. Given the known physiological, behavioural, metabolic, and molecular consequences of lack of sleep, understanding the biological basis of short sleep duration is fundamental. Although behaviourally induced short sleep also occurs as a consequence of commitments of modern life, an important genetic contribution has been identified. Studies analysing the differences in sleep duration between monozygotic and dizygotic twins estimated the heritability of sleep duration in the order of 31–44% [4, 5].

Common and rare genetic variants have also been described as associated with this phenotype. Although an initial GWAS based on the Framingham cohort did not find any genome-wide significant single-nucleotide polymorphisms (SNPs) associated with sleep duration [6], another larger GWAS in a population with European ancestry found a significant association in an intronic variant of *ABCC9* in the discovery phase, but not on replication [7]. This gene encodes one of the 17 transmembrane domains of the pore-forming subunit of an adenosine triphosphate (ATP)-sensitive potassium channel (K_{ATP}) that serves as a sensor of cellular metabolism. However, the association between this variant and sleep duration was also not significant in other studies [8–10]. On the other hand, significant associations with other variants in *ABCC9* and sleep duration [11] and depressive symptoms have been found [10]. Knocking down the expression of the homologue of this gene in *Drosophila* was associated with reduced sleep amounts at night [7]. Whether variations in *ABCC9* are associated with sleep duration or with a shared mechanism between sleep duration and depression symptoms, this gene likely plays a role in the control of sleep/wake, suggesting that further investigation is needed.

In a GWAS in a Finnish cohort, no genome-wide significant associations with sleep duration were found [9]. However, some of the suggestive associations were replicated in a follow-up sample. Among the most interesting findings, the authors found an association in the *KLF6* locus. This gene encodes Kruppel-like factor 6, a transcription factor that functions as a tumour suppressor. Higher expression of *KLF6* in circulating mononuclear lymphocytes was related to shorter sleep duration, and its expression in these cells was increased with experimental sleep restriction, suggesting this gene as a modulator of the sleep/wake regulation.

A study from the CHARGE consortium used self-reported sleep duration and genotyping data from 18 community-based cohorts

and found two genome-wide significant associations in European individuals. One of the significant associations was in the *PAX8* locus, which replicated in an independent African-American sample [8]. This gene encodes a thyroid-specific transcription factor involved in thyroid development and function [12], which could be potentially involved in the relationship between sleep regulation and metabolism.

Sequencing studies in individuals with extreme phenotypes in regard to sleep duration were also conducted. He *et al.* investigated two individuals who slept for 6 hours with no evidence of daytime impairments and identified a mutation in exon 5 of the *BHLEH41* (class E basic helix–loop–helix protein 41) gene, also known as *DEC2*. This mutation results in a proline-to-arginine substitution in the protein and had its sleep-affecting properties validated experimentally in *Drosophila* and mice [13]. A further study sequenced *DEC2* in two other individuals with particular sleep phenotypes and identified two new mutations in this gene [14]. In one subject, who was a member of a dizygotic twin pair, the twin with the mutation slept 2 hours less per day and had substantially less performance lapses during prolonged sleep deprivation than the other twin. The other mutation was found in three unrelated individuals, but no obvious effect of this variant on sleep duration. Interestingly, the mutations that were linked to differences in sleep showed clear functional consequences in model organisms, by affecting key mechanisms of the molecular circadian clock [14]. Based on these findings, it is expected that other variants of *DEC2* and other genes that affect the molecular circadian clock can result in short sleep.

Due to the difficulty in defining a reliable and objective phenotype that represents the habitual sleep duration, most of the studies rely only on noisy self-report measures, and conclusive studies are still not available. More objective assessment of sleep duration includes the use of actigraphy-based rest–activity patterns and GWAS, with these objective parameters only conducted recently [15], as described in more detail later in this chapter. Nevertheless, the progress so far indicates that some candidate genes deserve further functional characterization of their roles in sleep/wake regulation.

Genetics of insomnia

Similar to sleep duration, there is a lack of comprehensive studies on the genetics of insomnia, partly because of the uncertainty in defining the appropriate phenotype. Although insomnia is a prevalent condition with defined clinical diagnostic criteria, it is difficult to establish a common biological mechanism, potentially due to the diverse underlying causes. Nevertheless, family and twin studies have been conducted, utilizing self-report measures of insomnia traits, showing that a moderate degree of the variability of these phenotypes can be explained by genetic factors.

Patients whose insomnia began in childhood reported a positive family history of sleep complaints at a higher rate than those with adult-onset insomnia [16]. In a large Australian twin study, additive genetic influences were found for sleep quality, initial insomnia, sleep latency, ‘anxious insomnia,’ and ‘depressed insomnia,’ with heritability ranging from 32% to 44% [4]. In a twin study from the Vietnam Era Twin Registry [17], estimates ranged from 21% to 42% for trouble falling or staying asleep, waking up several times per night, and waking up feeling tired and worn out. In a recent longitudinal

study in a representative sample of twins, there was moderate heritability in the univariate analysis (22–25%), but when accounting for the longitudinal measurement, heritability increased substantially, especially in females (59%), compared to males (38%) [18].

A GWAS for insomnia, defined using a series of questions about sleep patterns, was conducted in Korea, and an association was found with a variant in the *ROR1* locus that was not genome-wide significant [19]. This gene encodes the receptor tyrosine kinase-like orphan receptor 1, a protein that modulates synapse formation and was indicated as a potential candidate explaining genetic variability in this insomnia phenotype. Another GWAS in an Australian twin cohort did not find any genome-wide significant associations [20]. The strongest associations were between self-reported sleep latency and the *CACNA1C* locus, a gene that encodes the calcium voltage-gated channel subunit alpha 1 C and was repeatedly associated with bipolar disorder and schizophrenia [19] (see Chapters 59 and 60). This finding did not replicate in a second cohort but was then subsequently replicated in a different study [10]. More recently, genome-wide associated variants in the *RFX3* locus were reported with self-reported sleep latency [21]. This gene encodes the RNA-binding protein—Fox-1 homolog 3—and is believed to have a role in neuron-specific alternative splicing and to be co-expressed with genes involved with calcium channel activity and signalling of the neurotransmitter gamma-aminobutyric acid (GABA) [21]. Thus, it is of potential interest as a candidate in the aetiology of insomnia.

The fact that insomnia is mainly based on self-reported symptoms and clinical evaluation could partially explain the lack of reproducibility of studies aiming to find a strong biological basis of this disease. In this sense, objective measurements of insomnia-related traits, such as actigraphic recordings, can provide a more robust characterization of some of the phenotypes that compose the condition. Recently, the first GWAS on actigraphic sleep phenotypes found a genome-wide significant association between a variant in the *UFL1* locus and actigraphy-derived sleep efficiency on week days [15]. This gene encodes the ubiquitin-fold modifier 1 specific ligase 1, a protein that participates in the regulation of apoptosis and vesicle trafficking in the endoplasmic reticulum. Variants in other genes (*DMRT1* and *CSNK2A1*) were also associated with sleep latency and deserve further investigation. *DMRT1* encodes the double sex and Mab-3-related transcription factor 1, a protein involved in sexual differentiation and embryonic development, and *CSNK2A1* encodes the alpha subunit of casein kinase II, involved in the regulation of circadian rhythms. Even though studies can achieve more biologically meaningful phenotypes by using objective assessment, it is important to note that there is often a discrepancy between these measures and self-reports of sleep in patients with insomnia [22].

Genetics of narcolepsy and hypersomnia

Narcolepsy is one of the most successful examples for identifying genetic factors in sleep disorders. Based on evidence from studies in mice and dogs, narcolepsy is caused by a disruption in the orexin signalling system, including selective loss of orexin-producing neurons. Although only a single patient with a mutation in the orexin receptor gene was described [23], it is established that patients with narcolepsy present with very low levels of this neuromodulator in the cerebrospinal fluid [24].

Early studies showed a 10–40 times increase in the risk of narcolepsy for someone with a first-degree relative with narcolepsy when compared to the general population [25]. In accordance with the evidence from familial aggregation, there is an established relationship between specific human leucocyte antigen (*HLA*) alleles and narcolepsy [26]. *HLA* encodes the proteins that compose the major histocompatibility complex class II expressed in immune cells, which are involved in presenting foreign peptides to receptors on T cells. In many populations, the *DQB1*0602* allele is strongly associated with narcolepsy (odds ratio approximately 250), particularly in cases that also present with cataplexy, also known as type 1 narcolepsy [27].

Regardless of its strong association with type 1 narcolepsy, the *DQB1*0602* allele is frequent in the general population, with its prevalence ranging in different ethnic groups from 12% in Japanese to 38% in African-Americans [28]. Thus, it is commonly found in many individuals without narcolepsy. In this sense, it could be that the presence of *DQB1*0602* could make individuals more susceptible to environmental insults, in a gene–environment interaction fashion. In addition, multiple gene variants other than *DQB1*0602* may be involved in narcolepsy.

In order to identify additional variants, a series of GWAS where both cases and controls were positive for the *DQB1*0602* allele were conducted. Three variants within the T cell receptor alpha (*TRCA*) locus were significantly associated with narcolepsy and were replicated in independent Caucasian and Asian samples [29], as well as in a study in Chinese patients [30]. This association within *TRCA* was also replicated in a study aimed to evaluate variants relevant to the immune system, which also identified significantly associated variants in other genes such as cathepsin H (*CTSH*) and tumour necrosis factor (ligand) super-family member 4 (*TNFSF4*) [31].

Further studies investigating *DQB1*0602*-positive individuals found additional loci associated with narcolepsy. A significant association with a variant in the promoter region of *CCR1*, a gene that encodes the chemokine (C-C motif) receptor 1, was reported and replicated in an independent cohort, as well as found to be associated with *CCR1* gene expression and lower migration indexes in monocytes with a *CCR1* ligand [32]. Moreover, a single nucleotide variant in the purinergic receptor subtype P2Y11 (*P2RY11*) gene locus was also associated with narcolepsy and presented functional evidence of decrease in gene expression, as well as increased sensitivity of CD8+ T cells to ATP-induced cell death [33]. Interestingly, the *P2RY11* gene locus is within a region where other genes, such as *PPAN*, *EIF3G*, and *DNMT1*, are present, so the signal detected in this GWAS could be related to variants of the other genes in this region. Further studies replicated these signals and identified a strong signal in a haplotype involving *P2RY11/EIF3G* in European and Chinese cohorts [34]. Mutations in the DNA methyltransferase 1 (*DNMT1*) gene in individuals with autosomal dominant cerebellar ataxia, deafness, and narcolepsy supported the role of this region [35]. This gene encodes an enzyme responsible for maintaining methylation patterns in development and is required for the differentiation of CD4+ cells into T regulatory cells. Additionally, a genome-wide copy number variation (CNV) analysis in a Japanese cohort identified an enrichment of rare and large CNVs in different immune response-related genes, as well as duplications in the Parkinson's disease protein 2 (*PARK2*) gene in patients, compared to controls [36]. The protein encoded by this gene also participates in antigen

processing and presentation, supporting the existence of an autoimmune component against orexin-producing neurons [37].

In regard to environmental influences and supporting the role of the immune system in the physiopathology of narcolepsy, a strong relationship between this sleep disorder and upper airway winter infections was described. There was a significant increase in the onset of narcolepsy after the 2009 H1N1 influenza pandemic [38], and a follow-up GWAS revealed additional loci in the *HLA* region in cases with narcolepsy with onset after the 2009 pandemic [39].

Despite efforts in the characterization of the genetic basis of type 1 narcolepsy (narcolepsy with cataplexy), a growing number of studies have been investigating the role of genetics in other forms of excessive somnolence such as essential hypersomnia syndrome (EHS). This condition differs from narcolepsy mainly because of the absence of cataplexy, but the sleep-related symptoms are indistinguishable [40]. The *DQB1*0602* allele is also associated with EHS, although not as strongly as narcolepsy with cataplexy [41]. Similarly, variants in the *TCRA* locus were described as associated with EHS in *DQB1*0602*-positive individuals [42]. A more recent GWAS in *DQB1*0602*-negative individuals with EHS reported three new loci associated with the condition (*NCKAP5*, *SPRED1*, and *CRAT*), all of which contain genes previously related to other neuropsychiatric diseases [43]. *NCKAP5* encodes NCK-associated protein 5 that still has unknown function. *SPRED1* encodes sprouty-related EVH1 domain-containing 1, a protein phosphorylated in response to growth factors. *CRAT* encodes carnitine *O*-acetyltransferase, a key enzyme in β -oxidation of fatty acids. These genes were described as candidates in EHS but still need replication and functional follow-up.

Genetics of chronotype and circadian rhythm disorders

One of the mechanisms through which an organism responds to temporal changes in the environment as a consequence of the light–dark cycle is through regulation of the ‘biological clock’. This system, also known as the molecular circadian clock, consists of autoregulatory feedback loops involving the transcription, translation, and degradation of proteins encoded by the clock genes. This set of genes includes *PER1*, *PER2*, and *PER3*, and *CRY1* and *CRY2*, as well as *CK1 δ* , *CK1 ϵ* , *CLOCK*, *NPAS1*, *NPAS2*, *DEC2*, *BMAL1*, and *BMAL2* [44]. Given the existence of a comprehensive molecular pathway regulating the generation of circadian rhythms, it is expected that variation in genes in this system could affect circadian behaviours and disorders.

Chronotype is known as the behavioural outcome that results from the generation of endogenous biological rhythms and interaction with the environment. Individuals can be classified as an evening type (that is, ‘night owls’), morning type (that is, ‘larks’), or intermediate. Several twin and family studies have estimated that chronotype is a moderately heritable trait, with genetic factors potentially explaining as high as 50% of the variability in this phenotype [45, 46]. This estimate can also be affected by the type of environment in which the individual lives, that is, urban or rural [47].

Linkage studies of extended families with circadian rhythm sleep disorders, primarily advanced sleep phase syndrome (ASPS), allowed the identification of specific rare variants that segregate

with the disorder. A serine-to-glycine mutation in the clock gene *PER2* was reported in a family [48], and different mutations in the *CK1δ* gene were identified as the causal variant in other two studies [49, 50], supporting the role of the molecular circadian clock in ASPS. Interestingly, mouse knockouts for these genes also replicate the phenotypes seen in humans.

Common genetic variants in other genes of the molecular circadian clock, such as *CLOCK*, *PER1*, *PER2*, and *PER3*, are also associated with chronotype and other circadian rhythm disorders [51–53], but not replicated in other studies [54, 55]. One of the most studied variants is a variable number of tandem repeats polymorphism in *PER3* resulting in four or five repeats of a 54-bp motif in exon 18 [56]. This polymorphism was associated with delayed sleep phase syndrome and diurnal preference [57, 58]. The association was replicated in Brazil [59] and South Africa [60], but not in Colombia [61] or in Norway [62].

Given the evidence provided by genetic associations studies, as well as the functional nature of this polymorphism, a more in-depth characterization of sleep and circadian phenotypes was performed to evaluate the role of these variants of *PER3*. Although no significant differences were found in circadian phenotypes, differences in sleep and wake behaviour in response to sleep deprivation were found between individuals carrying *PER3*^{4/4} and *PER3*^{5/5} genotypes [63]. *PER3*^{5/5} carriers showed increased slow-wave sleep, as well as electroencephalographic markers of slow wave activity and greater decrement in cognitive performance, in response to sleep deprivation. These findings was complemented by another study suggesting that *PER3*^{4/5} is associated with greater behavioural resiliency to sleep restriction when compared to *PER3*^{4/4} [64], and *PER3*^{5/5} carriers showed a more pronounced impact of sleep deprivation on sustained attention, with increased sleepiness, than *PER3*^{4/4} carriers [65].

Genome-wide approaches were also used to potentially identify genetic loci related to circadian phenotypes. In an early family-based study in the Framingham cohort, a linkage peak close to the *CSNK2A2* gene was found with usual bedtime. This gene encodes the catalytic unit of casein kinase 2 that was described as an important component in the molecular circadian clock [6]. More recently, a large GWAS in >89,000 customers of European ancestry of the personal genetics company 23andMe, Inc. identified 15 genome-wide significant loci associated with self-reported morningness. This study also found an enrichment of associated variants of genes in circadian and phototransduction pathways [66]. In addition, another large GWAS in the UK Biobank cohort in >100,000 individuals of European ancestry validated eight loci and reported a consistent effect of all the 15 loci reported by Hu *et al.* in 2016. A meta-analysis combining results of both studies reinforced the role of three loci: *PER3*, *VIP* and *TOX3* [67]. *VIP* encodes vasoactive intestinal peptide, a key molecule in the central nervous system. Intracerebroventricular administration of this peptide was found to increase the rapid eye movement sleep time in rabbit. *TOX3* encodes TOX high mobility group box family member 3 and was previously associated with restless legs syndrome (RLS) [68].

has been diagnosed primarily using solid symptom-based criteria [69] that allowed the identification and validation of a number of genetic risk factors, establishing it as a relevant disorder. Positive family history [70, 71], twin studies [72, 73], and complex segregation analyses [74, 75] supported the existence of an important genetic component in RLS. Most studies reported the heritability of RLS to vary between 40% and 65% [76].

Linkage analyses within large-family pedigrees were able to identify significant genetic loci linked with RLS on chromosomes 12q22–23.3, 14q13–22, 9p24–22, 2q33, 20p13, 16p12.1, 4q25–26, 17p11–13, 19p1 [76], and 13q32.3–33.2 [77]. Follow-up candidate region case-control association studies in these regions were able to find significant variants associated with RLS and potential candidate genes. Significant associations with single-nucleotide variants in *NOS1* [78] and *PTPRD* [79] were described and replicated in independent cohorts. *NOS1* encodes nitric oxide synthase 1 and has been associated with pain perception and sleep-wake control [80]. *PTPRD* encodes protein tyrosine phosphatase receptor type delta, involved in long-term potentiation in memory formation and abnormal axon targeting to motoneurons during development in mice [81, 82].

GWAS were also conducted, and the first two reports were published simultaneously and independently in Caucasian populations. One study in German and French Canadian cases, who were diagnosed by face-to-face interview with expert clinicians, identified and replicated variants associated with RLS in three different loci: *MEIS1*, *BTBD9*, and *MAP2K5/SKOR1* [83]. The other study of cases from Iceland and the United States used self-assessment questionnaires that contained the essential diagnostic criteria, as well as leg actigraphy to assess periodic limb movements during sleep, also identified variants in *BTBD9* associated with RLS. Interestingly, the association was only found in cases that also showed periodic limb movements during sleep, and this variant was also associated with ferritin levels [84]. The associations between variants in *MEIS1*, *BTBD9*, and *MAP2K5/SKOR1* have been confirmed in further independent investigations [76]. Also, an excess of loss-of-function alleles in *MEIS1* was found in RLS cases, compared to controls [85], supporting the role of these genetic loci in RLS. The functional roles of *MEIS1* (limb axis formation and neuronal differentiation), *SKOR1* (neuronal differentiation), *MAP2K5* (muscle cell differentiation), and *BTBD9* (iron and ferritin metabolism and sleep fragmentation) corroborate the associations found in variants within these genes and the pathophysiology of RLS and might suggest the role of developmental abnormality. However, better characterization of the molecular mechanisms that integrate these genes in the syndrome in humans is still warranted.

An exome sequencing study identified a rare variant in *PCDHA3* segregating in a family with multiple cases of RLS, and two additional rare missense variants in unrelated cases [86]. *PCDHA3* is expressed in neurons, and its product is present at synaptic junctions in neural cell–cell interaction [87]. This is another plausible candidate for the genetics of RLS.

Genetics of restless legs syndrome

RLS is another successful example of how genetics has helped to identify the pathophysiology of a sleep-related condition. This disorder

Genetics of obstructive sleep apnoea

Obstructive sleep apnoea (OSA) is a highly prevalent complex condition characterized by partial or complete blockage of the airway

during sleep that leads to a repetitive reduction in blood oxygen saturation [88]. Some of the major risk factors include older age, male gender, and obesity [89], although not all cases of the disease can be explained by these factors. This suggests a high degree of heterogeneity and indicates an interesting phenotype to conduct genetic investigations.

An initial study of a single family with a high prevalence of OSA suggested for the first time the existence of an important genetic component [90]. Further investigation reported that some of the most common symptoms of OSA also aggregate in families [91], along with more refined measurements of apnoeas and hypopneas during sleep [92, 93]. Addressing the confounding effect of obesity, which is a major risk factor for OSA, the Cleveland Family Study found an increased relative risk of OSA in first-degree family members, even after controlling for body mass index [94]. This approach was supported by another investigation that identified familial aggregation of specific craniofacial features in less obese cases of OSA [95], suggesting that factors other than obesity also play an important role in the genetics of this disorder. In addition to familial aggregation, the heritability of OSA ranges between 21% and 84%, depending on the phenotype used to define the disorder and the population studied [96, 97].

There has been, however, little progress in identifying relevant and causal genetic variants accounting for the variability in OSA. Due to the heterogeneity of the phenotype, as well as technical and statistical limitations, linkage and association studies failed to report consistent results [98–100]. This led to meta-analyses of candidate genes failing to find evidence that the majority of the reported associations were replicable [98, 101], except for a polymorphism in the promoter of the *TNFA* gene. Given the participation of inflammatory response in the physiopathology of OSA [102], tumour necrosis factor alpha is an important candidate contributing to key consequences of OSA. A study in paediatric OSA patients showed higher tumour necrosis factor plasma levels, particularly in carriers of the promoter polymorphism in the *TNFA* gene [103]. In addition, these patients also presented significantly increased symptoms of excessive daytime sleepiness, suggesting that this variant might explain, in part, this particular phenotype in paediatric OSA.

A genetic association study with variants across 2000 candidate genes relevant to heart, lung, blood, and sleep disorders in the Cleveland Family Study and the Sleep Heart Health Study found a genome-wide significant association between the apnoea–hypopnea index and a variant in the *LPAR1* gene and another in the *PTGER3* gene [104]. The *LPAR1* gene encodes lysophosphatidic acid receptor I, a pro-inflammatory protein expressed in the developing cerebral cortex [105] and associated with changes in behaviour and craniofacial abnormalities in mice knockouts [106]. The product of the *PTGER3* gene—the prostaglandin E2 receptor—was described as a modulator of neurotransmitter release in central and peripheral tissues. Both genes seem to participate in important molecular pathways that could partly explain the aetiology of OSA.

Only recently has a large-scale GWAS on OSA quantitative traits been performed, in Hispanic/Latino cohorts. The authors identified two genome-wide significant candidate regions associated with the apnoea–hypopnea index and respiratory event duration in the *GPR83* and *C6ORF183/CCDC162P* loci, respectively. *GPR83* encodes a G-protein receptor expressed in different brain regions of importance to OSA, and linked to body temperature, metabolism, and

inflammatory response regulation. *C6ORF183* and *CCDC162P* are pseudogenes, and this locus was associated with red blood cell traits. Additional loci involving other plausible genes were also identified, supporting the involvement of inflammatory and hypoxia signalling pathways, as well as sleep-related gene sets [107]. However, these associations have still not been independently replicated.

Given the complexity and different proposed mechanisms and pathways contributing to OSA, the genetic study of the major risk or protective factors of this disorder can be an interesting approach and has not been explored so far. For example, there are multiple obesity and body mass index genetic loci identified by GWAS [108], but the genetic correlation between obesity and OSA is yet to be determined. Other opportunities for investigation involve the genetics of major components of OSA pathophysiology such as fat distribution [109], soft tissue volume [110], craniofacial structures [111], and hypoxic response [112], as well as other respiratory physiological parameters without genetic characterization to date. Additionally, understanding the role of ancestry and how it affects the identification of genetic risk factors of OSA has already been proposed [113], but not explored at its full potential. Although it seems a challenging task trying to dissect the complex genetic architecture of OSA, it certainly offers an exciting opportunity for future research.

Conclusions

The genetics of sleep disorders is an emerging and rapidly evolving field in sleep medicine. Some disorders, particularly narcolepsy and RLS, present more consistent results; however, the majority of sleep-related traits still lack a robust characterization of their genetic basis. Sleep-related traits are heterogenous phenotypes, and a complex genetic architecture is expected, requiring more robust and objective ways to characterize intermediate phenotypes, as well as larger sample sizes to detect the expected low effect of variants explaining the variability in these traits. In addition, most of the identified genetic regions lack a comprehensive functional characterization of the gene and sometimes rely only on the effect of the variant on the closest gene, and not within a genomic context. Given the relationships between sleep and neuropsychiatric disorders, and the promising opportunity of more refined genetic and phenotypic characterizations, understanding the genetic basis of sleep and wake regulation could partially inform the aetiology of other relevant mental and neurological conditions for public health awareness. While understanding the genetic aspects of sleep/wake disorders imposes a challenge, it is an example of the genetic study of complex and multifactorial traits in humans.

Multimodal imaging of sleep–wake disorders

Umberto Moretto, Dylan Smith, Liliana Dell’Osso, and Thien Thanh Dang-Vu

Introduction

The understanding of sleep and its disorders has vastly improved in recent years, aided significantly by technological and methodological advancements in neuroimaging techniques, which allowed for more precise neuroanatomical insight into the activity of the sleeping brain. Indeed, the brain does not ‘turn off’ during sleep and, in fact, remains active throughout the sleep cycle. While it is difficult to obtain a direct measure of neuronal activity, neuroimaging techniques have allowed sleep researchers to safely detect its correlates in human subjects during sleep and sleep/wake transitions.

The widely available research methodology include magnetic resonance imaging (MRI) and functional MRI (fMRI), magnetic resonance spectroscopy (MRS), positron emission tomography (PET), and single-photon emission computed tomography (SPET or SPECT), described in more detail in Chapter 12. When used in sleep research, these neuroimaging techniques can be powerful tools for illuminating the complex neuronal activities that shape brain function throughout the different stages of sleep.

Neuroimaging is particularly useful for studying sleep disorders. For example, insomnia has been associated with an excess of activity in brain regions responsible for processing emotion, as well as with a marked lack of activation in networks normally responsible for the inhibitory regulation of these regions, and these differences tend to be most pronounced during transitions from wakefulness to sleep. Although less consistent than functional imaging studies, neuroimaging of brain anatomy in insomnia suggests alterations in the compositional integrity of discrete brain structures such as the hippocampus and prefrontal cortex, as well as the rostral anterior cingulate cortex. Taken together, neuroimaging techniques have proven to be a powerful tool in understanding the neural mechanisms underlying sleep and pathologies leading to sleep disorders. This chapter will provide an overview of these imaging methods and discuss findings they have provided pertaining to sleep, insomnia, and other sleep–wake disorders. While this chapter focuses selectively on neurological disorders of sleep, we encourage the reader to consult dedicated works for a comprehensive overview of sleep disorders [1].

Imaging in normal sleep

As described in detail in Chapter 109, the current predominant model of human sleep divides this physiological state into four stages, based on the characteristics of brain activity, muscle tone, and eye movements, with the main differentiation being between rapid eye movement (REM) sleep from non-REM (NREM) sleep, which is composed of stage N1, N2, and N3 sleep. Stage N3 sleep was previously further divided into stages 3 and 4 of sleep, but these were consolidated due to a lack of evidence for a neurophysiological difference between them. During a night of sleep, the brain continuously cycles through these stages in periods of approximately 90 minutes.

N1 sleep marks the transition from wakefulness to sleep. This stage of sleep, which normally constitutes 5–10% of total sleep time, shows a slower pattern of brainwave activity, compared to the awake state, when measured by electroencephalography (EEG). Stage N1 is followed by stage N2 where two distinct microarchitectural EEG patterns—K-complexes and spindles—are visible. Slow waves, also referred to as K-complexes during stage N2, are typified by a large ($>75 \mu\text{V}$), low-frequency (0.5–2 Hz) negative peak, followed immediately by a lower-frequency positive inflection. Spindles are short bursts of approximately 11–15 Hz activity lasting approximately 0.5 seconds. Spindles are thought to reflect brain processes involved in gating out of sensory stimuli that might otherwise wake the sleeper, as well as other cognitive functions such as memory consolidation. N2 sleep generally comprises 45–55% of total sleep. The next stage of NREM sleep N3 is also known as slow-wave sleep (SWS) due to an increased prevalence of slow waves on the EEG. Commonly known as ‘deep sleep’, N3 occurs mostly during the first half of a full night’s sleep and constitutes 15–25% of total sleep time. REM sleep, characterized by rapid eye movements, is the stage of sleep most associated with dreaming. Hallmarks of REM sleep include muscle atonia, as well as an EEG profile more similar to the awake state than that of NREM sleep. For this reason, REM sleep is also known as ‘paradoxical sleep’. REM sleep usually accounts for 20–25% of total sleep and occurs mostly during the second half of a normal night’s sleep.

Imaging in NREM sleep

During NREM sleep, cortical neuron activity transitions into a pattern of slow oscillations, alternating between brief bursts of neuronal firing ('up' states), followed by long intervals of hyperpolarization ('down' states). This oscillation forms the basis of cortical synchronization in NREM sleep, which is observed on EEG as spindles and slow waves. As EEG-indexed synchronization increases, down-state hyperpolarization is also associated with decreases in regional cerebral blood flow (rCBF) using PET, with gradual decreases during the transition from wakefulness to N1 and N2, reaching a minimum during N3 [2].

The induction of NREM sleep seems to be facilitated by a decreased activity in the brainstem tegmentum and its ascending pathways, as evidenced by human PET studies showing decreased activity in the pontine tegmentum during light NREM extending to the mesencephalic tegmentum during SWS [3]. Sleep spindles are thalamocortical in origin, generated by the activity of GABAergic thalamic reticular neurons and are reflected by rCBF decreases in thalamic areas during NREM sleep [3].

Moreover, the cerebral cortex also shows SWS deactivation, albeit with larger rCBF decreases in frontal and parietal cortices, with less deactivation observed in the primary cortices [3]. The observed decreases in rCBF are likely due to a larger net contribution of the down state to the overall PET signal, which is averaged across periods of several minutes. However, recent studies utilizing combined EEG and fMRI have confirmed a transient increase of brain responses in cortical and subcortical brain areas during slow waves and spindles [4, 5].

Studies of functional connectivity in NREM sleep have shown attenuated connectivity of the default mode network (DMN). The DMN, a functional neural network highly active in the absence of any stimuli or task, shows uncoupling, particularly between its anterior (medial prefrontal) and posterior (precuneus, posterior cingulate) nodes, during deep sleep [6]. In general, there is evidence that transitioning from light to deep NREM sleep is associated with uncoupling of functional neural networks in favour of an increase in local connectivity [7]. This is in line with recent consciousness theories, according to which decreasing levels of functional connectivity are the physical correlates of decreasing levels of consciousness.

Imaging in REM sleep

In contrast with NREM sleep, REM sleep is defined by a marked desynchronization of brain waves, more closely resembling the awake state in general, with some areas showing increased activity, compared to wakefulness, and decreased activity in others.

During REM sleep, rCBF is increased specifically in limbic and paralimbic areas, the pontine tegmentum, thalamic nuclei, amygdaloid complex, anterior cingulate, orbitofrontal and insular cortices, and hippocampal formation [3, 8]. In contrast, the middle and inferior prefrontal gyri, posterior cingulate, and precuneus tend to show decreases in rCBF during REM [3, 8].

Induction of REM sleep is also believed to originate in the brainstem, as evidenced by increased activation of the mesopontine, which is thought to activate the thalamus and, in turn, the cortex [9]. Neurons in the pons generate ponto-geniculo-occipital waves, which can be recorded at different levels of this pathway: the pons, the lateral geniculate bodies, the occipital cortex, and limbic areas

[10, 11]. A time course analysis of BOLD responses during REM sleep showed activation of the pons, the thalamus, and the visual cortex, in association with REM [12]. PET-indexed rCBF analysis showed coupling of the lateral geniculate bodies, the occipital cortex, and REM during REM sleep, but not in wakefulness [13].

REM sleep has also been observed to exhibit a unique pattern of functional connectivity, exemplified by a curious dissociation between striate and extrastriate cortical areas, which is opposite to that seen in wakefulness [14]. The DMN, previously mentioned to show uncoupling in NREM sleep, demonstrates recoupling again during REM sleep between the anterior and posterior nodes of the DMN, similar to the awake state [15]. However, other changes in DMN functional connectivity occur during REM sleep such as an anti-correlation between the DMN and the thalamus, as well as sensorimotor areas [15].

Dreams, a hallmark of REM sleep, may also be related to distinct neurophysiological activity. Increased activation of the amygdala during REM is likely related to the strong emotional content experienced in dreams, and deactivation of areas associated with working memory, such as the dorsolateral prefrontal cortex, might explain the discontinuity commonly reported by dreamers [8]. The vivid visual and auditory content of dreams has been linked to hyperperfusion within occipital and temporal lobes, while the feeling of movement may be explained by increased activity within premotor and motor cortices [3, 14]. These movements are not acted out by the sleeper in normal conditions due to muscle atonia, another characteristic of REM sleep.

Imaging in insomnia

Insomnia, defined by difficulty in sleep initiation, continuity, or quality, which leads to significant daytime impairments, has only relatively recently been considered from a neurological point of view. Current theories ascribe the aetiology of insomnia to alterations in neural control over sleep–wake regulation systems. An imbalance in these systems may be due to increased activity in networks contributing to arousal (hyperarousal), or hypofunction of those responsible for initiating or maintaining sleep [16].

A summary table of functional neuroimaging studies of insomnia can be found in Table 113.1. Compared to normal sleepers, individuals suffering from insomnia show a decrease in rCBF in the basal ganglia, medial frontal, parietal, and occipital cortices, and this decrease is most prominent in NREM sleep [17]. Interestingly, basal ganglia activity seems most sensitive to cognitive behavioural therapy for insomnia (CBTi), with one study showing a 24% increase in basal ganglia rCBF, coupled with a 43% improvement in average sleep latency, following CBTi [18]. A landmark PET imaging study in primary insomnia (that is, in the absence of major comorbidities) showed a lack of reduction in brain glucose metabolism from wakefulness to sleep, lending credence to the hyperarousal theory of insomnia where brain metabolism maintains a profile more similar to the awake state in insomnia, compared to good sleepers [19]. Specific brain areas that were affected by this failure to reduce glucose metabolism during wake–sleep transition included the ascending reticular activating system, thalamus, hypothalamus, hippocampus, amygdala, and anterior cingulate, insular, and medial prefrontal cortices. Conversely, during wakefulness, these areas—particularly the

prefrontal cortex—showed relatively reduced glucose metabolism in insomnia sufferers, compared to good sleepers. While this initial study utilized a small sample size, a replication study comparing 44 primary insomnia sufferers with 40 good sleepers showed insomnia to exhibit smaller sleep–wake differences in glucose metabolism in brain regions involved in cognition (prefrontal), self-referential processes (precuneus/posterior cingulate), and emotion (prefrontal, fusiform/lingual gyri) during NREM sleep. These differences can be seen in Fig. 113.1. Moreover, consistent with previous findings, activation of these areas was impaired during wakefulness in insomnia, compared to good sleepers [20]. Another PET study of insomnia sufferers found that measures of WASO (wake after sleep onset) positively correlated with metabolism in the pontine tegmentum and in thalamocortical networks in a frontal, anterior temporal, and anterior cingulate distribution [21].

Neuroimaging studies investigating the waking state and cognition in insomnia have generally focused on fMRI-indexed activation of specific brain areas or networks, compared to healthy good sleepers. Insomnia was associated with lower prefrontal cortex activation during a verbal fluency task, compared to controls, and this decreased activation was partially restored after CBTi [22]. A different study showed that insomnia sufferers failed to decrease DMN activation during a working memory task, whereas controls showed attenuation of the DMN in favour of the activation of more task-specific brain areas [23]. This inability to switch neural activation patterns to those required for specific tasks may explain subjective complaints of diminished cognitive performance in insomnia. Additionally, DMN activation has also been linked to rumination in other disorders, and thus failure to attenuate this network may also provide a biological basis for cognitive rumination associated with insomnia [24, 25]. An fMRI-based investigation into amygdala activation in insomnia found heightened activation in response to insomnia-related stimuli, compared to controls, but this difference was not observed when insomnia-unrelated stimuli were tested, supporting the use of insomnia-specific cognitive restructuring that is routinely performed during CBTi [26].

MRS-based investigations in insomnia have been less consistent. Some studies have shown lower relative concentrations of brain GABA in insomnia, compared to controls, both globally [27] and localized to the occipital and anterior cingulate [28]; however, a later study showed an increase in occipital GABA

concentrations [29]. A more recent study failed to replicate these results, showing no difference in GABA levels between insomnia sufferers and controls in the areas of interest (anterior cingulate cortex and dorsolateral prefrontal cortex) [30]. While the direction of effect is inconsistent, possibly due to different times of MRS data acquisition (morning vs bedtime), dysregulation of GABA neurotransmission may be a potential target for both identification and treatment of insomnia and thus warrants further study. An MRS study of phosphocreatine revealed lower levels in grey matter of insomniacs in comparison to controls. Given the fact that lower levels of this metabolite are markers of an increased energy demand, this finding provides further evidence for the hyperarousal theory of insomnia [31].

Structural MRI investigations (with volumetry and VBM analyses) in insomnia have also been inconsistent, with some observations failing replication and others not surviving statistical corrections. A summary table of structural neuroimaging studies of insomnia can be found in Table 113.2. There is some evidence for reduced hippocampal volume in insomnia, but these results are not universal [32–35]. In one study, hippocampal volume was shown to be negatively correlated with insomnia duration and arousal indices; however, no significant differences in hippocampal volume were observed between insomnia sufferers and controls [34]. A different small-sample study did report significant deficits in bilateral hippocampal volume in insomnia [32]. This was later corroborated by a different group using a larger sample size that further showed a negative correlation between CA1 volume and sleep quality [36]; the combined volume of CA3, CA4, and the dentate gyrus was also negatively correlated with cognitive performances in verbal fluency, verbal memory, and verbal information processing tasks [36]. Other areas that seem to be affected in insomniacs are the rostral anterior cingulate cortex, found to be increased in volume [37], the prefrontal (dorsolateral, orbitofrontal, medial frontal), precentral, superior, and middle temporal cortices, the precuneus, and the cerebellum, found to display decreased grey matter volume in insomniacs [38–40]. The pineal gland has also been a focus of neuroanatomical research due to its involvement in regulation of the circadian rhythm via melatonin production and release. One study revealed volume reduction of the pineal gland in insomniacs, compared to controls, with pineal gland volume also negatively correlating with age in insomnia, but not in controls [41].

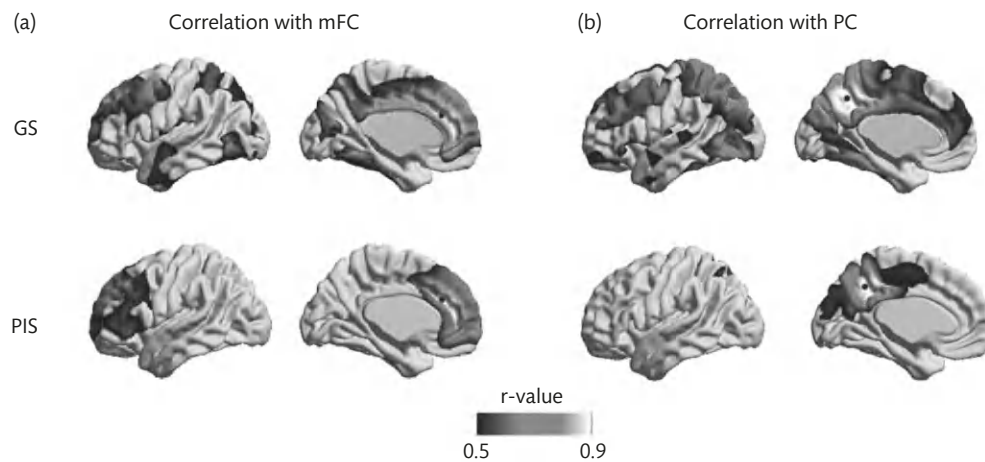

Fig. 113.2 Structural covariance of cortical thickness—good sleepers (GS), compared to individuals with persistent insomnia symptoms (PIS). Insomnia sufferers showed a marked reduction in the spatial extent of cortical thickness correlations with regions of the default-mode network, that is, (a) the medial frontal cortex (mFC) and (b) the precuneus (PC).

Updated from [89].

Finally, a few studies investigated brain connectivity in insomnia. A recent structural MRI study found decreased cortical thickness correlation (that is, structural covariance) between anterior and posterior regions of the DMN in individuals with persistent insomnia symptoms (see Fig. 113.2), suggesting decreased connectivity within the DMN, and this decrease was negatively correlated with sleep quality [40]. This contrasts with other data showing increased structural covariance between sensory and motor cortices in insomnia [42]. Resting-state fMRI studies showed that insomnia was associated with disruption of medial prefrontal cortex functional connectivity with the right medial temporal cortex and left medial temporal lobe functional connectivity with the left inferior parietal cortex [43], as well as superior parietal lobe functional connectivity with the dorsolateral prefrontal cortex [44]. In line with the concept of emotional dysregulation in insomnia, resting-state fMRI data also showed increased functional connectivity between the amygdala and other regions such as sensorimotor cortices [45].

Overall, neuroimaging studies of insomnia have been mainly conducted in individuals with primary insomnia and gave further support to the hyperarousal theory—reduced deactivation during the sleep–wake transition [19], difficulty deactivating irrelevant cognitive processes [23], enhanced activity and connectivity of threat and emotional neuronal circuitry [26, 45], and reduced concentration of inhibitory neurotransmitters [28] all contribute to the incapacity to modulate levels of cortical arousal across the sleep–wake cycle. Recent data also suggest complex patterns of altered neural connectivity in insomnia. The significance of these abnormalities in structural and functional connectivity remains unclear, and further studies are warranted to confirm and clarify the relevance of these findings for the pathophysiology of insomnia.

Imaging in other sleep disorders

Narcolepsy

Narcolepsy is a disorder characterized by irresistible bouts of sleep throughout the day, often associated with REM-related features such as sleep paralysis, cataplexy, and hallucinations. Type 1 narcolepsy is characterized by cataplectic episodes and decreased cerebrospinal fluid levels of hypocretin. In the absence of these criteria, narcolepsy is classified as type 2. Significant DTI-indexed differences were observed between these two subtypes of narcolepsy, whereas no differences were observed between type 2 and healthy controls, suggesting the two types may result from different pathological mechanisms, with type 2 being a milder form with no apparent structural brain pathology [46]. Therefore, the bulk of neuroimaging research in narcoleptic patients focuses on type 1.

A meta-analysis of VBM in MRI studies of narcolepsy found selective grey matter loss in multiple brain areas, thought to be related to a damaged orexin/hypocretin pathway and emotional regulation system [47]. Unsurprisingly, multiple studies found alterations in the hypothalamus where orexinergic neurons are located [48], as well as the fronto-temporal cortex [47]. Further MRI analysis found a reduction in amygdalar volume, possibly serving as a mechanism for dysfunctional emotional regulation in the disorder [49].

Two fMRI studies sought to elucidate the nature of altered response to affective stimuli in narcolepsy via the presentation of humorous stimuli. Interestingly, while both studies observed

increased amygdalar responses in patients, compared to healthy controls, observations in the hypothalamus were inconsistent. One study showed a decrease in hypothalamic response in response to affective stimuli [50], whereas the other study showed an increase in hypothalamic response, with the exception of one participant who experienced a cataplectic attack during the study and showed dramatic reductions in hypothalamic activity [51]. While these results seem to suggest an overdriven emotional network in narcolepsy, the role of the hypothalamus is not clear. The inconsistency in these results may be due, in part, to the relatively small sample sizes utilized in these studies.

Restless legs syndrome

Restless legs syndrome (RLS) is characterized by an unpleasant and uncomfortable feeling in the legs, accompanied by the urge to move them in order to relieve this sensation. It occurs during the evening and at night, when sitting or lying down, and sometimes interferes with sleep onset.

The mechanism underlying RLS pathogenesis is hypothesized to involve inhibition of adrenergic, opiate, and dopaminergic descending inhibitory pathways [52]. This is supported by the observation that dopamine antagonists exacerbate RLS and dopamine agonists relieve symptoms [53].

Striatal dopamine transporter (DAT) and D2 receptor dysregulation in RLS has been extensively investigated using SPECT, but the results have been contradictory, pointing towards dysregulation, rather than a net increase or decrease of receptors [54, 55].

Similarly, PET studies using C-raclopride have found conflicting results on striatal D2 receptor binding, with differences across studies attributed to drug-naïve patients used in some studies, while others assessed patients on medication which can downregulate D2 receptors [56]. Opioid PET studies using C-diprenorphine showed no difference between RLS patients and controls; however, a relationship between RLS severity and decreased opioid binding was found, possibly due to competitive endogenous opioid release in response to pain [57].

Structural MRI studies have shown evidence of alterations in pulvinar grey matter in RLS, compared to controls, though it is unclear whether these alterations are a cause or a consequence of the syndrome [58]. A study using VBM found grey matter decreases in the primary sensorimotor cortex [59], and a DTI study revealed white matter alterations in this same area, as well as in the thalamus [60]; however, these anatomical deviations, compared to controls, were not significant when drug-naïve subjects were included [61, 62].

Functional MRI studies during resting state showed reduced thalamic connectivity with the right parahippocampal gyrus, right precuneus, right precentral gyrus, and bilateral lingual gyrus, as well as increased connectivity with the temporal and other areas. Interestingly, there was a negative correlation between RLS severity and right parahippocampal gyrus connectivity with the thalamus, suggesting dysfunction at the level of somatosensory information processing [63].

MRS studies of RLS point towards thalamic dysfunction, with one study showing decreased *N*-acetyl aspartate (NAA) concentrations and NAA/creatine (Cr) ratios in the medial thalamus of RLS participants, compared to controls, indicative of neuronal damage, but

without showing fMRI or DTI-indexed alterations [64]. Another study found increased glutamate–glutamine/creatine ratios in the thalamic region of RLS patients, compared to controls, and interestingly, this ratio correlated with WASO [65], supporting the involvement of a glutamatergic arousal system in RLS. GABA was also investigated, with no difference in levels between RLS patients and controls. However, a positive correlation was found between thalamic GABA levels and RLS severity, as well as a negative correlation between cerebellar GABA and this same measure [66]. This suggests a role for the thalamus and the cerebellum in the modulation of RLS intensity.

REM sleep behaviour disorder

REM sleep behaviour disorder (RBD) is a parasomnia characterized by movements or vocalizations which occur during REM sleep and are consistent with enactment of dream content. This disorder is often idiopathic but can also be comorbid with other neurological disorders or related to pharmacological effects (for example, antidepressants). The majority of idiopathic RBD patients will eventually develop neurodegenerative alpha-synucleinopathies such as Parkinson's disease (PD), multiple system atrophy, and Lewy body dementia [67].

A study attempting to elucidate the pathways involved in human RBD has employed SPECT, combined with video polysomnography, with injection of a radiotracer during an RBD episode. Increased metabolism was shown in premotor areas, the interhemispheric cleft, the periaqueductal area, the dorsal and ventral pons, and the anterior lobe of the cerebellum. Interestingly, no activation of the basal ganglia was observed, as is observed during wakeful movements. However, this study used a small sample size and no control group [68]. Other SPECT studies have reported differences in brain activation, compared to healthy controls, during resting wakefulness. A study in awake SPECT patients found decreased activity in the temporo-parietal and frontal cortices, as well as increased activity in the putamen, pons, and right hippocampus [69], and these findings have been replicated using larger populations [70, 71]. Decreased rCBF in the parietal, occipital, limbic, and cerebellar regions was observed in a group of idiopathic RBD patients, and a 2-year follow-up with the same individuals revealed further reduction of rCBF in the medial portions of the parieto-occipital lobe, with a significant decrease in rCBF in the right posterior cingulate [72]. A 3-year longitudinal SPECT study of 20 idiopathic RBD patients reported that half of these participants developed a neurodegenerative disease and hippocampal hyperperfusion was predictive of the development of neurodegeneration [71].

Due to a high degree of comorbidity with nigrostriatal dopamine pathway disorders, a number of studies have focused on unveiling a link between RBD and dopaminergic abnormalities. RBD patients showed a significant reduction in striatal DAT receptor densities, compared to controls, but not compared to PD patients [73]. Attempts to re-create these findings have been mixed, with some studies showing DAT density decrease in only a minority of RBD patients [74, 75]. Longitudinal studies of dopaminergic function have also shown a link between RBD and neurodegeneration, with presynaptic DAT densities in the substantia nigra being predictive of later onset of alpha-synucleinopathies in RBD [76]. No differences were found between RBD, PD, and healthy controls when post-synaptic D2 receptors were probed [73]. SPECT investigations

of serotonergic pathways also failed to show any involvement of these pathways in RBD [77].

Anatomical analyses using MRI confirmed that degeneration in RBD is not limited to the substantia nigra but is also observed in neighbouring pathways, as evidenced by reduced neuromelanin signal intensity in the nearby caeruleus/subcaeruleus complex; this reduction was a better predictor of alpha-synucleinopathies, compared to clinical measurements [78]. Structural studies of RBD using VBM and DTI have also revealed bilateral putamen volume decrease [79], increased hippocampal grey matter density [80], and white matter alterations in brain areas involved in REM sleep regulation [80, 81]. Decreased cortical thickness in the frontal cortex, the lingual gyrus, and the fusiform gyrus was also recently reported [82]. Using a large sample of PD patients, a recent study observed smaller volumes in the pontomesencephalic tegmentum in PD patients with probable RBD, compared to PD patients without RBD and healthy controls [83]. This area contains neurons involved in the promotion of REM sleep and muscle atonia, and it is interesting to note that animals which have lesions in this area will show RBD-like symptoms, including dream enactment and loss of REM atonia, supporting the view that the pons is a key region for RBD [84]. Furthermore, PD with probable RBD had decreased volumes extending to other subcortical and cortical regions whose loss may contribute to the dysregulation of sleep–wake states and motor activity underlying RBD in PD patients [83]. Moreover, PD patients with comorbid RBD showed reduced thalamic volume, compared to PD patients without RBD, in a VBM study [85].

MRS studies failed to reveal any differences between metabolic peaks of NAA/Cr, choline/Cr, and myoinositol/Cr ratios in the pontine tegmentum and the midbrain between idiopathic RBD patients and healthy controls [86], and between PD and RBD patients in the pontine region [87].

Taken together, these findings indicate an involvement of brain structures including (but not limited to) the pontine nuclei and the nigrostriatal dopaminergic system in the pathophysiology of RBD, although more work is required to elucidate the precise pathways involved in giving rise to this condition. The often bizarre dream enactments associated with RBD are a powerful reminder of the very active and often emotional state of the brain during REM sleep.

Conclusions

There is still much to discover. New technological advancements in neuroimaging will allow researchers to run studies at higher and faster resolutions, which will be essential to truly elucidate the precise neural networks involved in the deceptively complex physiological state we call sleep. Furthermore, larger data sets, standardization of methodological procedures, and multimodality of imaging techniques will aid the field of sleep neuroimaging, as it expands and incorporates new results. As we further our understanding of pathologies in sleep-related neural pathways, innovative treatment interventions may emerge from better knowledge of the neural mechanisms of sleep disorders. As the physical, psychological, and cognitive costs of dysfunctional sleep become more apparent, the impetus for finding solutions to disorders of sleep will surely increase. With hope, future research in sleep neuroimaging will enable novel treatments for the many disorders of sleep.

Management of insomnia and circadian rhythm sleep–wake disorders

Simon D. Kyle, Alasdair L. Henry, and Colin A. Espie

Introduction

While sleep–wake disorders are common and impairing, they are underdiagnosed and undertreated. This notwithstanding, recent developments in the science of sleep and sleep disorders, described in Chapters 109 to 113, have given rise to the burgeoning field of sleep medicine. There has been a surge in the number of accredited sleep centres, training opportunities for health care professionals, and sleep-specific societies, all with the aim of improving sleep disorder recognition, diagnosis, and treatment.

In this chapter, we will focus on the evidence-based management of insomnia and circadian rhythm sleep–wake disorders (CRSWDs), the two classes of sleep disorder most commonly encountered in psychiatric practice. Other sleep disorders, like non-rapid eye movement (NREM) and rapid eye movement (REM)-related parasomnias, obstructive sleep apnoea (OSA), and restless legs syndrome (RLS) and periodic limb movements of sleep also co-vary with psychiatric disorder and its treatment; their recognition and diagnosis are covered in Chapter 110, but their management is beyond the scope of this chapter (for further in-depth reading, see *Oxford Textbook of Sleep Disorders* [1]).

Insomnia disorder

Insomnia disorder (ID) is characterized by persistent problems (≥ 3 days per week for ≥ 3 months) with sleep initiation and/or maintenance, resulting in significant impairment to quality of life (QoL) [2–4]. ID is the most common sleep disorder and the second most prevalent mental health complaint in Europe, affecting 10–12% of the adult population [5, 6]. Historically viewed as a symptom of a so-called ‘primary illness’, ID is now recognized as: (1) a disabling, non-remitting condition in its own right [3]; and (2) a causal factor in the evolution and maintenance of physical and mental ill-health, particularly depression and cardiometabolic disease [7]. This change in understanding is reflected in the recent reclassification of primary and secondary insomnia into one overarching category (‘Insomnia disorder’) in both DSM-5 and the International Classification of

Sleep Disorders, third edition (ICSD-3) [8]. Prospective data also suggest that persistent insomnia is a robust risk factor for all-cause mortality, after adjustment for potential confounding factors [9]. Although UK data are limited, extrapolation from per person cost data calculated in Canada [10] suggests that direct and indirect costs of insomnia are likely to exceed £14 billion per year. Associated costs reflect increased health care utilization, higher rates of workplace absenteeism, reduced productivity (‘presenteeism’), and increased accident risk [11, 12].

While insomnia is a heterogenous condition, most likely comprising multiple phenotypes [7, 13], contemporary theoretical models posit that key cognitive and behavioural processes serve to disrupt sleep–wake regulation [14–18]. In Spielman’s stress-diathesis conceptualization, genetic vulnerability (for example, [19]) is assumed to interact with precipitating factors (for example, stress, illness), stimulating an acute episode of insomnia. Cognitive and behavioural responses to this acute sleep loss (for example, extension of time in bed, napping, altered light exposure), driven, in part, by dysfunctional beliefs and attitudes about sleep, create sleep preoccupation and effort, conditioned arousal, sleep fragmentation, and increased night-to-night sleep variability. The end-state is persistent hyperarousal across cognitive, autonomic, and cortical domains, eroding sleep continuity and architecture and negatively affecting daytime functioning [20]. This dysfunctional arousal may also manifest in *the report of poor sleep*, despite an absence of gross sleep impairment on polysomnographic recordings [21–23].

It extends logically that treatment of insomnia should address cognitive and behavioural maintenance factors. There are two main evidence-based treatment modalities for the management of insomnia. The first comprises cognitive behavioural therapies (CBTs), reflecting a ‘high-level’ approach aimed at addressing sleep-related behaviours and cognitions, effectively *clearing the path* to normal sleep. The second, more ‘low-level’ approach involves direct pharmacological induction of sleep through, for example, the administration of hypnotics. The National Institute for Health and Care Excellence (UK) and prominent organizations in the United States (American College of Physicians) [24] endorse CBT as the *first-line treatment* for chronic insomnia, while hypnotics are recommended

only for short-term use due to the risk of tolerance, withdrawal effects, and next-day side effects. We will now summarize each treatment approach.

Cognitive behavioural therapy

CBT is a multicomponent psychological therapy, usually delivered over 4–8 sessions by a trained health care professional and after a thorough clinical history. Techniques typically have a lifestyle focus (for example, sleep hygiene), behavioural focus [for example, sleep restriction therapy (SRT), stimulus control, relaxation techniques], and cognitive focus (for example, addressing unrealistic expectations about sleep, paradoxical intention). Table 114.1 summarizes the main ingredients of CBT and proposed treatment targets. It should be noted that sleep hygiene education has no evidence as a standalone intervention in the management of insomnia but is typically incorporated to ensure that patients have basic knowledge about factors that inhibit or facilitate sleep.

Compared to CBT for other psychological disorders, insomnia-focused CBT places greater emphasis on behavioural vs cognitive modification (for an example of CBT session coverage, see Fig. 114.1). Indeed, behavioural components have the largest evidence base as standalone treatments [25, 26], and their level of implementation within multicomponent CBT is reliably associated with sleep improvement [27]. This is, in part, because sleep can be improved through attention to its fundamental biological regulation. For example, SRT, a core component of CBT, is considered to be a *psychobiological treatment* because it takes advantage of sleep homeostasis to reduce arousal and consolidate nocturnal sleep. Thus, patients are asked to keep a sleep diary for 1–2 weeks to enable calculation of the average time in bed and the average sleep duration (Table 114.2). SRT restricts time in bed to match self-reported sleep time—with the rationale that time in bed awake can maintain fragmented and poor-quality sleep. Restriction of time in bed, coupled with standardization of bed and rise-times each day, addresses both homeostatic and circadian regulation of the sleep–wake cycle, increasing

the probability that patients will sleep through their allocated window each night. The successful pairing of sleepiness/sleep and the bedroom environment may also help to address conditioned (hyper)arousal that is presumed to play a role in insomnia maintenance. Titration of the sleep window each week helps to establish a robust new sleep–wake pattern for the patient and identify core sleep need. SRT has been associated with reductions in cognitive arousal, sleep effort, core body temperature, and night-to-night sleep variability [26, 28, 29].

It should be noted that any treatment that has potential to do good also has the potential to do harm—and psychological interventions are no exception [30]. SRT should be avoided or carefully adapted for populations where acute sleep loss may stimulate episodes, relapse, or symptom exacerbation (for example, epilepsy, bipolar disorder, parasomnia). Patients should also be educated about driving risks during acute implementation since vigilance is known to be compromised and daytime sleepiness enhanced [28, 31].

CBT is effective across a range of contexts, for example when delivered by different professional groups (for example, nurses, masters-level psychologists), through different delivery formats (groups, face-to-face, over the phone, Internet), and to diverse populations (for example, those with both medical and psychiatric comorbidity). The most comprehensive meta-analysis of CBT trials to date showed a large effect size (Hedges $g = 0.98$) for insomnia severity and medium to large effects for sleep continuity measures [32]. Treatment effects do not vary for patients with/without comorbid disease, by age, or whether or not patients use sleep medication. Importantly, recent studies also showed generalized benefits of CBT on other parameters of health and well-being, including inflammatory markers [33] and depressive symptoms [34]. Despite a large evidence base and endorsement in clinical guidelines, provision of CBT for insomnia within health care settings remains very limited [35]. Those in primary care are likely to receive sleep hygiene advice or be prescribed hypnotic and/or sedative antidepressant medication (off-label). Digital interventions therefore provide a unique opportunity to facilitate access at scale. Espie and colleagues [36, 37] have shown that automated CBT delivered by an animated

Table 114.1 Principal components of cognitive behavioural therapy (CBT) for insomnia [106]

Therapy component	Description
Cognitive therapy	Identify, challenge, and change dysfunctional beliefs and attitudes about sleep and the consequences of poor sleep that may contribute to sleep-related arousal. Use paradoxical intention techniques to reduce attempts to control sleep
Sleep hygiene	General recommendations that promote healthy sleep habits and practices that are conducive to healthy sleep. These can include altering the bedroom environment, scheduling a consistent pre-sleep routine, avoiding arousal-promoting activities, and limiting alcohol, caffeine, and nicotine before bed
Stimulus control	Behavioural instructions aimed at eliminating the association between the bedroom and arousal; instead, strengthening the bedroom environment as a stimulus for sleep and sleepiness. Examples include: only using the bedroom for sleep-related activities; only going to bed when sleepy/tired; leaving the bedroom when unable to sleep within approximately 15 minutes, and returning only when sleepy ('quarter of an hour rule')
Sleep restriction	A behavioural intervention which involves restricting and standardizing a patient's time in bed, with the aim of increasing homeostatic sleep pressure, overriding cognitive and physiological arousal, and strengthening circadian control of sleep. Tailored prescription of bedtime and rise-time over several weeks leads to improved sleep consolidation and quality
Relaxation techniques	Techniques that provide cognitive and somatic relaxation for the patient that may facilitate sleep onset/reinitiation, including progressive muscle relaxation, mindfulness, breathing meditation, and guided imagery

- (a)
- ### Session 1 Sleep Information
- Aim:** To learn about normal sleep processes and about sleep disorders
- to understand the need for sleep and its functions
 - to understand sleep pattern and how it varies during the lifetime
 - to understand sleep as a process with stages and phases
 - to understand factors which adversely affect sleep pattern and sleep quality
 - to understand the effects of sleep loss
 - to understand the concept of insomnia and how it can be measured
 - to understand personal sleep histories and patterns in the above context
 - to begin to correct previous misunderstandings about sleep and sleeplessness
- (b)
- ### Session 2 Sleep Hygiene & Relaxation
- Aim:** To introduce practical steps towards developing a healthy sleep pattern without recourse to drugs
- to review progress so far and maintain treatment goals
 - to create a bedroom environment that is comfortable for sleep
 - to take regular exercise which promotes fitness and enhances sleep
 - to develop a stable and appropriate diet
 - to reduce the undesirable effects of caffeine upon sleep
 - to moderate alcohol consumption and eliminate 'night-caps'
 - to support people reduce and stop taking sleeping pills
 - to design individualised reduction programmes
 - to learn relaxation skills to apply in bed
- (c)
- ### Session 3 Sleep Scheduling
- Aim:** To re-shape sleep patterns to correspond with individual sleep needs and to strengthen sleep rhythms
- to review progress so far and maintain treatment goals
 - to develop a good pre-sleep routine
 - to distance waking activities from the bedroom environment
 - to establish a strong bed-sleep connection
 - to eliminate wakefulness from bed
 - to define restricted parameters for the individual's sleep period
 - to increase sleep efficiency through scheduling sleep in relation to needs
 - to eliminate daytime napping
 - to establish a stable night to night sleep pattern
 - to encourage and support people in changing their sleep routines

Fig. 114.1 Session-by-session (a–e) aims for a 5-week multicomponent CBT programme.

(d)

Session 4 Cognitive approaches

Aim: To learn ways of reducing the mental alertness, repetitive thoughts and anxiety which interferes with sleep

- to review progress so far and maintain treatment goals
- to identify thought patterns which interfere with sleep
- to develop accurate beliefs and attitudes about sleep
- to prepare mentally for bed by putting the day to rest
- to learn thought distraction and imagery techniques
- to reduce efforts to control sleep and allow it to happen naturally
- to utilise these techniques to combat intrusive thoughts
- to encourage and support people in changing their mental approach

(e)

Session 5 Developing a strong & natural sleep pattern

Aim: To integrate advice from previous sessions and to maintain implementation at home

- to review progress so far and maintain treatment goals
- to systematically rehearse the elements of programme
- to address implementation problems experienced
- to plan further adjustments to the sleep period to maintain sleep efficiency
- to encourage and support people in maintaining their new sleep routines and their mental approach
- to learn relapse prevention approaches if a sleep problem recurs

Fig. 114.1 Continued

Table 114.2 Sleep restriction therapy guidelines

Sleep restriction therapy guidelines	Instructions
1	Patient instructed to record a sleep diary for 1–2 weeks to obtain average nightly sleep duration, for example 5 hours 30 minutes (rounded to nearest 15-minute interval). This acts as the designated sleep window
2	Therapist, in collaboration with patient, sets a morning 'rising time', for example 6.30 a.m.
3	A 'threshold time' is then calculated by subtracting the average nightly sleep duration from the specified morning rising time, for example 6.30 a.m. – 5 hours 30 minutes = threshold time of 1 a.m.
4	Patient is instructed not to enter bed prior to their designated 'threshold time' and to exit bed on, or prior to, set 'rising time'
5	Patient follows this prescribed schedule every night, including weekends. Avoid driving or operating heavy machinery if experiencing excessive daytime sleepiness
6	Weekly modifications to the sleep window are based on sleep efficiency values (total time asleep/total time in bed × 100): If sleep efficiency ≥90%: increase sleep window by 15 minutes If sleep efficiency <85%: decrease sleep window by 15 minutes

therapist outperformed two control conditions. This was an important trial because it incorporated an active comparator therapy (so-called imagery relief therapy, or IRT), which deliberately excluded the presumed active ingredients of CBT but was plausible because it focused on routines preparatory to sleep. Trials that so convincingly demonstrate superiority over the non-specific effects of attention and therapy involvement are rare. In addition to scale, digital technology can facilitate better matching between insomnia phenotype and specific CBT techniques [38], which may further potentiate treatment gains and reduce non-response [39].

Pharmacotherapies

Hypnotics

Short-term use (3–4 weeks) of sleep-prompting medication is recommended for acute insomnia (for example, insomnia caused by temporary stressor, jet lag, etc.) [40] or for chronic insomnia that fails to respond to CBT as the first-line treatment [24]. Both benzodiazepines (for example, lormetazepam) and non-benzodiazepine positive allosteric GABA-A receptor modulators (for example, zolpidem, zopiclone—the so-called ‘z-drugs’) are approved for the short-term management of insomnia (for dose and half-life of commonly prescribed insomnia medications, see Table 114.3). Careful consideration of pharmacological properties and risk–benefit profile, as well as any specific individual contraindications (for example, comorbidities, medications), is necessary to optimize and tailor pharmacological treatment for each patient.

These medications modify sleep and arousal via allosteric modulation of the GABA-A receptor complex, potentiating the inhibitory effects of GABA on the central nervous system. It should be noted, however, that, in general, they do not re-create normal sleep. Indeed, they may suppress power density in the low-frequency range during NREM sleep [41] and impair sleep-dependent brain plasticity [42]. Meta-analyses showed hypnotics to reliably improve insomnia symptoms, relative to placebo, when administered over a short period of time [43]. However, more recent analyses showed smaller effect size differences when

specifically investigating elderly patients [44] or when considering both published and unpublished trials of z-drugs [45]. Importantly, there is no evidence that treatment gains from hypnotics last beyond their discontinuation. Only a handful of trials have compared hypnotics directly with CBT, finding that treatment effects are comparable in the short term but that CBT outperforms medication at follow-up [46, 47].

Owing to the longer half-life of traditional benzodiazepines, physicians increasingly prefer to prescribe shorter-acting z-drugs [48]. Z-drugs are also considered more effective due to their greater selectivity for the $\alpha 1$ subunit, thus enhancing activity in terms of sedation and limiting more generic effects involved in the interaction with other subunits [49]. Despite this assumption, meta-analyses suggested there are limited differences in efficacy or adverse effect profiles [44, 50]. Both are associated with an increased risk of adverse effects, including falls, driving accidents, and psychomotor impairment. Epidemiological studies also suggested that long-term use of hypnotics is associated with an increased risk of infection, depression, cancer, and mortality [51], although the direction of the causal relationship may be open to question.

Melatonin receptor agonists, orexin antagonists, and off-label medication use

Melatonin receptor agonists, which act on MT_1 and MT_2 receptor sites in the suprachiasmatic nucleus (SCN) of the hypothalamus, are also licensed for the management of insomnia. Ramelteon (8 mg) is the only approved melatonin agonist for insomnia on the market (United States) and has been investigated in more than a dozen trials. Although demonstrating low potential for abuse and limited side effects, in comparison with GABA-mediated hypnotics, ramelteon appears to have only modest effects on sleep latency and little/no impact on wake-time after sleep onset or total sleep time [52]. Kuriyama *et al.* [53] meta-analysed 13 placebo randomized controlled trials of ramelteon, finding statistically significant, but small, effects for subjective sleep latency (mean difference = 4 minutes, compared to placebo) and self-reported sleep quality. Circadin® (2 mg), an extended-release melatonin agonist, is approved in Europe for those over 55 with insomnia. Trials have documented small to medium effects for sleep continuity parameters, sleep quality, and daytime functioning, and the safety profile appears encouraging [54, 55].

The first orexin receptor antagonist (suvorexant) has been approved by the US Food and Drug Administration (FDA) for the management of insomnia (it is not yet licensed in Europe). Orexin-producing neurons in the lateral hypothalamus innervate ascending arousal systems, helping to generate and sustain wakefulness. Hence, antagonism of orexin A and B receptors may promote sleep through blockade of the wake drive and insomnia-related hyperarousal. Prolonged treatment with suvorexant (30–40 mg) for between 3 and 12 months has been found to effectively treat insomnia symptoms, and benefits persist even after a prolonged (2-month) discontinuation phase [56, 57]. While reports of somnolence are increased, relative to placebo, the adverse effect profile appears less impairing than that of hypnotics [58]. It must be noted that the FDA recommends a maximum dose of 20 mg suvorexant—due to concerns about somnolence—but clinical trial data are less robust for this dose, relative to 30–40 mg.

Table 114.3 Benzodiazepines and non-benzodiazepine GABA_A receptor positive allosteric modulators frequently used for treatment of insomnia [107]

Drug	Usual dose (mg)	Half-life (hours)
Benzodiazepines		
Flunitrazepam	0.5–2	16–35
Flurazepam	15–30	48–120
Lormetazepam	0.5–1	8–15
Nitrazepam	5–10	25–35
Temazepam	10–30	10–20
Triazolam	0.125–0.250	1.4–4.6
GABA_A receptor modulators		
Zolpidem	5–10	2–4
Zopiclone	3.75–7.5	5–6

Reproduced from *Handb Exp Pharmacol.*, Spiegelhalter K, Nissen C, Riemann D, Clinical Sleep–Wake Disorders II: Focus on Insomnia and Circadian Rhythm Sleep Disorders, pp. 1–16, Copyright (2017), with permission from Springer International Publishing AG.

A number of other drugs are also used ‘off-label’ to treat insomnia, including sedative antidepressants, anti-neuroleptics, and atypical (second-generation) antipsychotics. This is not evidence-based practice [24, 39]. For example, the most frequently prescribed sleep aid in the United States is the sedative antidepressant trazodone; yet there is a paucity of trials to inform efficacy or risk–benefit profile [59].

Circadian rhythm sleep–wake disorders

CRSWDs manifest because of alterations to the endogenous circadian clock (intrinsic CRSWDs) or when there is gross misalignment between the sleep–wake cycle and the 24-hour social environment (extrinsic CRSWDs). Patients typically present with difficulty initiating sleep or maintaining sleep, or excessive sleepiness, with corresponding negative effects on daytime functioning. Because the circadian clock runs at slightly longer than 24 hours (approximately 24.2 hours), alignment between our internal rhythms and the 24-hour social environment requires daily adjustment. Light, physical activity, and melatonin are the main synchronizers of the clock and therefore form the backbone of contemporary CRSWD management. We will now provide an overview of evidence-based treatments for the following intrinsic CRSWDs: delayed sleep–wake phase disorder (DSWPD)/advanced sleep–wake phase disorder (ASWPD), irregular sleep–wake schedule disorder, and non-24-hour sleep–wake disorder. While we emphasize treatments that are endorsed by the American Academy of Sleep Medicine (AASM) task force [60], the highly specific patterning of sleep–wake timing in individual patients necessitates a tailored approach when managing CRSWDs. For the correct administration of light therapy and exogenous melatonin, it is important that the clinician is able to estimate the circadian phase. Core body temperature nadir and rise in endogenous melatonin [dim light melatonin onset (DLMO)] are the two most robust indicators of phase position. While procedures are currently

being developed to reliably assess the circadian phase at home [61], clinicians will typically have to rely on questionnaire measures (sleep diary logs or psychometrics) to infer the circadian phase. In general, as a rule of thumb, the nadir of the core body temperature occurs 2 hours before habitual sleep offset, while DLMO initiates about 2–3 hours prior to habitual sleep onset (Table 114.4).

Delayed sleep–wake phase disorder

DSWPD is one of the most common CRSWDs, affecting approximately 2% of the population [62]. It is characterized by a sleep schedule that occurs significantly later than desired or what would be considered ‘normal’ by society. Patients with DSWPD present with habitually delayed sleep onset and wake-times, or difficulties with sleep onset and rising when attempting to adhere to a more typical sleep schedule. When able to sleep on their preferred schedule, sleep duration and quality are normal [8]. While the aetiology of DSWPD remains unclear, longer-than-average circadian periods [63], hypersensitivity to light in the evening [64], and sleeping through the advanced period of the phase response curve in the morning [65] are all thought to play a role in perpetuating phase delay. DSWPD is overrepresented in adolescents, most likely due to puberty-related changes in sleep homeostasis and circadian timing, compounded by inflexible social schedules. Several treatments have been proposed to advance the circadian phase in DSWPD, including chronotherapy, melatonin, and phototherapy.

Chronotherapy

Chronotherapy, or prescribed sleep scheduling, is a behavioural intervention aimed at creating a desired sleep–wake pattern by systematically delaying bedtime and rise-time by 3 hours each day [66]. Because the clock runs at >24 hours in most humans, it is easier to phase-delay than phase-advance the sleep–wake cycle. Upon achieving the desired time, individuals are instructed to rigidly adhere to strict rules around sleep and wake activity, avoiding activities that may encourage phase drift. Chronotherapy appears

Table 114.4 Summary of clinical presentation, typical sleep–wake schedule, and evidence-based treatments for CRSWDs, based upon current AASM guidelines

CRSWD	Clinical presentation	Typical sleep–wake pattern	Recommended treatments
DSWPD	Difficulty falling asleep and waking at times considered normal	Delayed sleep onset (2–6 a.m.) and wake-time (10 a.m.–1 p.m.)	Melatonin (0.5–3 mg) 1.5–6.5 hours prior to bedtime/DLMO
ASWPD	Difficulty maintaining wakefulness and sleepiness in early evening, combined with early morning awakening or sleep maintenance difficulties	Early sleep onset (6–9 p.m.) and wake (2–5 a.m.)	Bright light therapy (≥ 2500 lux) for 4 hours, starting at 8 p.m., or 4000 lux between 9 and 11 p.m.
N24SWD	Bouts of insomnia symptoms and excessive daytime sleepiness, interspersed with periods of normal alertness	Bedtime and wake-time are consistently delayed (by, for example, 1 hour) each day	Melatonin 2–3 hours before desired bedtime (0.5–5 mg) when circadian phase is approaching normal clock time, or melatonin agonist (tasimelteon) 1 hour prior to desired bedtime
ISWRD	Insomnia symptoms or excessive daytime sleepiness	Inconsistent and irregular patterning	Morning bright light (≥ 2500 lux) for 2 hours (between 8 and 11 a.m.) in elderly individuals with dementia

ASWPD, advanced sleep–wake phase disorder; CRSWD, circadian rhythm sleep–wake disorder; DLMO, dim light melatonin onset; DSWPD, delayed sleep–wake phase disorder; ISWRD, irregular sleep–wake rhythm disorder; N24SWD, non-24-hour sleep–wake disorder.

Source: data from *J Clin Sleep Med*, 11(10), Auger RR, Burgess HJ, Emens JS, *et al.*, Clinical practice guideline for the treatment of intrinsic circadian rhythm sleep–wake disorders: advanced sleep–wake phase disorder (ASWPD), delayed sleep–wake phase disorder (DSWPD), non-24-hour sleep–wake rhythm disorder (N24SWD), and irregular sleep–wake rhythm disorder (ISWRD). An update for 2015: an American Academy of Sleep Medicine Clinical Practice Guideline, pp. 1199–236, Copyright (2015), American Academy of Sleep Medicine.

effective in laboratory demonstrations (for example, [66]), and there is some supporting evidence from observational studies (for example, [67, 68]); however, there is a dearth of robust randomized controlled trials in the home environment. Potential for creating free-running in some patients has also been observed [69]. Given the lack of controlled outcome studies, the AASM states that there is insufficient evidence to warrant recommendation of prescribed sleep scheduling for individuals with DSWPD [60].

Morning phototherapy

Timed light therapy, also known as phototherapy, aims to take advantage of the potent role of light as a synchronizer of circadian physiology. Exposure to bright light in the morning is intended to bring about a phase advance in those with a delayed phase (while evening light can phase-delay). Phototherapy is considered more practical than chronotherapy and can harness both artificial and natural light sources. Light is typically delivered using light boxes or other specifically designed devices that emit bright broad-spectrum light (for example, re-timer glasses [70]). Light boxes usually deliver between 2500 lux and 10,000 lux, although it is important to bear in mind that these measurements are recorded at the level of the box, and not the eye [71].

A number of studies have examined the efficacy of timed light exposure in DSWPD. Rosenthal *et al.* administered 2500-lux light to patients for 2 hours between 6 a.m. and 9 a.m., in addition to light restriction in the evening. Findings revealed a phase advance in core body temperature and increased alertness in the morning [72]. Another study found that bright light (2700 lux) administered via a mask phase-advanced markers of melatonin metabolism following extended treatment for 26 days [73]. Despite these positive findings and a rich literature on the phase-shifting properties of light in healthy controls [71], there is a dearth of high-quality clinical studies. The field lacks trials with adequate sample sizes, clinical outcome measures, and appropriate control groups. Based on the low quality of evidence to date, the AASM was recently unable to recommend light therapy for the management of DSWPD, either as a monotherapy or in combination with other treatments [60]. They did, however, note that evidence is higher for the use of light therapy for children and adolescent DSWPD populations, in combination with behavioural intervention. Given the robust phase-shifting effects of light in experimental studies, there is an urgent need to develop a strong evidence base in clinical populations.

Melatonin

Exogenous melatonin administration can shift the circadian clock to earlier or later times. Melatonin phase response curves, based on average responses from healthy participants, demonstrate phase advances when administered in late afternoon or early evening, between 5 and 7 hours before habitual bedtime [71]. Munday *et al.* randomized DSWPD patients ($n = 13$) to one of three arms: 4 weeks of placebo, melatonin 0.3 mg or 3 mg, administered 1.5–6.5 hours prior to habitual sleep onset. Both melatonin groups displayed phase advance in DLMO, the magnitude of which was strongly correlated with the time of melatonin administration (earlier times being the most effective) [74]. A meta-analysis of nine randomized, double-blind, placebo-controlled studies confirmed that administration 1.5–6.5 hours prior to DLMO was effective at phase-advancing the clock and reducing sleep onset latency by a mean of 23 minutes [75].

At present, the AASM recommends timed melatonin for the treatment of DSWPD in adults, children, and adolescents. However, further research is required to establish optimum parameters (timing and dose), as well as long-term safety [60].

Advanced sleep–wake phase disorder

ASWPD is characterized by persistent advancement of the major sleep period (for example, sleep onset at approximately 6–9 p.m. and sleep offset at approximately 2–5 a.m.). This advancement manifests as habitual difficulty maintaining wakefulness in early evening and wake-up times that are several hours earlier than normal. When attempting to delay sleep to a more conventional clock time—for example, to engage in social activities—patients typically experience significantly curtailed sleep duration and next-day sleepiness. The prevalence of ASWPD increases with age [76, 77], which may be a function of an age-related phase advance [78]. Possible explanatory mechanisms include a shortened endogenous circadian period and increased retinal sensitivity to light in the morning [79]. Treatment in this population relies on timed light therapy during the evening or delaying the portion of the phase response curve to bring about a phase delay of the sleep window.

Evening phototherapy

One study in older adults showed that administration of bright light (4000 lux) between 7 and 9 p.m. for a 12-day period resulted in a 2-hour delay in core body temperature nadir and a reduction in nocturnal awakenings [80]. A more recent study by Lack and colleagues randomized 24 adults with early morning awakenings to either a bright light condition (2500 lux from 8 p.m. to 1 a.m. for two consecutive nights) or a control arm (dim red light). Participants in the bright light group evidenced a 2-hour delay in both melatonin and core body temperature rhythms and reported reductions in wake-time during the night, as well as increased total sleep duration [81].

Other studies have shown more variable results. In a study involving older adults ($n = 47$) with ASWPD, exposure to evening light (265 lux) for 2–3 hours had no effect on circadian or actigraphy outcomes. Despite this, participants reported significantly delayed sleep onset and perceived the treatment to be effective [82]. The low light intensity (just 265 lux) may have attenuated phase-shifting effects. However, a further study comparing bright light (10,000 lux) with dim light placebo similarly failed to find significant effects on sleep or circadian variables in older adults [83]. Key limitations of studies to date include gross variability in light therapy intensity and limited recruitment of well-defined ASWPD patients. This may account for the heterogeneity in trial evidence. Despite these limitations, there is some evidence to support the use of bright light therapy in early evening in those with ASWPD, which is supported by the AASM task force.

Melatonin

Based on melatonin phase response curves, it is theoretically plausible that morning administration of melatonin will phase-delay the timing of the sleep–wake cycle. At present, however, there is little to no robust evidence regarding the effectiveness of melatonin in ASWPD [60]. Concerns about the potential for sleepiness during the day may have limited progress in this area. Morning administration of melatonin should be examined in carefully designed studies.

Non-24-hour sleep-wake disorder

Non-24-hour sleep-wake disorder (N24SWD) is the result of the SCN failing to synchronize with the 24-hour light-dark cycle; thus, sleep-wake schedules drift progressively later each day. Patients typically experience bouts of nocturnal insomnia and daytime somnolence, the severity of which will depend on when the patient tries to sleep in relation to the current phase of the endogenous rhythm. The condition is relatively rare in sighted individuals and instead primarily affects those with total blindness due to an inability to perceive photic stimuli, impairing entrainment to the 24-hour light-dark cycle [84]. Disease mechanisms in sighted individuals may include decreased responsiveness to light entrainment or an unusually long free-running circadian period that is outside the range of entrainment [79]. Across individuals with N24SWD, treatments aim to synchronize patients' endogenous body clock with the 24-hour light-dark cycle and are initiated when the sleep-wake pattern is approaching the normal/desired clock time.

Phototherapy

In sighted individuals, timed light exposure has been suggested as an appropriate intervention, but controlled studies are limited. Correct timing of light is important since inappropriate timing may worsen the current rhythm or induce an undesired shift in position. In a handful of case studies, administration of bright light was found to facilitate entrainment [85–88]. Nevertheless, long-term administration of this treatment appears to be difficult for patients to manage in the home environment, relative to melatonin [85]. Given the small evidence base and the absence of controlled trials, light therapy cannot yet be recommended as an effective treatment for N24SWD in sighted individuals.

Melatonin and melatonin receptor agonists

Evidence in support of melatonin for N24SWD comes from observational studies in non-sighted individuals [89–92] and sighted individuals [85, 93, 94]. Successful entrainment depends on correct timing of melatonin since administration when the individual's free-running phase is not approaching normal can have adverse consequences and result in unwanted phase shifts. Using a placebo-controlled crossover design, Lockley and colleagues showed that administration of 5 mg of melatonin at 9 p.m. for a full circadian cycle resulted in entrainment in non-sighted individuals with N24SWD [95].

In recent years, the development of melatonin agonists has increased treatment options for those with N24SWD. Tasimelteon is an MT₁/MT₂ agonist which has recently been approved for treatment of N24SWD by both the FDA and the European Medicines Agency. Two consecutive placebo-controlled trials examined the effect of tasimelteon in non-sighted patients diagnosed with N24SWD. In the first of these (SET trial), participants were randomly assigned to either tasimelteon (20 mg) or placebo, 1 hour before the desired bedtime and once per day for 26 weeks. It was found that 24% of individuals receiving tasimelteon became entrained (vs 0% in the placebo arm) and patients in this group had increased night-time sleep and reduced daytime sleep [96]. The subsequent RESET trial sought to examine the effect of withdrawal from tasimelteon on entrainment. Following initial entrainment, individuals were randomized to either placebo (withdrawn group)

or continued tasimelteon. The group maintained on tasimelteon remained entrained, while those allocated to placebo withdrawal reverted back to non-24-hour rhythms [96]. Although some side effects were reported (headache, elevated liver enzymes, nightmares), tasimelteon has clear benefits for those with N24SWD. The AASM recommends melatonin for the treatment of N24SWD in blind individuals, but not in sighted individuals, given the limited evidence base for this latter population.

Irregular sleep-wake rhythm disorder

Irregular sleep-wake rhythm disorder (ISWRD) is characterized by the absence of a clearly defined pattern in the sleep-wake cycle. While total sleep time may be normal, sleep bouts are fragmented and usually distributed in naps across a 24-hour period. There is no primary night-time sleep episode. Thus, the amplitude of the rest-activity rhythm is low and patients often report insomnia symptoms and excessive daytime sleepiness. The condition primarily affects older adults, especially those with dementia, other neurodegenerative disorders, and neurodevelopmental disorders and individuals in care home facilities.

Loss of SCN neurons, driven by dementia pathology, may be one contributor to circadian disorganization, impairing the ability to generate and sustain consolidated bouts of sleep and wakefulness [97, 98]. For patients who are institutionalized (for example, in care homes), lack of a structured schedule, reduced physical activity, and reduced exposure to light may all contribute to ISWRD [99]. The primary goal of treatment in such patients is to establish consolidated nocturnal sleep and eliminate/reduce daytime sleep episodes.

Phototherapy

A number of studies have examined the effectiveness of timed bright light exposure in dementia patients, but findings have been inconsistent. In one study, nursing home patients with dementia were exposed to morning bright light (8–11 a.m.) for 2 hours each day for 2 weeks. Following the treatment period, patients displayed increased actigraphy-defined sleep efficiency and decreased nocturnal wake-time. Although these improvements were maintained for 4 weeks post-treatment, by 16 weeks, all improvements returned to near baseline levels [100]. Mixed effects have been shown across a number of other studies [101–103], and a recent Cochrane review found no overall effect of light therapy on cognitive function, sleep, challenging behaviour, or psychiatric symptoms in patients with dementia [104]. Taken together, there appears to be some support for the use of bright light in patients with ISWRD, but heterogeneity in design limits solid conclusions. One clear issue is the poor delineation of patient groups with ISWRD on study entry, with many studies recruiting patients with dementia and sleep difficulties (broadly defined), rather than with diagnosed ISWRD. The AASM recommends bright light as a *possible* treatment in ISWRD patients with dementia. Nevertheless, it seems clear that further research is required to optimize treatment parameters and obtain a definitive understanding of treatment benefits.

Pharmacotherapies

Melatonin is not currently recommended for patients with ISWRD and dementia. A recent Cochrane review of four randomized controlled trials of melatonin concluded that there was no evidence of superiority, relative to placebo [105]. Similarly, current evidence

and practice parameters argue against the use of sleep-promoting hypnotics in demented patients with ISWRD, owing to the potential for side effects, including falls, confusion, and physiologic dependence [60].

Summary

Insomnia and CRSWDs are common and impairing sleep disorders. CBT is the first-line treatment for chronic insomnia, while hypnotics should only be used sparingly and for a short period of time. Digital technology is helping to disseminate evidence-based CBT to insomnia patients, while improved understanding of sleep-wake neurobiology is helping to refine pharmacological approaches beyond conventional hypnotics. Human circadian science clearly shows that melatonin and light therapy can effectively reset the clock, but these insights have only partially translated into therapeutics for patients with CRSWDs. High-quality randomized controlled trials are required to establish standardized treatment guidelines and inform on optimal timing of circadian therapeutics in the management of CRSWDs.

The sexual dysfunctions and paraphilias

Cynthia A. Graham and John Bancroft

Introduction

Sexual relationships are central to the lives of most of us. The sexual component of those relationships can go wrong in various ways. This may be secondary to other difficulties in the relationship, mental health problems, specific sexual vulnerabilities of the individual, or the impact of disease or medication on sexual response. This chapter will describe the more common sexual and paraphilic disorders. Evidence related to prevalence, aetiology, and treatment will be briefly reviewed. Practical guidance on how to carry out assessment and plan a treatment programme for individuals and couples with sexual dysfunction will be provided.

Sexual dysfunctions

Clinical features

Sexual problems in men

The most common sexual problems presented by men are erectile disorder (ED), premature or early ejaculation (PE), and low sexual desire. Delayed or absent ejaculation is a relatively infrequent complaint.

Erectile problems

Penile erection is a tangible and fundamental component of a man's experience of sexual arousal, and a lack of erection in a sexual situation often has significant negative effects on self-esteem and sexual confidence. Irrespective of whether or not there are peripheral explanations for impaired erections (for example, vascular disease), the reactions of the man and his partner have a major influence on how problematic the erectile difficulty becomes. Sexual problems in partners of men with ED have also been reported as common [1].

Low sexual desire

Low sexual desire is sometimes linked with erectile and/or ejaculatory concerns [2]. Men with low sexual desire often report a decline in their initiation of sexual activity and in their responses to a partner's attempts to initiate. Many men with low sexual desire also report a reduction in 'spontaneous' erections. However, a man can experience low sexual desire without having any erectile difficulties,

although he may require more direct tactile stimulation to achieve erections.

Premature ejaculation

The key feature of PE is that ejaculation occurs prior to, or shortly after, vaginal penetration [2]. Many men also report feeling a lack of control over ejaculation and anxiety about PE occurring in future sexual encounters [3].

To meet the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) diagnostic criteria for PE, ejaculation must occur within approximately 1 minute of vaginal penetration and before the man wishes it [2]. PE can be lifelong or acquired; occurring after a period of normal ejaculatory latency, acquired PE usually has a later onset.

Delayed ejaculation

Delayed, infrequent, or absent ejaculation occurs in men, although it is much less common than PE. A man might have difficulty ejaculating only during sexual activity with his partner and in some cases only during penetrative intercourse, or the problem may be evident even during masturbation. Delayed or absent ejaculation is a common side effect of selective serotonin reuptake inhibitor (SSRI) medications, suggesting that the primary effect of such drugs is on the triggering of orgasm [4].

Pain during sexual response

While there is no male sexual pain disorder listed in either the International Classification of Diseases (ICD) or DSM, pain during sexual response in men can occur [5].

Sexual problems in women

Loss of sexual arousal and/or desire

Most surveys have suggested that low sexual desire is the most common sexual problem reported by women. However, low sexual desire is a heterogeneous problem category, and the relationship between sexual arousal and sexual desire in women is particularly complex. Many women do not differentiate between 'arousal' and 'desire' [6], and awareness of 'desire' is usually accompanied by some degree of central arousal, whether or not any genital response is perceived [7]. There is also considerable overlap or comorbidity between problems related to sexual arousal and desire in women [8].

Although traditionally seen as the counterpart to penile erection in men, vaginal response is not central to the experience of sexual arousal in women. Vaginal dryness does not necessarily indicate lack of arousal, and conversely, a woman may experience lack of sexual arousal and yet have vaginal lubrication. An increase in vaginal blood flow has been consistently demonstrated in women reacting to sexual stimuli, whether or not they find the sexual stimulus appealing; this led Laan and Everaerd [9] to call this an 'automatic' response. The relevance of vaginal response to sexual arousal in women therefore remains unclear. Tumescence of the clitoris, on the other hand, may be more directly comparable to male genital response, but this is less easily assessed and less clearly perceived by women, compared with penile erection in men.

Problems with genito-pelvic pain

Pain during attempted or complete vaginal entry is a common sexual problem in women with a wide range of possible causes. Fear of pain or vaginal intercourse and tension of the pelvic floor muscles are common diagnostic features [2]. Sexual pain is also frequently associated with a lack of sexual desire and/or arousal and with avoidance of sexual situations. Sometimes pain only occurs when provoked; for example, vulvar vestibulitis syndrome is a condition associated with pain on touching the labia or vaginal introitus.

Problems with orgasm

Difficulty experiencing orgasm is not uncommon in women. Often this is situational in that orgasm is possible with masturbation, but not during sexual interaction with the partner. The capacity to experience orgasm varies considerably across women. Some women reach orgasm easily if sufficient arousal occurs; others may require more specific or more intense stimulation, and an estimated 10–15% are unable to experience orgasm throughout their lives [10]. In identifying a problem as primarily orgasmic, one needs to first establish that appropriate sexual arousal has occurred. Orgasmic difficulties can be lifelong or can be acquired, that is, problems developed after a period of normal orgasmic functioning.

Persistent genital arousal disorder

Persistent genital arousal disorder (PGAD) is a recently recognized, but fairly uncommon, sexual problem in women. It is characterized by genital and breast vasocongestion and sensitivity which persists for hours or days and is only temporarily relieved by orgasm; genital sensations are unaccompanied by any subjective sense of sexual desire and excitement but instead are perceived as intrusive [11].

Classification

The two major classification systems for sexual dysfunction are the American Psychiatric Association's DSM and the World Health Organization's ICD. The fifth edition of the DSM was published in 2013 [2] and ICD-11 was published in 2018 [12]. Efforts were made to harmonize the groups of disorders in ICD-11 with those included in DSM-5 [13].

DSM-5 comprises major changes in the classification of sexual disorders [14]. Specific duration and severity criteria were added to all of the sexual disorders—a requirement that the symptoms must have persisted for a minimum duration of approximately 6 months

and have been experienced on all or almost all (approximately 75–100%) of sexual encounters. There is also the requirement that the symptoms cause 'clinically significant distress in the individual' [2].

Regarding female sexual disorders, there were other significant changes. Major criticisms of DSM-IV were the high comorbidity between diagnoses of sexual disorders, the 'genital' focus of the diagnostic criteria, and the neglect of psychological and relationship factors [15–17]. In response to these criticisms and to growing evidence on the overlap between arousal and desire in women, in DSM-5, 'Hypoactive sexual desire disorder' and 'Female sexual arousal disorder' were deleted and a new disorder 'Female sexual interest/arousal disorder' (FSIAD)—was added. The criteria for FSIAD include subjective, behavioural, and physical aspects of sexual interest/arousal. There were also significant changes made to female sexual pain disorders, with both vaginismus and dyspareunia deleted from DSM-5, and a new diagnosis 'Genito-pelvic pain/penetration disorder' (GPPPD) introduced (for the rationale for these changes, see [18]).

For women, the DSM-5 diagnostic categories are FSIAD, female orgasmic disorder, and GPPPD. For men, the categories are ED, PE, male hypoactive sexual desire disorder, and delayed ejaculation. Substance/medication-induced sexual dysfunction, other 'specified sexual dysfunction', and 'unspecified sexual dysfunctions' are diagnoses that can be applied to both men and women.

An important aspect of the DSM definition of sexual dysfunction is how we define a 'clinically significant disturbance', with connotations of abnormal or impaired function, and how this is distinguished from a 'sexual problem' in a more general sense. Relevant to the question of when a sexual problem becomes a 'dysfunction' is a theoretical approach called the dual control model [19, 20]. This postulates that sexual response results from an interaction between excitation and inhibition, involving relatively discrete neurophysiological systems in the brain. A central assumption of the model is that individuals vary in their propensity for both sexual excitation and sexual inhibition and that 'normal' levels of inhibition are adaptive, reducing sexual responsiveness in circumstances where sexual activity is best avoided. It is predicted that high levels of inhibition will be associated with vulnerability to sexual dysfunction, and low levels with an increased likelihood of engaging in high-risk sexual behaviour.

This faces us with the seemingly obvious, but fundamental, challenge of deciding whether a loss of sexual interest or responsiveness is an understandable, or even adaptive, reaction to current circumstances or is a result of 'malfunction' of the sexual response system, which can be appropriately called a 'sexual dysfunction'. This challenge is also central to assessment that identifies the key factors causing the sexual problem and how they should best be treated. A strategy for carrying out such assessment, which we have called the 'three-windows approach,' will be outlined further.

Epidemiology

Many early epidemiological surveys assessed sexual problems that were relatively short term and did not ask respondents about whether they experienced any distress about symptoms. An example of this was the US National Health and Social Life survey, which asked if symptoms had occurred 'for several months or more' during the past year, but not whether the symptoms were distressing [8]. Forty-three per cent of women and 31% of men were identified as having a 'sexual dysfunction'. These figures were widely cited as evidence that sexual dysfunction is 'a significant public health problem' [8, p. 544].

More recent surveys, including the UK's third National Survey of Sexual Attitudes and Lifestyles (Natsal-3), have asked about the duration of symptoms and about associated distress [21]. These findings have demonstrated that transient sexual difficulties are very common, but more persistent problems and distress about one's sex life much less so. For example, 51.2% of women and 41.6% of men reported experience of one or more sexual problem during the previous year [21], but distress was reported by only 10.9% of women and 9.9% of men. Prevalence estimates for sexual problems also show marked reductions when duration criteria are applied; in Natsal-3, of those reporting lacking interest in sex, 35.1% of men and 55.8% of women said that the problem lasted 6 months or more [22].

Prevalence rates for specific problems vary considerably. This, in part, can be attributed to variations in how sexual problems are defined and whether distress about symptoms is assessed. Most epidemiologic research assessing sexual dysfunction was conducted in Western countries, but the limited evidence we have from other countries shows that estimated prevalence rates vary widely across cultures [23–25].

There has been more consistency across studies in the associations found between factors of possible aetiological relevance and sexual functioning. In women, sexual problems are more frequent in those with mental health problems and relationship difficulties [26, 27]. In a survey of American heterosexual women aged 20–65 years, 24.4% reported marked distress about their sexual relationship and/or their own sexuality [28]. The best predictors of distress were markers of mental health and the quality of the emotional relationship with the partner. Physical aspects of sexual response in women, such as arousal and orgasm, were relatively poor predictors.

In men, age has a predictable negative effect on erectile function [29]. Most studies have also found an association between age and loss of sexual desire [30]. There is some evidence that PE is more commonly reported by younger men than older men [21].

The association between age and sexual problems in women is more complex. Whereas the level of sexual interest typically decreases with age, older women are less likely to regard this as a problem [28]. An important predictor of sexual problems is whether a woman has a current sexual partner and, among partnered women, whether the partner has sexual difficulties [31]. Although the postmenopausal decline in oestrogens is relevant to vaginal lubrication, other factors such as mental health and the quality of the sexual relationship are more important determinants of sexual well-being than menopausal status [32].

Aetiology

Before considering the factors that can cause sexual problems, it is worth underlining the important way that sexual function differs from most other physiological response systems. Although involving physiological mechanisms, sexual responses are most often experienced in the context of a relationship. This highlights the importance of keeping the interactive relationship components in mind when trying to assess and treat sexual problems. Sociocultural factors are also crucial to understanding how sexual problems are experienced [33]. Much of the focus in medical treatments of sexual problems has been on the individual patient, with relationship and sociocultural aspects largely ignored. The more specific aetiological factors can now be considered using the 'three-windows approach' [4].

The first window—the current situation

Through the first window, a variety of factors in the individual's current relationship and situation may be relevant. Relationship problems, particularly resentment and insecurity within a relationship, are of particular importance. For many individuals, feeling secure and being able to 'let go' are necessary for them to enjoy sex. Other factors that may be important include: poor communication between partners about their sexual feelings and needs; misunderstandings and lack of information; unsuitable circumstances and lack of time, for example fatigue, lack of privacy; concerns about pregnancy or sexually transmitted infections; and low self-esteem and poor body image.

The second window—vulnerability of the individual

Although a wide range of factors can impact on our sexuality, it is also clear that individuals vary substantially in the extent to which they are affected by such factors, particularly in terms of an associated inhibition of sexual response. Such vulnerabilities are likely to have been evident in earlier episodes in the current relationship or in earlier relationships.

1. Negative attitudes. Long-standing attitudes, usually stemming from childhood, that sex is inherently 'bad' or immoral are likely to interfere with an individual's ability to become involved in, and enjoy, a sexual relationship.
2. Need to maintain self-control. In some individuals, difficulty in 'letting go' sexually reflects a more general need to maintain self-control, particularly in the presence of another person.
3. Earlier experience of sexual abuse or trauma. There is now an extensive literature on the impact of sexual abuse on subsequent sexual adjustment. Whereas the mediating mechanisms are not well understood and are likely to be complex, a history of such experience should be regarded as potentially relevant to current sexual difficulties.
4. Propensity to sexual inhibition. The dual control model, discussed earlier, has led to psychometrically validated measures of propensity to sexual excitation and inhibition in men [34] and women [35]. In men, as predicted, there is a clear association between low sexual excitation and/or high sexual inhibition propensity and erectile problems, but no association with PE [36]. In women, there is a strong relationship between sexual inhibition propensity and reports of sexual problems [37, 38]. Particularly important is one inhibition subscale (labelled 'arousal contingency') that reflects susceptibility for sexual arousal to be easily affected by situational factors, for example if the circumstances are not 'just right'. Although further research is needed, these measures of sexual inhibition and excitation may prove valuable in explaining patterns of impaired sexual response and helping in the selection of appropriate treatment.

The third window—health-related factors that alter sexual function

Mental health and sexuality

Psychiatric problems are commonly associated with sexual problems (for a review, see [4]). Reduction in sexual interest and, to some extent, sexual arousability is generally accepted as a common

symptom of depressive illness [39]. In contrast, sexual interest tends to be increased in states of elevated mood such as hypomania [40].

With anxiety, the clinical evidence is much more limited. Higher rates of sexual dysfunction in patients with anxiety disorders have been reported [41]. Individuals with panic disorder may be particularly likely to report sexual problems. PE is a common sexual problem in men with social phobias [42].

Although most studies have focused on negative effects of mood disorders on sexual interest and response, there is evidence that a minority of individuals experience increased sexual interest during negative mood states. This paradoxical pattern has been reported in non-clinical samples of men [43] and women. [44] Although the origins of this pattern are not yet understood, it may be problematic in various ways, for example associated with sexual risk-taking or leading to sex being used as a mood regulator.

The impact of schizophrenia on sexuality is complex. Sexual thoughts and behaviours are common in schizophrenia, and there may be a relative increase in sexual activity [45].

Physical health and sexuality

Poor physical health is associated with decreased sexual activity and reduced sexual satisfaction at all ages [46]. The impact of poor physical health on sexuality may be relatively non-specific. For example, loss of well-being and energy associated with chronic illness is likely to cause reduced sexual interest and arousability. Psychological reactions to the illness or condition (for example, the effects of breast cancer on a woman's body image, and hence her sexual enjoyment) may also be important. In addition, there are a variety of ways in which health problems can directly affect sexual interest and/or response (for a review, see [4]):

1. Damage to the neural control of genital response. This can involve peripheral mechanisms (for example, autonomic and peripheral neuropathy) or disease in the spinal cord (for example, multiple sclerosis). Injury or surgery causing nerve damage may be involved (for example, spinal cord injury, prostatectomy, or hysterectomy). The most likely consequences are ED in men and impaired vaginal response in women. Brain abnormalities, such as epilepsy or cerebral tumour, can affect central control of sexual response, the precise effect depending on the site of the abnormality or tumour. In some cases, the result is loss of sexual interest and arousability; rarely, there is disinhibition of sexual behaviour.
2. Impairment of vascular supply of the genitalia. Genital response is dependent on increased arterial inflow, as well as alteration in venous outflow.
3. Alteration of endocrine mechanisms affecting sexual interest, arousal, and response. In the male, any cause of lowered testosterone (T) levels is likely to produce loss of sexual interest and, to a varying extent, impairment of erectile response.

In women, lack of oestrogen is associated with impaired vaginal lubrication. The effects of sex steroids, either oestrogens or androgens, on sexual interest and arousability are much less predictable. The evidence is consistent with there being a proportion of women who depend on T for their normal level of sexual interest, but there are many women who can experience substantial reductions in T without obvious adverse sexual effects.

Hyperprolactinaemia, usually resulting from pituitary adenomas and hypersecretion of prolactin, may be associated with loss of sexual interest and, in men, with ED. However, this is not always the case. The precise role of prolactin in human sexuality is not understood.

Some diseases affect sexuality through more than one of the mechanisms described. Diabetes mellitus is a good example. In diabetic men, ED can result from small-vessel vascular disease and also autonomic and peripheral neuropathology. Lowered sexual interest and impairment of genital response have also been reported in diabetic women.

Side effects of medication

We can now consider the main adverse sexual effects resulting from medication (for a review, see [47]).

Antidepressants

SSRIs, by inhibiting the 5-HT_{1A} receptor, increase serotonergic transmission. The most predictable side effect, in both women and men, is inhibition of orgasm and ejaculation [48]. Other negative effects include reduced sexual interest and arousability, though they are less predictable and not always easy to distinguish from the sexual effects of the affective disorder being treated. Tricyclic antidepressants also commonly produce sexual side effects.

Antipsychotic medication

These drugs, used for treatment of schizophrenia and other psychotic disorders, involve a balance of dopamine antagonist and 5-HT agonist effects. The most common side effects are ED and ejaculatory difficulties in men, and orgasmic dysfunction in women.

Antihypertensive medication

Many drugs used to treat hypertension interfere with male sexual response. Beta-blockers (for example, propranolol), by blocking smooth muscle relaxation and leaving alpha-1-induced contraction unopposed, commonly cause ED. Centrally acting antihypertensives (for example, guanethidine) also interfere with sexual response, impairing erection and blocking ejaculation. Clonidine, an alpha-2 agonist, can also cause erectile problems. In this case, the principal effect is likely to be reduced central arousal. For a review of the effects of antihypertensive medication on male sexual response, see [49].

The effects of drugs on women's sexuality have received far less attention. Research has mostly focused on difficulties in achieving orgasm. As orgasm only occurs after sufficient sexual arousal, these effects may reflect impairment of arousal, but this has not been adequately assessed. Steroidal contraceptives, although associated with markedly reduced levels of free T, decrease sexual interest only in a minority of women [50].

Management

In this section, we will first describe the principles of sex therapy and the main forms of psychological and pharmacological treatment, followed by an outline of the process of assessment and selection of a suitable treatment plan. There is growing recognition that integration of psychological and pharmacological methods, with emphasis

on the couple, may be the most appropriate treatment model for most couples [3, 51].

Sex therapy

Although the approach first introduced by Masters and Johnson [52] has been adapted in various ways, the core treatment techniques remain. Originally developed for helping couples, the techniques can be modified for use with individuals and with same-sex, as well as heterosexual, couples.

The key elements of the therapeutic process are:

1. Clearly defined tasks that the couple are asked to attempt before the next therapy session.
2. Those attempts, and any difficulties encountered, are examined in detail.
3. Attitudes, feelings, and conflicts that make the tasks difficult to carry out are identified.
4. These are modified or resolved, so that subsequent achievement of the tasks becomes possible.
5. The next tasks are set, and so on.

The tasks are mostly behavioural in nature. They are chosen to facilitate the identification of relevant issues but, in some cases, are sufficient in themselves to produce change. The behavioural programme is in three parts. In the first part, the couple are asked to avoid any direct genital touching or stimulation and to focus on non-genital contact, alternating who initiates and who does the touching. These first non-genital steps are effective in identifying important issues in the relationship such as lack of trust or counterproductive stereotypical attitudes (for example, once a man is aroused, he cannot be expected not to have intercourse). Once this stage can be carried out satisfactorily, and related problematic issues dealt with, the programme moves on to the second part, which allows genital touching to be combined with non-genital touching, with penile–vaginal intercourse still ‘out of bounds’. In this second part, more intra-personal problems, such as long-standing negative attitudes about sex or the sequelae of earlier sexual trauma, are likely to emerge. In the third part, a gradual approach to vaginal–penile contact and insertion is undertaken. Here the most relevant issues are ‘performance anxiety’ and fear of pain.

As the behavioural tasks reveal key issues that need to be resolved before moving on to the next stage, a variety of psychotherapeutic approaches, including cognitive behavioural techniques, can be utilized. Although the stage at which particular issues emerge does vary from case to case, there is a tendency for problems identified through the ‘first window’, particularly those related to lack of trust and unresolved resentment, to appear during the first stage of the programme. Intra-personal issues (for example, as seen through the ‘second window’) are more likely to be recognized during the second stage.

The goals of therapy include helping the individual to accept and feel comfortable with his or her sexuality and helping the couple to establish trust and emotional security and to enhance their sexual enjoyment and intimacy. An important point is that these goals do not necessarily include reversal of specific sexual dysfunctions. There are exceptions; for example, there are specific behavioural techniques to deal with PE and orgasmic disorder (for details of these techniques, see [4]). However, the overriding principle is that, assuming there is

no abnormality of the basic physiological mechanisms involved in sexual response, normal sexual function will return once these goals are achieved. In cases where impairment of physiological mechanisms does exist, the goals of sex therapy are still helpful and integrate well with the use of pharmacological treatment.

Practical aspects

Although sex therapy varies in duration, 12 sessions over 4–5 months is typical. The therapist adjusts to the particular needs of the individual or couple. Treatment begins weekly, with the interval between sessions extended once major issues like unexpressed resentment or communication problems have been dealt with. The last two or three sessions are spaced out over a few months, so that the couple have an opportunity to consolidate their progress and cope with any setbacks before termination.

Other psychological treatments

Apart from sex therapy, a range of other psychological treatments have been used to treat sexual dysfunction, either on their own or as a supplement to sex therapy. Two particular approaches that have generated the most interest and evaluation are cognitive behavioural therapy (CBT) and mindfulness-based intervention. There is a large literature supporting the important role for cognitive factors in the aetiology and maintenance of sexual disorders (for a review, see [53]), which suggests that CBT approaches could be effective.

Pharmacological treatments for men

Erectile disorders

The introduction of phosphodiesterase type 5 (PDE-5) inhibitors had a major impact on the treatment of ED. After the approval of sildenafil in 1998, other PDE-5 inhibitors, for example tadalafil and vardenafil, became available. Although these drugs were effective for approximately 75% of men, there was evidence that many men did not continue with the medication [54]. In one study done in eight countries, 2912 men identified with ED were followed up; 58% of them had sought medical help for ED, but only 16% of men maintained their use of PDE-5 inhibitors [54]. In addition, although these medications have a generally good safety and side effect profile, there are some contraindications to their use (for example, use of nitrates).

Other pharmacological treatments that were widely used before PDE-5 inhibitors became available, such as apomorphine and intracavernosal injections of phentolamine, used in combination with papaverine, are now primarily recommended for men with ED for whom PDE-5 inhibitors are either contraindicated or have been ineffective [51, 55].

Other drugs that are still in development to treat ED in men include bremelanotide, a melanocortin agonist and a synthetic peptide analogue of a naturally occurring hormone called alpha-melanocyte-stimulating hormone (MSH) [56].

Premature ejaculation

Pharmacological treatments used for PE include SSRIs and clomipramine, a tricyclic antidepressant, and topical administration of prilocaine/lidocaine. One drug—dapoxetine, a novel, short-acting SSRI—has received approval for the treatment of PE in over 30 countries [3]. All of these medications can be taken either daily or on an as-needed basis.

Delayed or absent orgasm/ejaculation

At the present time, there is no accepted pharmacological treatment for delayed or absent ejaculation or orgasm [57].

Low sexual desire

The most treatable, but relatively infrequent, cause of loss of sexual desire in men is hypogonadism. Where androgen deficiency is evident, T replacement is indicated. If loss of sexual desire is associated with hyperprolactinaemia, treatment with dopamine agonists, such as bromocriptine, is recommended.

Pharmacological treatments for women

Following the success of PDE-5 inhibitors in treating ED, there were attempts to use sildenafil to treat sexual arousal disorder in women, but the results were disappointing [58]. Attention shifted to treatment of low sexual desire in women and the use of T. Although Intrinsa, a T patch, was approved in 2006 by the European Medicines Agency, this was only for treatment of low sexual desire in women with surgically induced menopause.

The first medication to receive approval by the US Food and Drug Administration for the treatment of hypoactive sexual desire disorder in premenopausal women was flibanserin, a medication with mixed effects on serotonergic and dopaminergic transmitter systems that was originally evaluated as an antidepressant but was ineffective [59]. Flibanserin was approved amid a great deal of controversy about its safety and efficacy. Two systematic reviews on the efficacy and safety of flibanserin reached inconsistent conclusions regarding its efficacy [60, 61].

There are other drugs in development to treat women's sexual desire problems, including subcutaneously administeredbremelanotide and medications that combine sildenafil and T or T and bupropion.

Evaluation of treatments

There have been many more studies testing the effectiveness of pharmacological treatments for sexual dysfunction than of psychological or combination therapies [62]. With the exception of research on female sexual pain disorders, there has been a serious shortage of outcome research on psychological treatments. This lack of research does not reflect a lack of growth in sex therapy or of new approaches [63].

Three systematic reviews of the efficacy of psychological interventions to treat sexual dysfunction in men and women have been published [64–66]. For women, the strongest evidence exists for the use of CBT and mindfulness-based interventions in the treatment of low sexual desire [53]. For female orgasmic disorder, multimodal treatment programmes involving techniques such as directed masturbation, sexual skills training, and sex education can be effective approaches [53]. As mentioned, there have been several controlled outcome studies on psychological interventions for sexual pain disorders, and these suggest that psychological therapies are effective treatments, supporting a biopsychosocial approach [67].

For men, there have been few outcome studies on psychological treatments for ED, but the limited evidence suggests that group or couple therapy is superior to individual therapy and that combined

treatments (PDE-5 inhibitors and psychological therapy) are effective [53]. For the treatment of PE, there is limited and inconsistent evidence for the effectiveness of psychological interventions. For low sexual desire and delayed ejaculation, there are very few controlled outcome studies.

Planning a treatment programme

Assessment

When couples present with sexual difficulties, one of them is usually regarded as having the problem, but both partners should be carefully assessed, whenever possible. There are three stages to assessment: (1) to facilitate the decision about whether sex therapy is appropriate; (2) to identify issues relevant to the sexual problem that need to be resolved; and (3) to determine whether medication or other treatments are required.

Keeping in mind the distinction between a sexual problem that is adaptive or appropriate, given an individual's current circumstances, and one that is maladaptive (and can perhaps be considered a 'dysfunction'), we can assess each individual's case through the three conceptual 'windows' described earlier. Are there problems in the couple's current relationship or situation which would make inhibition of sexual responsiveness in either partner understandable or adaptive? Does either individual give a history that suggests vulnerability to sexual problems? Are there any mental or physical health issues or medication use in either partner that could be having a negative effect on sexual interest or response?

Although not all of the details can be obtained during the initial interview, assessment of the following topics should be carried out: the nature of the problem, including an assessment of the level of sexual interest and response in each partner; identification of other assessments that may be needed (for example, physical examination, blood tests); commitment and motivation of each partner to improving the relationship; and mental state assessment of each partner. If both partners are present, each should be interviewed separately, following a conjoint interview. As far as possible, questions should be asked about each individual's sexual history, the nature of the current relationship, contraceptive use and reproductive history, and alcohol or recreational drug use.

At the end of the initial interview, the clinician should provide a preliminary formulation of the nature of the problem and the types of intervention that may be helpful. Whatever treatment methods are used, it is important to continue to see the couple together to monitor progress and provide counselling, as needed.

If there is no evidence of causal factors of the kind viewed through the 'first' or 'second' window, then a trial of pharmacological treatment may be appropriate (although, as discussed, few pharmacological options exist for women). In such cases, a physical examination and, where relevant, laboratory investigations would normally be arranged before starting treatment. It is important to have a good 'clinical baseline' before embarking on pharmacological interventions.

If there are any indications of issues, particularly of the kind that invoke inhibition of sexual response, which need to be resolved, then pharmacological interventions should not be considered as a

first step. In many such cases, more assessment is required before these factors can be adequately assessed. There are then two options: (1) further interview(s) to explore such issues; or (2) starting on a programme of sex therapy. The rationale for the second option is as follows. The initial two stages of sex therapy (that is, involving non-genital and then genital touching, with no attempts at vaginal intercourse) are particularly effective at identifying relevant issues underlying the problem. Furthermore, the process involved in those early stages is likely to benefit any sexual relationship, even those without obvious problems. After three or four sex therapy sessions, a reappraisal would be made and a decision taken about whether to continue with sex therapy alone or to combine it with an appropriate pharmacological method. For example, with a couple where the man has erectile problems, it is easier to assess the indications for the use of a PDE-5 inhibitor after the couple have gone through the first two stages of the programme where there is no 'performance pressure' and no need for an erection to occur. Similarly, it is often informative to see what impact sex therapy has on the individual who has complained of reduced sexual desire, before attempting to deal with the problem pharmacologically or hormonally.

Ideally, the use of the pharmacological method should then proceed in combination with the continuation of the sex therapy programme. In that way, a gradual transition to a satisfying sexual relationship can be achieved without renewed 'performance pressures'. If, however, progress continues to be made with sex therapy, then the addition of pharmacological interventions may not be necessary. It should be explained to the couple that, whereas pharmacological treatments often have beneficial effects on sexual response, they do not 'cure' the problem, which is likely to recur once the medication is stopped.

Paraphilic disorders

Clinical features

The essential feature of a paraphilia is that it involves an intense, recurrent pattern of sexual interest, manifested in sexual fantasies, urges, or behaviour, to atypical objects or activities (typically those that do not involve sexual interaction with a consenting, phenotypically normal, physically mature human partner) [2]. A paraphilia can be considered a disorder if it: (1) causes distress or other negative impact to the individual or is harmful, or potentially harmful, to other people; and (2) is manifest over at least a 6-month period. There is high comorbidity between paraphilias and mood disorders and also consistent evidence that different paraphilias often co-occur [68, 69]. Substance use disorder, neurodevelopmental conditions, and mood disorders have been reported as highly prevalent among paraphilic offenders [70].

A large number of paraphilias have been mentioned in the literature, but most of them are rare. We will focus here on the paraphilic disorders that are most common and listed in DSM-5.

Voyeuristic disorder

The key feature is a recurring pattern of intense sexual arousal from observing an unsuspecting person or couple in the process of undressing or interacting sexually. The voyeur usually masturbates while 'peeping'.

Exhibitionistic disorder

This involves a pattern of recurrent and intense sexual arousal from exposing one's genitalia to an unsuspecting person, experienced in fantasies, urges, or explicit behaviour. In some exhibitionists, the urge to expose themselves occurs occasionally, possibly at times of crisis or emotional distress. For others, the idea of exposing is always sexually stimulating and may feature in their masturbation fantasies.

Frotteuristic disorder

This involves recurrent and intense sexual arousal from touching or rubbing against a non-consenting person, which is experienced in fantasies, urges, or explicit behaviour. Such individuals are also more likely to experience exhibitionist and voyeuristic disorders, and to show mood and antisocial personality disorders.

Sexual sadism disorder

This is defined as recurrent and intense sexual arousal, as manifested by fantasies, urges, or behaviours, from the physical or psychological suffering of a non-consenting person.

Sexual masochism disorder

This involves recurrent and intense sexual arousal from the act of being humiliated, beaten, or bound. Individuals who engage in BDSM (bondage, dominance and submission, sadism, and masochism) which is consensual and not associated with distress would not be diagnosed with either sexual sadism disorder or sexual masochism disorder.

Paedophilic disorder

This term relates to an adult (16 years or older) being sexually attracted to a prepubertal child, engaging in sexual fantasies involving a child of either sex, and/or engaging in sexual activity with such children. In DSM-5, there is also the requirement that there must be at least a 5-year age difference between the individual and the child.

Fetishistic disorder

This refers to recurrent and intense sexual arousal in response to a specific part of the body or to the use of non-living objects, for example rubber or leather.

Transvestic disorder

This is a particular form of fetishism in which recurrent and intense sexual arousal arises from cross-dressing. There is evidence that some fetishistic transvestites end up transitioning to transgendered women.

Classification

In DSM-5, there were several changes in the classification of paraphilias. Firstly, a distinction was made between paraphilias and paraphilic disorders, the latter involving behaviour that is currently either causing distress or impairment to the individual with the paraphilia or a risk of harm to others [2]. There are eight paraphilic disorders listed in DSM-5: voyeuristic disorder, exhibitionistic disorder, frotteuristic disorder, sexual masochism disorder, sexual sadism disorder, paedophilic disorder, fetishistic disorder, and transvestic disorder; there are also categories for 'other specified paraphilic disorder' and 'unspecified paraphilic disorder'. In the

revision of ICD (ICD-11), several disorders listed in ICD-10 (fetishistic disorder, fetishistic transvestism, and sadomasochism) were removed from the list of paraphilic disorders [71].

Leading up to DSM-5, there were controversial proposals to introduce new disorders such as hypersexual disorder [72] and paraphilic coercive disorder [73], but these were not approved by the American Psychiatric Association. There has also been a long running and highly complex debate about whether paraphilic disorders should be removed from the DSM altogether [74].

Epidemiology

The prevalence of paraphilic disorders is largely unknown. A consistent finding, however, has been that most paraphilias and paraphilic disorders are much less common in women than in men.

In a representative Swedish sample, 7.7% of respondents reported at least one incident of being sexually aroused by watching others having sex and 3.1% reported at least one occasion of being sexually aroused by exposing their genitals to a stranger [68].

In a representative Australian sample of 19,307 men and women aged 16–59 years, 1.8% of sexually active respondents (2.2% of men and 1.3% of women) had been involved in BDSM over the past year [75]. It is important to note that these prevalence estimates relate to paraphilic interests, and not to paraphilic disorders.

In a recent online survey of 8718 German men, 4.1% reported sexual fantasies involving prepubescent children, 3.2% reported sexual offending against prepubescent children, and 0.1% reported a paedophilic sexual preference [76]. Reviewing the literature, Seto *et al.* [69] concluded that the upper-limit prevalence of paedophilia in community settings ranged from 1% to 3% in men.

Langstrom and Zucker [77], in a representative sample of 2450 Swedish men and women, asked 'Have you ever dressed in clothes pertaining to the opposite sex and become sexually aroused by this?' Positive answers were given by 2.8% of men and 0.4% of women. However, we have no idea how many of these individuals repeated this behaviour and, in particular, how many had a transvestic disorder.

Aetiology

There are many theories for the aetiology of paraphilias, with the most support for those involving conditioning or neurodevelopmental factors (for a review, see [78]). Because of the strong comorbidity between different paraphilic disorders, there may be common causal factors across paraphilias [69].

Although individuals with paraphilic disorders are most often seen in forensic and prison settings, they can also present in general psychiatric settings [69]. Regarding assessment, there are problems with reliance on self-report alone, and the diagnosis of a paraphilic disorder typically requires integrating many different sources of information, including a mental status examination to establish whether there are any concurrent psychiatric conditions and a careful sexual history [69]. It is important to assess whether the paraphilic interest or behaviour is stronger or weaker than normophilic interests or behaviour. Psychophysiological assessment of sexual arousal patterns, using penile plethysmography or viewing time of sexual stimuli, can be useful in this regard, particularly for individuals with a paedophilic disorder. For a review of the available self-report (through clinical interview or questionnaires) measures used in the assessment of paraphilias, see [69].

Management

While there is no evidence that paraphilic disorders can be 'cured' [69], there is some support for pharmacological treatments such as anti-androgens and antidepressants to reduce sexual drive, in particular for men with paedophilia [78]. Cognitive behavioural approaches are often used, usually as one component in a multimodal treatment programme [78].

Evaluation of treatments

There has been limited outcome research on treatments for the various paraphilic disorders. Although used for many years, based on a review of outcome studies, Zucker and Seto [78] concluded that there was no strong empirical evidence that pharmacological treatments to reduce sexual drive had any effect on rates of reoffending. To date, there have been very few large, controlled outcome studies of either pharmacological or psychological interventions for the treatment of paraphilic disorders.

Conclusions

Overall, sexual dysfunctions in one or other partner of a relationship are potentially treatable in many cases. The basic sex therapy approach described in this chapter can be effective on its own or in combination with other psychological interventions such as mindfulness-based therapy or with pharmacotherapy. Paraphilias, which are of most significance when they lead to illegal behaviour, are more difficult to treat. Further research is needed on these conditions.

Gender dysphoria

Els Elaut and Gunter Heylens

Introduction

In the past few years, the media have covered the lives of transgenders as never before. Caitlin Jenner was on the cover of *Vanity Fair* in July 2015, and the Netflix series *Orange is the New Black* featured a trans character—Sophia Burset—embodied by a trans woman Laverne Cox. At the same time, multi-disciplinary gender clinics worldwide are reporting on rapidly growing numbers of individuals voicing a desire for gender-confirming treatment (GCT) [1–2].

Terminology and developmental pathways

The terminology used in this chapter is summarized in [Table 116.1](#). The term ‘gender dysphoria’ (GD) was first mentioned by Norman Fisk (1974) [3] to describe discomfort with the assigned gender (assignment based on biological sex), leading to a desire for sex re-assignment surgery (SRS). Until recently, gender clinics were mostly consulted by trans women (individuals who were assigned male at birth but who identify as female) and trans men (individuals who were assigned female at birth but who identify as male) requesting counselling concerning the desired social transition from one gender role to the other and requesting medical interventions (hormone treatment and genital surgery) to transition from one sex to another. Evidence shows that GCT in individuals with GD is effective [4] and leads to an improvement in psychological symptoms, improved quality of life, and diminished GD [5]. Next to the symptom, and now an official DSM-5 diagnosis, of GD today, the clinician will note a spectrum of words used to describe individuals whose gender identity, gender role behaviour, and/or gender expression do not match (or ‘conform to’) current local expectations and stereotypes within the binary system of male–female in society (for example, genderqueer, gender variant, genderfluid, a-gender, non-binary, transgender, trans, transsexual). Today, not all individuals with GD presenting in gender clinics desire the full range of GCTs [6]. This confronts clinicians with the challenge of providing care in the absence of evidence-based treatment for these individuals with non-binary identities [7]. This evolution of an increased awareness for a broad gender variance has led to the use of the term ‘transgender’, a term coined by activist Virginia Prince, referring to a diverse group of individuals who cross or transcend culturally defined categories

of gender, including transsexual people, cross-dressers, drag queens and kings, non-binary people, and gender variant people [8].

Two taxonomies are dominant in describing the phenomenology of GD—based on sexual orientation [9] and on age of GD onset [10]. Blanchard proposed two possibilities in GD development (with perhaps different aetiologies), based on sexual orientation [9]: a ‘homosexual’ and a ‘non-homosexual’ (relative to birth sex) subtype ([Table 116.2](#)). Also, the non-homosexual group develops differently in trans women and men; for example, the age of first clinical contact only differed between homosexual and non-homosexual trans women, and not trans men [11]. Pioneers in transgender health care were under pressure to identify prognostic factors and select the right candidate for treatment, leading to a search for the ‘true transsexual’, in whom minimal post-treatment regret would be expected. In the past, clinicians have been reluctant to offer treatment to the non-homosexual group, based on (limited) evidence that regret would be more prevalent in older individuals requesting treatment [11]. This categorization based on sexual orientation hence stirs controversy until today. Individuals with GD are sometimes cautious in disclosing the history of their GD or their sexual orientation, due to fear of being denied GCT, a concern historically not unfounded.

Recently, categorization based on the age of GD onset has been used increasingly. Researchers define adults with GD who recall childhood cross-gender behaviour and identification as ‘early onset’, while adults in whom the indicators of GD arise during puberty, or much later, are considered ‘late onset’ [12]. This categorization refrains from the older terms of homosexual and non-homosexual but uses the terms ‘androphilic’ (sexually attracted to men) and ‘gynephilic’ (sexual attracted to women) to refer to sexual attraction without making assumptions about sex or gender. A recent review shows that categorization based on the anticipated post-treatment heterosexual behaviour of trans women and men (as proposed by Blanchard’s typology) might not be very predictive of a good outcome after GCT [10]. Contrary to early treatment protocols, sexual orientation is currently no longer a decisive factor in treatment decisions. Considering the potential psychosocial consequences of becoming part of not one minority group (the transgender community), but two (the gay and lesbian and bisexual communities), and the need to assess the individual’s skills in dealing with minority distress, sexual orientation might still be a topic in need of clinical attention.

Table 116.1 Summary of the terminology used in this chapter

Sex	The biological aspect of gender, mostly based on primary and secondary sex characteristics
Gender	The psychosocial aspect of sex, subjective experience
Assigned gender	Apart from assigning a legal sex (in most countries, male or female, based on a newborn's primary sex characteristics), children are also assigned a certain gender (role and identity), for example expectations on crying behaviour, having a calm or more aggressive temper, showing an interest in stereotypical clothing, toys, hairstyle, etc.
Experienced gender	Or gender identity; the subjective experience of being male, female, genderqueer, or otherwise
Gender role	Behaviours that are—within a certain culture and time—associated with being male or female and hence are expected from men and women
Transgender	An umbrella term referring to a group of individuals who cross or transcend culturally defined categories of gender, including transsexual people, cross-dressers, drag queens and kings, non-binary people, and gender variant people
Cisgender	Opposite of transgender; people whose gender identity matches the sex and gender assigned at birth
Trans woman	An individual assigned the male gender at birth who identifies as a woman
Trans man	An individual assigned the female gender at birth who identifies as a man
Non-binary	An umbrella term for all not exclusively male or female gender identities; also genderqueer, genderfluid, etc.
Cross-dressing	The act of assuming a gender expression commonly associated with another gender; does not necessarily imply a direct correlation with gender dysphoria, a transgender identity, or fetishist arousal
Androphilia and gynephilia	Terms used to describe sexual orientation without attributing a sex or gender assignment (in contrast to the terms gay, lesbian, or bisexual); androphilia describes sexual attraction to men or masculinity; gynephilia refers to sexual attraction to women or femininity

Diagnostics

During the past decades, gender identity and gender role diagnoses underwent category migration and renaming, both in the American Psychiatric Association's (APA) *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and in the World Health Organization's (WHO) *International Classification of Diseases* (ICD) [13]. Transsexualism appeared for the first time in the DSM in 1980 ('Gender identity disorder of childhood (GIDC) and transsexualism') and was listed among the psychosexual disorders. In 1994, GIDC and transsexualism were merged into one diagnosis—'Gender identity disorder' (GID)—and clustered with paraphilias and sexual dysfunctions. In the preparation phase of DSM-5, a fundamental question was raised by some transgender activists and clinicians of whether the diagnosis of GID should be retained at all. Their main argument was that GID was not a mental disorder, a similar argument that led to the removal of homosexuality from DSM-II in 1973. The decision to keep the diagnosis within the DSM was based on two considerations: access to care (health care reimbursement) and reconceptualization of the diagnosis. The new concept of GD was introduced to emphasize the fact that incongruence between one's felt gender and assigned sex/gender (usually at birth) leading to distress and/or impairment was the core feature of the diagnosis [14].

Also in the eleventh revision of the ICD, GID will be replaced with the label of 'Gender incongruence' (GI) to a new section provisionally entitled 'Conditions related to sexual health' [15]. The main argument for shifting and renaming diagnoses is further destigmatization of trans people who are already at risk for discrimination and associated mental health problems.

Prevalence

While studies on the prevalence of both childhood GD and GD in adults are severely hampered by the uncertain methodology and diagnostic classification, a recent review calculated a meta-analytical general prevalence for GD in adults of 4.6 in 100,000 individuals, 6.8 for trans women and 2.6 for trans men. The review also found an increase in reported prevalence over the last 50 years [1]. This might still represent an underestimation of the true prevalence, as most studies are based on the number of adult individuals seen at specialized gender clinics or on the number of legal sex changes. Recently, population-based data have become increasingly available [16–18]. Conron *et al.* estimated 0.5% of adults consider themselves as 'transgender' (for example, 'a person born into a male body but who feels female or lives as a woman'), based on a probability sample in the United States of 28,176 adults aged between 18 and 64 years

Table 116.2 Differences between homosexual and non-homosexual subtype

Homosexual	Non-homosexual
Stronger cross-gender identity in childhood	Less cross-gender identity in childhood
Younger age at first clinical contact	Older age at first clinical contact
Lower prevalence of being (or having been) married	Higher prevalence of being (or having been) married
Less sexual arousal while cross-dressing in adolescence	Greater sexual arousal when cross-dressing in adolescence

[16]. Kuyper and Wijsen reported on a prevalence of 'gender incongruence' ('stronger identification with other sex as with sex assigned at birth') of 1.1% in men and 0.8% in women. When also assessing a dislike of the body and a wish to obtain hormones/surgery, the percentages drop to 0.6% and 0.2%, respectively [17]. Obtaining a psychiatric diagnosis and the level of distress in population-based surveys and self-report instruments remains difficult, and hence, these numbers cannot unequivocally be interpreted as a true epidemiological estimate of GD. These numbers of GI might well consist of a theoretical potential of individuals situated in the transgender spectrum that might eventually seek medical treatment.

Valid information on the prevalence of childhood GD is currently lacking entirely. An estimate of gender non-conforming/gender variant behaviour can be made, based on Child Behavior Checklist (CBCL) studies, pointing at 2.6% of boys and 5.0% of girls who 'behave like the opposite sex' and 1.4% of boys and 2.0% of girls who 'wish to be of the other sex' [19]. Therefore, gender non-conformity/gender variance appears to be more prevalent in girls than in boys. Interestingly, based on referral rates to gender clinics, the sex ratios for prepubescent children, adolescents, and adults have always been in favour of trans women. This might be a reflection of a historically lower societal acceptance of femininity in boys, compared to tolerance for masculinity in girls. In fact, gender clinics are currently reporting a change in both prepubescent children and adolescents with GD, such that more trans boys are presenting for care [20–21].

Associated psychopathology

The association between GD and psychopathology has been changing ever since the first publications on transsexualism in the middle of the twentieth century. Transsexualism was previously considered as a severe symptom of a psychiatric disorder (for example, schizophrenia), and it was assumed that both axis 1 and axis 2 disorders were highly prevalent in transsexualism. The viewpoint now is that transsexualism/transgenderism should no longer be included in psychiatric manuals (see Diagnostics, p. 1192) [22]. Previous attitudes were based on anecdotal, rather than systematic, evidence. Gender non-conformity is no longer judged as inherently pathological or negative. Nevertheless, more recently, methodologically sound research has shown a high prevalence of depression and anxiety symptoms in individuals with GD who are referred to gender clinics [23]. A review on the co-occurrence of mental health problems and GD clearly showed that severe psychiatric problems, such as schizophrenia and bipolar disorder, are not more prevalent in individuals with GD, compared to the general population. The prevalence of affective disorders, on the other hand, is considered to be 2–3 times as high as in the general population. Trans women are found to be more comparable to cisgender women, then to cisgender men, with regard to the prevalence and nature of associated psychopathology [24]. With regard to suicidality and self-harm, Zucker *et al.* reported on the results of 13 studies, showing that one in three adults with GD has experienced suicidal ideation or attempted suicide or engaged in suicidal or non-suicidal self-harm [14]. Results on the co-occurrence of axis 2 disorders and GD have been inconsistent with regard to prevalence and the nature of the personality disorder [24]. Recently, there has been increasing interest in the link between GD and autism spectrum disorder (ASD). Van Der Miesen

et al. concluded that there is evidence for an overrepresentation of co-occurring GD and ASD, compared to the general population, and that possible aetiological factors that could account for this co-occurrence are speculative [25].

Still, there are some limitations with regard to research in this field. Firstly, the sample size is still limited and only individuals attending a gender clinic and who are willing to participate are included. Secondly, no randomized controlled trials are available, mainly due to ethical reasons.

Several possible explanations for the overrepresentation of mental health problems in GD are formulated—experiencing an incongruence between one's assigned gender at birth and perceived gender leads to dysphoria, the negative psychological effects of belonging to a minority group, with the risk for prejudice, discrimination, and victimization [14].

Aetiology

As for studies on other psychological characteristics in humans, the role of nature (biological factors) vs nurture (psychosocial factors) in the development of GD has been a subject of debate. GD should be considered as an extreme variant of a gender-atypical development. This development starts from early childhood and is characterized by cross-gender behaviour and/or the stated wish to be of the other gender. Only a small proportion of children showing gender-atypical development fulfil the criteria for childhood GD, and with the onset of puberty (with the inherent physical changes, changing social interactions, and first romantic feelings), gender dysphoric feelings desist in the majority of children with GD [26]. Historically, psychosocial factors have accounted for the development of a cross-gender identity or GD. However, there is a lack of methodologically sound studies on the causal status of these factors in the development of GD. Furthermore, causal factors for the development of GD should already be present at a very early stage of development, that is, in the prenatal and/or early postnatal period [27]. Therefore, psychosocial processes are conceptualized as having a perpetuating role, rather than a causal role [14].

With regard to biological factors, most information is gained from genetic and brain imaging studies. Twin studies suggested a heritability of GD that varied between 62% [28] and 77% [29]. Heylens *et al.* found a significant difference between monozygotic twins and dizygotic twins with GD, suggesting a role for genetic factors [30]. In this study, almost 40% of the 23 monozygotic twins included were concordant for GD, in contrast to none of the 21 dizygotic twins. At present, no candidate genes have been found that can account for the development of GD. Studies have focused on genes involved in sex steroid biosynthesis, but results have been inconsistent. Genome-wide studies on GD patients could give more insight into the genetic basis for GD but are presently lacking.

The effects of (prenatal) hormones on the brain can be visualized using brain imaging techniques such as magnetic resonance imaging (MRI) and diffusion tensor imaging (DTI). An overview of neuroimaging studies in patients with GD is given by Kreukels *et al.* [31] and Guillamon *et al.* [32]. Both groups concluded that the brain phenotypes of trans women and trans men differed in various ways from those of control men and women with feminine, masculine, demasculinized, and defeminized features. Evidence for these

phenotypes is strongest for early-onset gynephilic trans men and androphilic trans women, and absent for androphilic trans men and gynephilic trans women, suggesting that there are different developmental pathways for different subgroups (based on sexual orientation and age of GD onset). Guillaumon *et al.* concluded that the origin of these phenotypes might be caused by atypical effects of sex hormones in specific cortical regions of trans men and trans women [32]. They hypothesized that these differences are due to differently timed cortical thinning in different regions. Functional alterations in the brain of individuals with GD have also been described, using task-related imaging studies (for example, visuo-spatial tasks, verbal fluency tasks) [31].

Finally, post-mortem studies have found that in trans women, specific brain structures (the interstitial nucleus, the bed nucleus of the stria terminalis, and the intermediate nucleus of the hypothalamus) have some sex-specific characteristics that are more similar to cisgender females than males [33–35].

In summary, gender identity development in general, and GD in particular, is the result of a complex interaction between multiple genetic and environmental factors. Genes encode hormones that exert an effect on sex-dimorphic neural structures during the prenatal period. Environmental factors then could have a pivotal effect on gender-atypical development during childhood or adolescence. Since time windows for the prenatal development of the genitals and the brain are believed to differ, individuals with GD experience an incongruence between their perceived gender identity and their body.

Clinical management of gender-dysphoric adults

Diagnostic assessment

Most individuals attending a gender clinic arrive with a self-diagnosis. During the diagnostic phase, a detailed clinical interview is most useful to confirm the diagnosis of GD. Standardized measures can be helpful to capture multiple indicators of gender identity and GD. These measures include the Utrecht Gender Dysphoria Scale (UGDS), and the Gender Identity/Gender Dysphoria Questionnaire for Adolescents and Adults (GIDYQ-AA) [48–49]. The latter uses a specific time frame and has similar items for males and females, in contrast to the UGDS. When associated psychopathology (see Role of the mental health professional, p. 1195) is likely, further diagnostic investigations can be important, in order to initiate appropriate treatment. This can be crucial since (severe) psychiatric comorbidity is a predictor of regret and a worse outcome after GCT [5, 22]. In recent years, the diagnostic phase has shortened and the approach to gender-dysphoric patients has become more individualized. Living in the preferred/experienced gender [the so-called real life experience (RLE)] is no longer a requirement for hormonal treatment. A study by Lawrence *et al.* showed no association between the duration of preoperative RLE and any outcome measure after GCT, except for happiness with the result [50].

GD should be distinguished from simple non-conformity to stereotypical gender role behaviour. Given the increased openness of atypical gender expressions by individuals, it is important that the clinical diagnosis is limited to those whose distress and impairment meet the DSM-5 criteria. Another diagnosis that should be accounted for is transvestic disorder (characterized by the association between cross-dressing and sexual excitement, leading to distress and/or impairment). Occasionally, transvestic disorder is accompanied by GD, and in many

cases of late-onset GD in gynephilic assigned males, transvestic behaviour is a precursor. Individuals suffering from body dysmorphic disorder, obsessive-compulsive disorder, and psychotic disorders can also present with symptoms that are similar to those typical for GD. Most often, these conditions can be differentiated from GD by the presence of other symptoms that are not related to the diagnosis of GD [22].

Role of the mental health professional

Recently, there has been a debate with regard to the role of the mental health professional (MHP) in diagnosing GD and associated psychopathology. With the introduction of the Standards of Care for the Health of Transsexual, Transgender, and Gender-Non-conforming People, Version 7 (SOC-7), any health professional who is appropriately trained in behavioural health and competent in the assessment of GD is authorized to make diagnoses and treatment recommendations [51]. This more liberalized approach is in contrast with the traditional position of MHPs as gatekeepers for adults with GD. It is too early to estimate which approach leads to the best outcome after GCT with regard to satisfaction with treatment and quality of life (for prognostic factors associated with outcome after GCT, see [8]). The SOC-7 states that GCT can be initiated if physical and/or mental health problems that co-occur with GD are sufficiently stabilized.

The use of psychotherapy merely to change a person's gender identity has been considered unethical (SOC-7). Still, psychotherapy or counselling could be useful to treat concomitant mental health problems and to deal with other issues such as grief and loss, sexual concerns, or problems related to partner relationship. If a specific treatment is needed, for example more specific psychotherapy for persons with personality disorders or pharmacotherapy for mood disorders, patients can be referred to a specialized MHP [52].

Endocrinological interventions

Based on a thorough assessment, a qualified MHP can write a referral letter to start hormone replacement therapy (HRT). The SOC-7 outlines several criteria for commencing HRT: persistent, well-documented GD; the capacity to make a fully informed decision and to consent for treatment, having reached the age of majority in a given country; and if significant medical or mental health problems are present, they should be reasonably controlled [51]. The administration of exogenous endocrine agents to induce feminizing or masculinizing changes is a medically necessary intervention, for which the Endocrine Society has issued very specific guidelines [53]. A safe and effective hormone regimen should: (1) suppress endogenous hormone secretion as determined by the person's genetic/biological sex; and (2) maintain sex hormone levels within the normal range for the person's desired gender [53]. HRT in trans women may consist of blocking androgen action (with anti-androgens, for example GnRHa, cyproterone acetate, spironolactone, finasteride) to decrease masculinization (diminishing body hair, frequency and firmness of erections, and muscle volume and strength) and oestrogens to achieve a more feminine presentation (breast development, softer skin, female fat distribution). Unfortunately, elimination of the hormonally induced natal sex characteristics is rarely complete—HRT does not alter voice, hand, feet, or shoulder dimensions [54]. In trans men, HRT may consist of synthetic progestins (for example, lynestrenol, medroxyprogesterone acetate) to interrupt menstrual bleeding, and testosterone to obtain more masculine features (deepening of the voice, increasing muscle mass and strength, beard and body hair

growth, decreased fat mass, male pattern baldness, etc.). Although generally, a good aesthetic result is achieved in trans men, the short stature and often broader hip configuration do not change with HRT.

Surgical interventions

Gender-confirming surgeries in trans women may include breast/chest surgery (augmentation mammoplasty), genital surgery (penectomy, orchidectomy, vaginoplasty, clitoroplasty, vulvoplasty), and/or other interventions such as facial feminization surgery, liposuction, lipofilling, voice surgery, thyroid cartilage reduction, gluteal augmentation, hair reconstruction, and various aesthetic procedures. It is recommended that trans women undergo HRT (minimum of 12 months) prior to breast augmentation, to maximize breast growth and surgical results. For genital surgery, two MHP referrals are recommended. Specifically for orchidectomy, the SOC-7 recommends 12 continuous months of HRT to introduce reversible testosterone suppression before undergoing irreversible surgery. For vaginoplasty, it is additionally recommended that the GD individual lives for 12 months in the congruent gender role. Typically, it is advised to stop all HRT at least 2 weeks prior to any surgical procedure, as oestrogens in particular cause an increased risk of thromboembolic complications [51, 55].

In trans men, gender-confirming surgeries may include subcutaneous mastectomy, hysterectomy/ovariectomy, vaginectomy, reconstruction of the fixed part of the urethra (if isolated, metoidioplasty), scrotoplasty, phalloplasty, and implantation of erection and/or testicular prostheses. It is recommended that trans men undergo HRT (minimum of 12 months) prior to 'internal' genital surgery (hysterectomy/ovariectomy), to introduce a period of reversible oestrogen suppression before irreversible surgery is performed. For 'external' genital surgery (metoidioplasty), it is additionally recommended that the GD individual lives for 12 months in the congruent gender role [51, 56].

Fertility

Although neglected for a long time, fertility issues have become an important topic in the care of transgender persons. The SOC-7 clearly emphasizes the need to discuss fertility options prior to any treatment or medical intervention, since GCT (especially genital reconstructive surgery) often has irreversible effects with regard to fertility. The development of new reproductive medicine techniques creates opportunities for preserving fertility in transgender persons. Before, losing fertility was accepted as the price to pay for transitioning [57]. For trans women, sperm cryopreservation is the simplest and most reliable method. Success rates regarding pregnancy are similar to preservation in cisgender patients. Fertility options in trans men include embryo cryopreservation, oocyte cryopreservation, and ovarian tissue cryopreservation. Each option requires the use of partner sperm or donor sperm and a recipient uterus. Success rates are lower, compared to trans women, and depend, besides specific expertise of a specialized fertility centre, also on the age of the patient at the moment of cryopreservation. An interruption of cross-sex hormones for 3 months is necessary to restore fertility, both in trans women and trans men [58].

Sexual health

Sexuality and relationships are vital parts of almost everyone's quality of life, including GD individuals. In the past, GD was often

considered to be a 'hyposexual' state. Most individuals consulting a gender clinic (80%) have had sexual experiences with a partner. About half also involved their genitals in partnered contact, although only a minority (10–15%) indicated pleasurable genital sensations. Also, most have experience with masturbation [59]. Thus, the idea of GD individuals as not being sexual creatures is an oversimplification. Sexual activity is there before, during, and after GCT. Hence, both health care providers and individuals considering whether to undergo GCT should have clear information on the potential sexual effects of treatment (for a more extensive review, see [60–61]).

While one might reduce the potential sexual effects of GCT to the effects of sex steroids (oestrogens in trans women inhibiting sexuality; testosterone in trans men stimulating sexuality), other factors such as better self-esteem, feeling more comfortable with the new genitalia, and being able to allow more sexual exploration should not be disregarded. With regard to sexual desire, when trans women and men are asked—in retrospect—whether treatment has decreased, increased, or not affected their sexual desire, remarkable results emerge. The majority of trans women (70%) report decreased sexual desire after treatment (hormones and surgery), while a minority report an increase (10%) or no effect (20%). For trans men, the picture is reversed; the majority report an increase (70%), and a minority a decrease (10%) or no effect (20%) [60]. Most trans women and men welcome these changes, as they value sexual functioning more closely resembling the 'typical' functioning of their identified gender [62]. A subgroup of trans women (one in five) experience distress from decreased sexual desire. It is unclear to what extent this subgroup struggle with developing sexual desire which is now less testosterone-driven and more driven by mental processes. In any case, GCT always demands sexual (re)development by the individual and within a partnership. Distress about both decreased (5%) and too much sexual desire (3%) is much less of a concern in trans men. Sexual arousal is found to increase after GCT [63], although it should be noted that trans women with a skin-lined vagina always need a lubricant for penetration. Trans men also cannot obtain an erection spontaneously, even with an erection prosthesis. Percentages for 'orgasm capacity' in trans women, the best studied aspect of sexuality in GD individuals, ranges from 27% to 100% and differs between countries and used techniques [61]. It should, of course, be noted that obtaining an orgasm is not only about functional nerves and adequate hormone therapy, but as much about knowledge, skill, and experience. Most trans men are able to reach orgasm after having a phalloplasty [63–64]. So both trans men and women appear to experience increased orgasmic functioning after GCT.

Post-treatment adjustment and prognostic factors

As GCT is, at least partially, an irreversible process, it is of major importance to look at outcome with regard to feelings of GD, quality of life, and psychological functioning post-treatment. A systematic review by Murad *et al.* showed that, after GCT, 80% of individuals diagnosed with GD reported significant improvement in gender-dysphoric feelings and 78% reported significant improvement in psychological symptoms [5]. Also with regard to quality of life and sexual function, 80% and 72%, respectively,

reported an improvement. Djehne *et al.* reported on 11 longitudinal studies investigating outcome of psychiatric disorders and psychopathology post-treatment and found that in the majority of the studies, scores on questionnaires measuring psychopathology and GD were similar to normative data [24]. In general, however, longitudinal studies on the effects of GCT are methodologically weak, and follow-up duration is limited. Only one study has a duration time of >10 years, showing an overall positive evaluation [65]. More discouragingly, a Swedish cohort study (average follow-up duration of 10.4–11.4 years) showed that overall mortality for sex-reassigned persons was higher during follow-up than for cisgender controls, particularly death from suicide. Sex-reassigned persons also had an increased risk for suicide attempts and psychiatric inpatient care [66]. The majority of the patients included in this study were diagnosed in the 70s and 80s and, along with altered societal attitudes towards persons with different gender expressions, received less qualitative care both for their GD and for co-occurring mental health problems.

Positive prognostic factors are early-onset GD and a homosexual subtype [5], being a trans man [5, 67], and a younger age at assessment [68], although results are inconsistent. Pre-existing psychopathology [5] and poor results of SRS [4] tend to have worse prognosis. Furthermore, inadequate social functioning, indicated by periodical or full dependence on social assistance, and poor support from the individual's family are considered to be negative predictive factors [69].

Regret after GCT, defined as GD in the new gender role and after GCT, and the explicit wish to revert to his/her original gender role is estimated to occur in <1% in trans men and <1–1.5% in trans women [70]. Risk factors for regret are: inadequate diagnosis of GD and/or major psychiatric comorbidity, absent or disappointing RLE, and disappointing surgical results [22, 70]. De Cuypere and Vercruysse concluded that inadequate diagnosis of GD and major psychiatric comorbidity are the predominant indicators for regret [69].

The question remains as to which part of GCT is essential with regard to improvement of psychological functioning: RLE in the preferred gender role, hormonal therapy, or SRS. Heylens *et al.* showed that after initiation of hormonal treatment, the level of psychological stress, as measured by Symptom Checklist-90 (SCL-90), became comparable to a general population control. SRS did not further change the level of psychological distress [71].

In general, GCT has proven to be the best method for treating GD. Clinicians should stay mindful of actual or potential psychiatric problems before the start of GCT and after its completion.

Core dimensions of personality pathology

Andrew E. Skodol and Leslie C. Morey

Introduction

For no realm of psychopathology has a categorical approach to classification and diagnosis proved more wanting than for personality pathology. A meta-analytic review of 177 studies with a combined sample of over 500,000 participants on the latent structure of various types of psychopathology [1] found little persuasive evidence for the existence of taxa (categories) for any of the personality disorders (PDs) classified by the DSM, with the possible exception of schizotypal personality disorder (STPD). Further, in a 2007 survey of PD experts, 87% believed that personality pathology was dimensional in nature [2]. Although the definition of PD categories by explicit diagnostic criteria since DSM-III has had beneficial effects in documenting substantial prevalence in community and clinical populations, high rates of associated social and occupational impairment, and a more chronic course for other mental disorders co-occurring with PDs, the approach embodied by the DSMs has also been fraught with problems. These include extensive co-occurrence of PDs, considerable heterogeneity within PD categories, arbitrary diagnostic thresholds without empirical bases, temporal instability, limited validity and clinical utility, and incomplete coverage of the full range of personality pathology [3]. Dimensional models of personality pathology have been proposed since the publication of DSM-III as alternative representations of PDs [4], with the goal of rectifying some of these problems. Debate and controversy over the best dimensional representations of personality pathology have played out over the past three or more decades, but considerable consensus exists now about fundamental core dimensions.

In this chapter, we will review the core *personality trait* domains underlying psychopathology in general, and personality pathology specifically. We will describe the core dimensions of *personality functioning* that can distinguish between personality styles and PDs and between PDs and other types of psychopathology. We will then review the development and longitudinal course, the impact on health and psychosocial functioning, and the clinical utility of core personality dimensions. Finally, we will illustrate how traditional PD subtypes can be rendered in terms of domains and facets of personality functioning and of personality traits in a 'hybrid' dimensional-categorical model.

Personality domains and the meta-structure of psychopathology

Co-occurrence of categorical mental disorders is very common in clinical populations and in the community, because certain types of signs, symptoms, and personality traits tend to vary together. This co-variation has led to attempts to understand the organization of psychopathology by identifying fundamental dimensions of psychopathology that undergird groups of disorders using factor analyses of disorders and their manifestations. Two broad dimensions, or 'spectra', of psychopathology, called *internalizing* and *externalizing*, have been identified that encompass a large number of non-psychotic mental disorders [5]. The process of internalizing involves the expression of mental problems by negative feelings and behaviours directed at oneself and includes symptoms of depression and anxiety, for example; externalizing involves the expression of such problems by negative feelings and behaviours directed at other people or things in one's environment and includes symptoms of aggression, defiance, and violence. A third broad spectrum of psychopathology has been identified that includes schizophrenia and other psychotic disorders and bipolar I disorder, and has been referred to as a *thought disorder* spectrum [6]. These spectra are fundamentally dimensional in nature, because a person can exhibit more or less internalizing, externalizing, or disordered thinking, rather than an 'all or nothing', 'present or absent' (that is, categorical) expression. Spectra also represent general, consistent tendencies or proclivities to think, feel, and act in certain ways, and thus reflect personality dispositions, that is, 'enduring patterns of perceiving, relating to, and thinking about the environment and oneself that are exhibited in a wide range of social and personal contexts' [7, p. 647].

Disorders within these three broad domains have been shown to not only co-occur, but also to share genetic, environmental, and temperamental risk factors, exhibit common cognitive and emotional processing abnormalities, and respond to similar treatments, even though they are assigned to different diagnostic classes in DSM-5. A classification of mental problems based on empirical associations can include both symptoms—relatively transient forms of psychopathology—and maladaptive personality traits that are thought to form the stable core of many mental disorders. Thus, personality trait domains can be viewed as the dimensional underpinnings of the meta-structure of psychopathology in general.

An extensive literature shows that personality constructs are organized empirically into 3–5 broad domains [8]. According to the most widely studied five-factor model (FFM) of personality, these domains are labelled as neuroticism (a tendency to be depressed, anxious, and stress-reactive), agreeableness (oriented towards empathy and getting along with other people), extraversion (a disposition to be outgoing, friendly, and emotionally positive), openness (a tendency to be curious and imaginative and to try new things), and conscientiousness (a tendency to be orderly and achievement-oriented). These domains organize both normal and abnormal personality [9], because normal- and abnormal-range personality variations are continuous with each other and there is no compelling evidence that they differ in kind, as opposed to degree [10]. In working to systematically introduce an empirically based trait assessment into DSM-5, the DSM-5 Personality and Personality Disorders (P&PD) Work Group developed a model that was consistent with the well-established FFM but was an extension that specifically delineated and encompassed the more extreme and maladaptive personality variants necessary to capture the maladaptive personality dispositions of people with PDs [11]. Although the Work Group's model was not placed in Section II 'Diagnostic criteria and codes' of DSM-5, it appears as an 'alternative' dimensional–categorical model of PDs in Section III 'Emerging measures and models'.

The alternative DSM-5 model of personality disorders (AMPD) describes personality pathology in terms of five broad trait domains, within the internalizing, externalizing, and thought disorder spectra. The domains and their definitions are as follows [7, pp. 779–81]:

1. *Negative affectivity*: frequent and intense experiences of high levels of a wide range of negative emotions (for example, anxiety, depression, guilt/shame, worry, anger, etc.) and their behavioural (for example, self-harm) and interpersonal (for example, dependency) manifestations.
2. *Detachment*: avoidance of socio-emotional experience, including both withdrawal from interpersonal interactions (ranging from casual, daily interactions to friendships to intimate relationships) and restricted affective experience and expression, particularly limited hedonic capacity.
3. *Antagonism*: behaviours that put the individual at odds with other people, including an exaggerated sense of self-importance and a concomitant expectation of special treatment, as well as a callous antipathy towards others, encompassing both unawareness of others' needs and feelings and a readiness to use others in the service of self-enhancement.
4. *Disinhibition*: orientation towards immediate gratification, leading to impulsive behaviour driven by current thoughts, feelings, and external stimuli, without regard for past learning or consideration of future consequences.
5. *Psychoticism*: exhibiting a wide range of culturally incongruent, odd, eccentric, or unusual behaviours and cognitions, including both thought process (for example, perception, dissociation) and content (for example, beliefs).

The personality trait domain of negative affectivity is the personality component of the internalizing spectrum of psychopathology. The trait domains of disinhibition and antagonism are the components of the externalizing spectrum. The trait domain of

psychoticism is the component of the thought disorder spectrum. A trait domain of detachment corresponding to a spectrum of pathological introversion has been found in many studies of the structure of mental disorders that have included PDs and/or pathological personality traits [12–14].

The most recent description of the PD proposal for ICD-11 also incorporates a personality trait domain schema for describing the variation in PD presentations [15]. The five trait domains included are negative affectivity, detachment, dissocial, disinhibition, and anankastic. Three of these domains are identical to the AMPD model, and dissocial corresponds closely with the AMPD antagonism domain, leaving the only difference between AMPD psychoticism and ICD-11 anankastic trait domains. The AMPD includes psychoticism to represent STPD traits in the model, and other structural studies have found that DSM-IV cluster A PDs load positively onto the thought disorder spectrum. Since STPD is not classified as a PD in ICD-11, psychoticism may be less necessary to capture the full range of PD in the ICD. Unlike the ICD-11 proposal, the AMPD conceptualizes anankastic (obsessive–compulsive) personality traits as the opposite pole of disinhibition (that is, low levels), although some empirical studies of the AMPD have suggested that it might potentially be better characterized as an independent dimension as in the ICD proposal [16]. Nonetheless, the clear similarity in these two independently developed approaches to the classification of PD speaks further to the consensus around the dimensional structure of pathological personality.

A number of researchers (for example, [8, 17]) have suggested that PD traits might be best represented as an integrative hierarchy, with broad dimensions of personality situated at the top of this hierarchy and specific trait constructs described at lower levels—with these lower-level constructs providing important bridges between personality pathology and syndromal disorders. Thus, each of the five broad trait domains of the AMPD includes from three to six more specific component trait facets. The trait facets and their definitions, used for the formulation of specific PDs according to the AMPD, can be found in DSM-5 [7, pp. 779–81].

PDs vary in their manifestations and complexity. Some PDs are related to internalizing mental disorders, such as depressive or anxiety disorders, because they are characterized primarily by traits of negative affectivity, for example depressivity or anxiousness. Dependent personality disorder (DPD) is an example of a PD within the internalizing spectrum of psychopathology. Some PDs are related to externalizing disorders, such as disruptive, impulse control, and conduct disorders or substance use disorders, because they are characterized by traits of disinhibition, for example impulsivity or risk-taking, and/or of antagonism, for example callousness, deceitfulness, or grandiosity. Antisocial personality disorder (ASPD) is an example of a PD within the externalizing spectrum of psychopathology. Some PDs are related to psychotic disorders and are characterized by traits of psychoticism, for example cognitive/perceptual dysregulation or unusual beliefs and experiences, with STPD as an example. Finally, some PDs represent constellations of broad domains; borderline personality disorder (BPD) has both internalizing and externalizing characteristics, and avoidant personality disorder (AVPD) is characterized by a combination of internalizing and detachment.

Appreciation of the relationship of pathological personality trait domains with the meta-structure of psychopathology in general makes the ubiquitous phenomenon of mental disorder comorbidity

understandable. Because symptom disorders and PDs share underlying predispositions, certain patterns of co-occurrence of categorical disorders can be expected to be observed more often than others. To represent psychopathology as co-occurring disorders when some more fundamental process is operative, however, obscures the search for aetiology and pathophysiology and complicates treatment selection [18].

Core dimensions of personality functioning

Since the same personality trait domains underlie both symptom disorders—such as depressive, anxiety, disruptive behaviour, and psychotic disorders—and PDs, core aspects of personality pathology that would distinguish PDs from other types of pathology, as well as from non-pathological personality ‘styles’, need to be identified. A PD is defined by general criteria in Section II of DSM-5 as an ‘enduring pattern of inner experience and behaviour that deviates markedly from the expectations of the individual’s culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment’ [7, p. 645]. The patterns are said to manifest in two or more of the following areas: *cognition, affectivity, interpersonal functioning, and impulse control*. Because these features are not specific to PDs and may characterize other chronic mental disorders, the DSM-5 Section III AMPD includes a more specific set of general criteria with which to define and identify PDs. According to this empirically derived model, PDs are characterized by *impairments in personality functioning*, including core functions of identity, self-direction, empathy, and intimacy, in combination with the presence of pathological personality traits [7, p. 761]. Impairment in personality functioning occurs on a continuum of severity, and greater severity of impairment in these core functions is proposed to both distinguish PDs from other types of psychopathology and from normal personality functioning. Given the presence of such impairment, various configurations of pathological personality traits can describe the myriad manifestations in the presentations of personality pathology.

The history of the study of personality is replete with classification models that are unitary, dimensional severity models [19]. From Sir Francis Galton’s model of ‘good and bad temper’, through James Cowles Prichard’s concept of ‘moral insanity’ and theorists such as Piaget, Erikson, and Loevinger, many personality-oriented writers emphasized a single developmental continuum over which individuals could vary, based on a principle of maturation that reflected greater (or lesser) degrees of self-control and prosocial behaviour. Along similar lines, Kernberg’s construct of ‘personality organization’ represents a classification of character pathology arrayed along a severity continuum, with a realistic and stable sense of identity and of the experience of others reflecting the healthy end of this continuum. In fact, the significance of a severity gradient in evaluating personality problems has been described for far longer than PD categories themselves. Even according to the FFM, which posits that these personality factors are largely independent of each other, different DSM PDs consistently have been shown to exhibit quite similar profiles, consisting of high neuroticism, low agreeableness, and low conscientiousness [20].

In a literature review of clinician-administered measures for assessing personality functioning performed for the DSM-5 P&PD

Work Group, Bender *et al.* [21] found that global measures of personality pathology all referenced fundamental impairments in self and interpersonal functioning—impairments that exist on a continuum of severity, can be measured reliably, and have considerable clinical utility in determining the type and degree of personality pathology, planning treatment interventions, and anticipating treatment course and outcome. To capture this severity continuum, a 5-point scale of impairment in personality functioning, ranging from little or none (0) to some (1), moderate (2), severe (3), and extreme (4) impairment and consisting of a global rating of self (identity and self-direction) and interpersonal (empathy and intimacy) functioning—the Level of Personality Functioning Scale (LPFS)—was developed. It was tested in secondary data analyses in over 2000 patients and community members, and the construct was found to relate to the probability of receiving any PD diagnosis and the total number of DSM-IV PD features manifested, as well as the probability of receiving two or more PD diagnoses as determined by semi-structured diagnostic interviews [22]. A subsequent study [23] determined that a clinician rating of ‘2 (moderate)’ impairment in personality functioning on the LPFS identified clinician-diagnosed DSM-IV PDs with solid sensitivity (0.846) and specificity (0.727), a cut-point which was incorporated into the DSM-5 AMPD’s general criteria for a PD. This severity continuum is designed to capture the variation between PDs (which may, on average, vary in the degree of impairment typically present), but also the heterogeneity within PD categories (where some manifestations of a specific PD may be more severe than others), and to be sensitive to change. The DSM-5 AMPD definitions of the core self and interpersonal functions are as follows [7, p. 762].

Self

1. *Identity*: experience of oneself as unique, with clear boundaries between self and others; stability of self-esteem and accuracy of self-appraisal; capacity for, and ability to regulate, a range of emotional experience.
2. *Self-direction*: pursuit of coherent and meaningful short-term and life goals; utilization of constructive and prosocial internal standards of behaviour; ability to self-reflect productively.

Interpersonal

3. *Empathy*: comprehension and appreciation of others’ experiences and motivations; tolerance of differing perspectives; understanding the effects of own behaviour on others.
4. *Intimacy*: depth and duration of connection with others; desire and capacity for closeness; mutuality of regard reflected in interpersonal behaviour.

The ICD-11 PD proposal also includes a dimensional personality pathology severity measure as its centrepiece. The scale would distinguish personality difficulty (not a disorder) from mild, moderate, and severe PD. The ICD-11 scale is to be based on interpersonal functioning only, without a self functioning component. However, recent research has demonstrated that self pathology adds incremental validity over interpersonal pathology in predicting overall severity of personality pathology [24], suggesting that the AMPD approach to characterizing severity may ultimately prove to be more valid.

In addition to clinician-rated measures (reviewed in [21]), self-report instruments to assess personality functioning also emphasize a self–other perspective. For example, the Severity Indices of Personality Problems (SIPP) [25] measures five domains of personality functioning: identity integration, self-control, relational functioning, social concordance, and responsibility. The General Assessment of Personality Disorder (GAPD) [24] measures self-pathology linked to failures in the development of an integrated self system or structure, and interpersonal pathology linked to failures in the capacity for intimacy, attachment, and co-operative behaviour.

Development and longitudinal course

Temperament can be viewed as personality traits that are present very early in life and appear to have biological origins. One widely studied model of childhood temperament is a three-factor model that includes negative affectivity, extraversion/surgency, and effortful control [26]. These personality trait domains are structurally, hierarchically, and developmentally related to the FFM domains described previously, in that neuroticism and negative affectivity and extraversion and extraversion/surgency are analogous constructs, conscientiousness and agreeableness develop from effortful control, and openness develops from extraversion [5]. So some continuity between basic temperament and personality trait domains seems likely, though relationships remain to be established through more longitudinal research.

Traditionally, personality pathology has not been assessed or diagnosed in children or young adolescents for a variety of reasons—personality was considered to be in flux; some immature attitudes and behaviours are developmentally appropriate, and diagnosis could be stigmatizing. DSM-5 Section II describes the onset of PDs as ‘traced back to at least adolescence or early adulthood’ and the course to be ‘stable and of long duration’ [7, p. 647]. However, other than ASPD, which has a minimum age of 18 years, PDs according to DSM-5 can be diagnosed in children or adolescents if an ‘individual’s particular maladaptive personality *traits* [italics added] appear to be pervasive, persistent, and unlikely to be limited to a particular developmental stage’ [7, p. 647]. Most mental disorders have an onset in some form in childhood or adolescence, and homotypic and heterotypic continuity characterize the course of psychopathology across the lifespan [27].

Dimensional approaches to conceptualization and measurement of pathological personality in children are being developed. A model including emotional instability, introversion, compulsivity, and disagreeableness has been proposed [28]. Child clinical researchers often advocate for assessing adolescents for personality pathology, and some have specifically endorsed the DSM-5 AMPD as an approach preferable to the standard categorical approach [29, 30]. The structure of four of the five AMPD trait domains—negative affectivity, detachment, antagonism, and disinhibition—has been replicated many times in adolescents. In addition to a trait dimensional approach, incorporation of a self–other dimension to distinguish personality from PD has been endorsed, in order to better understand the processes involved in the development of personality pathology [30]. Social adaptation and emotional regulation depend on the presence of a realistic and stable sense of self, and gratifying,

supportive, and maturation-promoting interpersonal relationships depend on accurate perceptions of others.

The context in which a young person’s personality develops is critical. Children and young adults are at increased risk for developing personality pathology if they have experienced physical, sexual, or verbal abuse or neglect in childhood. The personality profiles of mistreated children are characterized by high neuroticism, low agreeableness, low conscientiousness, and low openness to experience—a profile of maladaptive personality very similar to that reflecting PD in adulthood—which tend to persist [31]. Child and adolescent psychopathology of other types, such as depressive, anxiety, and disruptive behaviour disorders, have been shown in longitudinal studies to predispose to the development of personality pathology in adolescents and young adults. Even according to the categorical approach to the diagnosis of personality pathology in children, research has shown that although rates of PD features decrease over time, children who report higher rates are more likely to have PDs in young adulthood and to suffer from a host of other mental disorders and psychosocial problems. Thus, the identification of personality pathology in children and adolescents presents an opportunity for early intervention to prevent future adverse consequences.

Certain critical developmental periods are implicated in the genesis of personality pathology. Abnormal attachment to a primary caregiver, due to either separation or poor parenting, has been observed. Disrupted attachment early in life is likely to lead to impairments in emotional regulation and self-control [32]. Temperamentally high stress-reactivity in a child may itself contribute to problematic attachment. In adolescence, the development of a stable identity or sense of self is a major task and, when delayed or impeded, may lead to the development of personality pathology. In early adulthood, transitions such as leaving home, becoming economically self-sufficient, and being intimately involved with people outside of the family of origin are important developmental tasks. As a consequence, personality pathology often becomes evident when young people attempt these transitions.

Traditional PD diagnostic criteria have poor face validity in later life, because they often refer to occupational or interpersonal activities that may no longer be relevant to older adults. The few longitudinal studies of PDs over the lifespan suggest a drop in PD prevalence in older adults, but it is not known how much this finding is dependent on inapplicable criteria. Some argue that personality traits are generally stable across age, with slight decreases in (FFM) neuroticism, extraversion, and openness, and slight increases in agreeableness and conscientiousness. Trait expression in later life might, however, be a function not only of underlying neurobiology, but also of different (from youth) contextual factors varying over the lifespan. Thus, the degree of social, physical, occupational, or economic stress experienced by an individual over time may determine how stable or unstable personality appears [30].

Dimensional approaches to the conceptualization of personality pathology are appropriate for the study of development and longitudinal course, since change is a matter of degree and behaviours, such as excessive dependency or obstinacy, that are developmentally appropriate at certain ages but become inappropriate at other ages. Viewed developmentally, personality pathology may be considered a manifestation of delayed or obstructed development [33]. Recent rigorous prospective longitudinal studies have shown that PDs are much less stable over time than are implied in the traditional DSM

conceptualization [34, 35]. However, certain features of PD are more stable than others [36], perhaps because the severity of core personality pathology can fluctuate over time, related to situational or contextual factors, while the basic personality trait structure for any given individual may be more stable. Most studies of personality traits have shown that they change gradually over the lifespan until individuals reach the age of 50 [37]. In a clinical population, the stability of personality traits, as measured by the FFM (normal) or Schedule for Nonadaptive and Adaptive Personality (SNAP) (normal and pathological) models, was significantly higher than the stability of DSM-IV PD symptoms (that is, criteria) over 10 years of follow-up, suggesting that, from a longitudinal perspective, 'traits reflect basic tendencies that are stable and pervasive across situations, whereas ... [PD] symptoms reflect characteristic maladaptations that are a function of both basic tendencies and environmental dynamics' [38]. DSM-5 AMPD personality traits have been shown to be highly stable, to be prospectively predictive of psychosocial functioning, and to be dynamically associated with functioning over time [39]. In the Collaborative Longitudinal Personality Study (CLPS) sample, general PD features representing 'disorder' severity exhibited less stability than specific features representing 'style', consistent with the notion that personality functioning is the more dynamic and changeable aspect of personality pathology, while personality traits are stable [40].

Impact on health and psychosocial functioning

Physical health

PDs are known to have associations with a wide range of physical health disorders. In the National Epidemiological Survey on Alcohol and Related Conditions (NESARC), PDs within clusters A, B, and C were associated with multiple physical conditions, including cardiovascular disease, arthritis, diabetes, and gastrointestinal conditions [41]. The occurrence of physical disorders with a wide range of PDs suggests common underlying factors (that is, core dimensions) at work. From a review of population-based studies in England, Wales, Scotland, Western Europe, Norway, Australia, and the United States, Quirk and colleagues [42] concluded that the bulk of evidence supports associations between PDs from clusters A and B and cardiovascular disease and arthritis. As a result, PDs increase health care utilization, particularly in primary care. Individuals with PD have reduced life expectancy [43], with all-cause mortality predicted by alcohol and drug abuse, physical illness, and functional impairment [44].

Considerable evidence indicates that broad personality trait domains, such as neuroticism (that is, negative affectivity), adversely affect physical health and the quality and longevity of life [45]. In recent years, neuroticism has been found to be associated with asthma [46], obesity [47], Alzheimer's disease [48], and coronary heart disease [49]. Low conscientiousness (that is, disinhibition) has been found to increase the risk of diabetes [50] and risk of death [51].

The trait domain of conscientiousness appears to be protective against a number of physical conditions, possibly related to a more favourable inflammatory profile [52]. A meta-personality factor of 'stability', consisting of high conscientiousness, high agreeableness, and low neuroticism is associated with reduced cardiometabolic

risk, an association that was mediated by inflammation, autonomic function, and physical activity [53]. Lower-order FFM personality trait facets of straightforwardness, self-discipline, altruism, compliance, tender-mindedness, and openness to fantasy are associated with increases in life survival time [54].

Psychosocial functioning

All PDs, by definition, are maladaptive and accompanied by functional problems in school or at work, in social relationships, or at leisure. The requirement for impairment in psychosocial functioning is codified in DSM-5 Section II in its criterion C of the general diagnostic criteria for a PD, which states that 'the enduring pattern [of inner experience and behaviour, that is, personality] leads to clinically significant distress or impairment in social, occupational, or other important areas of functioning' [7, p. 646].

A number of studies have compared patients with PDs to those with no PD or with DSM-IV axis I disorders and have found that patients with PDs were more likely to be functionally impaired [55]. Specifically, they are more likely to be separated, divorced, or never married and to have had more unemployment, frequent job changes, or periods of disability. Fewer studies have examined quality of functioning, but in those that have, poorer social functioning or interpersonal relationships and poorer work functioning or occupational achievement and satisfaction have been found among patients with PDs than with other disorders. When patients with different PDs were compared with each other on levels of functional impairment, those with severe PDs, such as STPD and BPD, were found to have significantly more impairment at work, in social relationships, and at leisure than patients with less severe PDs, such as obsessive-compulsive personality disorder (OCPD), or with an impairing other mental disorder such as major depressive disorder (MDD) without PD. Patients with AVPD had intermediate levels of impairment.

Another important aspect of the impairment in functioning in patients with PDs is that it tends to be persistent, even beyond apparent improvement in PD psychopathology itself [34, 56]. The persistence of impairment is understandable if one considers that PD psychopathology has usually been long-standing and therefore has disrupted a person's work and social development over a period of time [57]. The 'scars' or residua of personality pathology take time to heal or be overcome. With time (and treatment), however, improvements in functioning can occur [35].

DSM-5 Section III criteria for PDs in the AMPD do not include a requirement for impairment in psychosocial functioning. This change is in keeping with some other disorders in DSM-5, which attempted to separate the manifestations of a disorder (that is, signs, symptoms, traits) from their consequences (that is, impact on occupational, social, and leisure functioning). Furthermore, Section III PDs all include specific impairments in *personality functioning* at a moderate level or greater. This change is consistent with the distinction between mental *functions* (for example, emotional regulation, reward dependence, reality testing) that lead to *symptoms* and the *disabilities* that accompany disturbances in these functions [58].

Interpersonal problems are probably most characteristic of people with PDs [59, 60], which, coupled with problems in the sense of self, are captured by the Section III LPFS and the A criteria for the six specific PDs and personality disorder–trait specified (PD-TS). Each of the six PDs has characteristic problems with empathy and intimacy, reflecting fundamental abnormalities in social cognition [61].

People with ASPD deceive and intimidate others for personal gain. Lacking in 'emotional empathy', they have no concern for the feelings of others and fail to express remorse if they hurt someone. In the area of intimacy, they are incapable of having mutually intimate relationships, as they exploit others or control them. Patients with histrionic personality disorder (HPD) and narcissistic personality disorder (NPD) need to be the centre of attention and require excessive admiration. Intimate relationships are generally shallow, and people are sought out primarily to bolster self-esteem. Empathic concerns centre on issues that have direct implications for the person with the PD.

Patients with OCPD have difficulties appreciating others' perspectives and need to control them and to have them submit to their ways of doing things. Intimacy is circumscribed by stubbornness and rigidity and a preference for engaging in tasks, rather than pursuing close relationships.

The interpersonal relationships of patients with AVPD and DPD are impoverished as a result of fear and submissiveness, respectively. Patients with AVPD are inhibited in interpersonal relationships because they are afraid of being shamed or ridiculed. Empathy is impaired because of a distorted sense of others' appraisal and an acute sensitivity to rejection. Patients with DPD will not disagree with important others for fear of losing their support or approval and will actually do things that are unpleasant, demeaning, or self-defeating in order to receive nurturance from them. With the self-sacrificing approach to relationships, real intimacy and empathy are elusive.

The empathy of patients with BPD is distorted and typically biased towards the negative tendencies and vulnerabilities of others. Intimate relationships are extremely challenging, with a pattern of becoming 'deeply' involved and dependent only to turn manipulative and demanding when their needs are not met. They have interpersonal relationships that are unstable and conflicted, and they alternate between over-involvement with others and withdrawal from them.

The degree of detachment associated with patients with paranoid PD, schizoid PD, and STPD serves as a pronounced impediment to empathy and intimacy in interpersonal relationships. Patients with schizoid PD manifest an apparent lack of need for closeness with others; people with paranoid PD do not trust others enough to become deeply involved; and patients with STPD have few friends or confidants, in part due to a lack of trust and in part as a result of poor communication and inadequate relatedness.

In addition to these core personality functions, personality traits have been found to predict concurrent and prospective function in psychiatric patients [62], with some specificity across different traits. Within the FFM traits, neuroticism was broadly related to impairment across the domains of social, occupational, and recreational functioning. Extraversion (low) was primarily related to social and recreational dysfunction, openness (low) to recreational dysfunction, agreeableness (low) to social dysfunction, and conscientiousness (low) to work dysfunction. Ro and Clark [63] compared adaptive-range traits to non-adaptive range traits in patient and non-patient samples and found that psychosocial functioning and personality traits were closely linked, particularly in patients. General well-being was negatively associated with neuroticism/negative affectivity and positively associated with extraversion/positive affectivity; social/interpersonal functioning was associated with dis/agreeableness and with conscientiousness/disinhibition,

and basic functioning was associated with conscientiousness/disinhibition.

Simms and Calabrese [64] found that Section III pathological personality traits incrementally predicted psychosocial impairment over normal-range personality traits, PD criteria counts, and common psychiatric symptoms. In contrast, the incremental effects of normal traits, PD criteria counts, and common symptoms were substantially smaller than for pathological personality traits. In the CLPS follow-along [65], PD criteria counts were strongly associated with impairment in psychosocial functioning at intake (more strongly than categorical PD diagnoses), but this relationship diminished over time. The best predictors longitudinally of impairment were models that combined normative traits and maladaptive variables (that is, the SNAP model or a model composed of a DSM-IV PD criteria count and FFM domains). At 6-, 8-, and 10-year follow-ups, the SNAP continued to be the most predictive and DSM PD criteria and FFM domains tended to provide substantial incremental validity to one another, supporting a hybrid model [66]. Also, in the CLPS sample, general PD features representing 'disorder' severity were more strongly related to psychosocial functioning concurrently and prospectively than specific features representing personality 'style' [40].

Clinical utility

In the official DSM-5 Field Trials, clinicians were asked to rate the usefulness of tested diagnostic criteria for all disorders. In both the Academic Centers and the Routine Clinical Practice Field Trials [67], the Section III PD model was rated as 'moderately', 'very', or 'extremely' useful by over 80% of clinicians. In the Academic Centers trial, more clinicians rated the Section III model as 'very' or 'extremely' useful, compared to DSM-IV than all disorders, except somatic symptom disorders and feeding and eating disorders. In the Routine Clinical Practice trial, the Section III model was more often rated as 'very' or 'extremely' useful, compared to DSM-IV than all disorders, except neurocognitive disorders and substance use and addictive disorders. In a separate investigation, Morey and colleagues [68] asked clinicians to rate the perceived utility of the proposed DSM-5 rendering of personality pathology, compared to DSM-IV. Questions addressed ease of use and usefulness for communication, patient description, and treatment planning. Although the clinicians were much more familiar with DSM-IV PDs, they rated all DSM-5 components generally as 'useful' or 'more useful' than DSM-IV for clinical description and treatment planning. Other than in ease of use and communication with other professionals, the LPFS was rated by clinicians as more useful than DSM-IV for patient description, communicating with patients about their problems, and treatment planning. Furthermore, the DSM-5 pathological trait system was rated by both psychiatrists and psychologists as easier to use and more useful for communication with other clinicians and with patients, for patient description, and for planning treatment than the DSM-IV conceptualization.

In addition to perceived utility, self interpersonal problems, such as insecure attachment and maladaptive schemas, have been shown to be associated significantly with PD psychopathology and impairments in psychosocial functioning, as well as to affect clinical outcome [3]. Self-other dimensions have discriminated different

types of PD pathology, predicted various areas of psychosocial functioning, and have shown to be moderators of treatment alliance and outcome. In the Morey and colleagues' survey [23], the single-item LPFS rating predicted variance in clinician ratings of psychosocial functioning, prognosis, and treatment needs over and above that predicted by all ten DSM-IV PD diagnoses combined (that is, diagnoses based on 79 total criteria).

In addition to the independent utility of pathological personality traits and of personality functioning in identifying and describing personality pathology and in planning and predicting the outcome of treatment, a number of recent studies support a model of personality psychopathology that specifically combines ratings of disorder and trait constructs. Each has been shown to add incremental value to the other in predicting important antecedent (for example, family history, history of child abuse), concurrent (for example, functional impairment, medication use), and predictive (for example, functioning, hospitalization, suicide attempts) variables [65, 66, 69, 70].

Dimensions and personality disorder subtypes

Each of the 'official' DSM-5 PDs can be characterized by specific impairments in personality functioning and by pathological personality traits in one or more of the DSM-5 trait domains of negative affectivity, detachment, antagonism, disinhibition, and psychoticism. Some of the simpler PDs have traits in only one domain. DPD can be described by three traits in the negative affectivity domain: submissiveness, separation insecurity, and anxiousness. Schizoid PD can be described by four traits in the detachment domain: withdrawal, intimacy avoidance, anhedonia, and restricted affectivity. Some of the more complex PDs have traits in more than one domain. Complexity in clinical presentation is also reflected by the common co-occurrence of categorical PDs with each other and with other mental disorders. Co-occurring disorders frequently, though not always, come from the same psychopathological spectrum or trait domain.

The DSM-5 alternative model includes six specific PDs—ASPD, AVPD, BPD, NPD, OCPD, and STPD—selected because of their empirical bases or their utility for clinicians [71, 72]. All PDs are required to have at least moderate impairment in personality functioning, according to the DSM-5 AMPD, because a moderate level of impairment has been empirically shown to identify PDs with maximal combined sensitivity and specificity.

PD trait domain and facet assignments were made on the basis of existing meta-analyses of FFM/PD relationships [73–75], with corroboration from data provided by clinicians that were gathered to inform the process [76]. In analyses of 33 data sets, O'Connor [73] found that DPD, AVPD, and BPD had high loadings on a factor resembling FFM neuroticism; antisocial, NPD, paranoid PD, and HPD loaded on a factor of low agreeableness; schizoid PD, STPD, AVPD, paranoid PD, and HPD (a negative loading) loaded on low extraversion, and OCPD loaded on conscientiousness. In terms of the DSM-5 trait model, these four factors would be represented by negative affectivity, antagonism, detachment, and low disinhibition, respectively.

In Morey and colleagues' study [76], ASPD was associated with traits from the antagonism and disinhibition domains. All seven traits assigned for the diagnosis of ASPD (four from the antagonism

domain and three from the disinhibition domain) had higher correlations with ASPD than any of the remaining traits in the AMPD model. STPD was associated with traits almost exclusively in the psychoticism and detachment domains, and again all six assigned traits had higher correlations with STPD than any of the other traits. BPD showed generally elevated trait associations across the negative affectivity domain, with the highest correlation being with emotional lability. Significant correlations were also found for risk-taking and impulsivity from the disinhibition domain. The two traits assigned to NPD—grandiosity and attention seeking—both had high correlations with the diagnosis. In addition, there were significant correlations with other traits from the antagonism domain such as callousness, manipulativeness, and deceitfulness. These traits of so-called 'malignant narcissism' were not assigned to NPD because to do so resulted in extensive overlap between the diagnoses of NPD and ASPD. Since reducing PD comorbidity was a goal of the AMPD, these traits were included as diagnostic 'specifiers' to be listed when warranted. OCPD had significant correlations with traits from different domains. The four highest correlated traits were assigned. AVPD had significant correlations with anxiousness from negative affectivity and several traits from the detachment domain, which were assigned. For each AMPD-specific disorder, except for STPD, it was shown that clinician ratings on the criterion A impairments in personality functioning significantly incremented the assigned traits in predicting a DSM-IV PD diagnosis, supporting the validity of the AMPD personality functioning and personality trait hybrid dimensional-categorical model.

Each PD also had a diagnostic algorithm for the trait ('B' criterion) developed from the Morey survey [77], consisting of a minimum number of assigned traits and, in some cases, a particular configuration of traits. The algorithm was developed to simultaneously maximize correspondence with DSM-IV PD diagnoses (to be minimally disruptive to clinical practice and research), to minimize overlap with other PD diagnoses (to reduce comorbidity), and to maximize relationships with functional impairment (to increase validity). The algorithms were successful in rendering DSM-IV PD diagnoses according to personality functioning impairments and pathological personality traits, with very good fidelity (correlations between DSM-IV and AMPD dimensional criteria counts for ASPD = 0.80; BPD = 0.80; AVPD = 0.77; NPD = 0.74; STPD = 0.60; OCPD = 0.57). The algorithm for the A criterion for specific PDs according to the alternative model of 'characteristic difficulties in any two of four areas' (that is, identity, self-direction, empathy, or intimacy) was found to be associated with the greatest combined sensitivity and specificity across the six specific PDs in the AMPD [77].

According to the AMPD, the other four official PDs in DSM-5, as well as any other PD presentations that would be diagnosed as 'other specified personality disorder' in DSM-5 Section II, may be diagnosed as PD-TS. Both the specific level of impairment (that is, moderate, severe, or extreme) and the specific pathological personality traits that describe the person would be noted.

Conclusions

The classification and diagnosis of personality pathology has been slowly, but inexorably, moving from a categorical to a dimensional model. A dimensional model better reflects the phenomena of

personality pathology, which are continuous in nature, and better describes the degrees of difference from normal personality and the degrees of severity. Core personality dimensions can represent the features that distinguish PDs both from normal personality functioning and from other forms of psychopathology, as well as the myriad manifestations of PD. A general consensus is that the personality trait structure of PD converges on a five-factor model of broad trait domains, with each factor composed of more narrow trait facets. The DSM-5 alternative model for PDs comprises an LPFS to identify PD and its severity and five trait domains of negative affectivity, detachment, antagonism, disinhibition, and psychoticism—the first four of which represent the pathological poles of the five factors of the five-factor model of normal personality—and their component trait facets. Personality traits and personality functioning variables will undoubtedly be more closely related than traditional categories to basic physiological and psychological processes underlying personality pathology. Personality traits and personality functioning have been shown to be associated with physical health problems and impaired psychosocial functioning, to guide treatment planning, and to predict a host of important outcomes. Clinicians find dimensional models more clinically useful than categorical models, despite their newness and unfamiliarity. The future for research and treatment of personality pathology lies in its dimensional conceptualization.

Basic mechanisms of, and treatment planning/targets for, personality disorders

Kate E. A. Saunders and Steve Pearce

Introduction

Personality disorders are a group of disorders characterized by a pervasive set of feelings and behaviours that impair an individual's ability to function. Even when standardized approaches are employed by highly trained clinicians, the consistency of diagnosis between different clinicians is highly variable [1]. Many commentators argue that this is inevitable because current diagnostic classifications are fundamentally flawed; their explanation is that personality dysfunction is a continuum and comorbidity between the different classes is ubiquitous [2]. This debate is not unique to personality disorder, and there is increasingly a move away from observational approaches to a more integrated approach where multiple sources of information are assimilated to better understand the basic dimensions of functioning underlying the full range of human behaviour, from normal to abnormal [3]. For personality disorder, this tension between dimensional and categorical approaches to diagnosis, in combination with the dominant role of psychoanalytic and behavioural models in treatment development, has resulted in a relative paucity of research into underlying neurobiology, cognitive psychology, or physiology. As a result, evidence-based treatment targets are few and based upon a small number of studies. The interpretation of the existing literature is limited by the internal heterogeneity of each specific personality disorder, a lack of consistency in the approach to diagnosis, axis I and II comorbidity, female gender bias, small sample sizes, and cross-sectional approaches. Borderline personality disorder (BPD) has been the focus of the majority of research in personality disorder, although there is some literature on antisocial personality disorder (ASPD) and schizotypal personality disorder (SPD). Studies of other personality disorders are too few in number to draw any firm conclusions about the mechanisms or treatment targets. In this chapter, we will review the current evidence for the basic mechanisms for personality disorder, relevant to treatment development, as well as review what current treatments reveal about potential treatment targets.

Neurobiologic targets

The neurobiology of personality disorder is poorly understood, and it seems unlikely that any of the disorders relate to the impairment of a single neurotransmitter system. This may, in part, relate to the inherent heterogeneity of personality disorder diagnoses, but also to the fact that the disorders emerge as a result of biological vulnerability in combination with environmental influences. However, the underlying neurobiology does provide useful insights into how/why personality disorders develop, and targeting specific neurotransmitter systems may lead to symptomatic relief and enhance the efficacy of existing psychological treatments. Biological approaches are widely used in the treatment of personality disorder, and there is evidence to support the role of a number of neurotransmitter systems.

Serotonergic system

There is considerable evidence implicating serotonin in personality disorder. Serotonin regulates amygdala hyperreactivity in BPD, thought to be a central neurobiological correlate of affective instability [4]. It has been proposed that the imbalance between prefrontal and limbic responsivity may relate to impaired serotonergic facilitation of top-down control [5]. Polymorphisms in the genes for the 5-HT₂ receptor, tryptophan hydroxylase, and the serotonin transport promoter are all found to be associated with BPD [6, 7], although these findings have not been replicated. However, there is more convincing evidence that gene-environment interactions are of greater relevance, with some studies suggesting that these genes mediate the impact of exposure to childhood trauma in BPD [8, 9]. The serotonin transporter gene is also associated with ASPD [10], and methylation of this gene has been shown to mediate the impact of childhood sexual abuse in ASPD [11]. Variants of monoamine oxidase (MAO), which metabolizes dopamine and serotonin, are also thought to have a role in the development of antisocial traits and again are implicated in outcomes following adverse events in childhood [12]. Positron emission tomography (PET) studies indicate that there is reduced serotonin transporter availability in

the prefrontal cortex in BPD, compared with healthy controls [13]. Blunted hormonal responses to serotonergic agonists, such as fenfluramine and meta-chlorpiperazine, have been observed in BPD [14, 15], and this blunting is associated with impulsivity, anger, and self-harm, but not the social or affective components of the disorder. Increased impulse aggression has also been shown to be associated with reduced prolactin release in response to fenfluramine in obsessive-compulsive personality disorder (OCPD) [16]. These findings are consistent with preclinical studies where reductions in serotonergic activity are found to be associated with aggression [17]. Fluoxetine (a selective serotonin reuptake inhibitor) has been shown to increase the metabolic rate in the orbitofrontal cortex and to significantly improve symptoms in individuals with aggressive-impulsive personalities [18].

Despite there being considerable evidence for a role of the serotonergic system in personality disorder, there is no convincing evidence that treatment with serotonergic drugs is associated with significant or sustained improvement in symptom profiles in clinical trials [19]. This may relate to a lack of serotonin receptor specificity (impulsivity is associated with 5-HT_{2a}, not 5-HT_{2c}, antagonism), the complexity of the interactions between different receptor systems associated with behavioural outcomes, and the need for targeting specific brain regions [20].

Dopaminergic system

The dopamine system has been a target of interest in SPD because of its similarity to psychotic disorders. SPD has been found to be associated with the catechol-*O*-methyltransferase enzyme (COMT), the D₄ receptor, and dopamine beta-hydroxylase genes. Decreased dopaminergic activity in the prefrontal cortex has been observed, but there appears to be evidence of compensatory activation in other regions, such as the striatum, suggesting that individuals with SPD may have greater buffering of subcortical dopaminergic activity than that found in those with schizophrenia [21, 22]. Homovanillic acid, a proxy for dopamine levels in the brain, has been found to be elevated in both plasma [23] and the cerebrospinal fluid (CSF) [24] in SPD. SPD is associated with enhanced dopamine release in response to amphetamine [25], and both amphetamine and pergolide have been shown to improve cognitive performance [26, 27].

Use of drugs for psychosis in personality disorder is widespread [28, 29]. In a recent systematic review of their use in SPD, there was little evidence found to support it [30]. In BPD, one meta-analysis concluded that dopamine antagonists were associated with worsening of symptom severity [19]. However, there is some evidence supporting reductions in symptom severity in BPD associated with olanzapine [31, 32], quetiapine [33], and aripiprazole [34]. Ziprasidone has not proved to be efficacious in BPD, despite having a similar pharmacological profile to aripiprazole [35].

Oxytocin

Given the centrality of interpersonal dysfunction to all personality disorders, and particularly BPD, there has been an increasing focus on oxytocin, a prosocial neuropeptide. The precise mechanism by which oxytocin exerts this effect is unknown, but there is substantial evidence in non-clinical groups that it promotes empathy, trust, and social reward [36]. There is some evidence to support the moderating role of alleles of the oxytocin receptor (*OXTR*) coding

gene in the development of BPD symptoms, following childhood adversity [37]. There is also evidence that methylation of *OXTR* genes occurs rapidly after exposure to stress [38], suggesting that oxytocin may play a role in enhanced stress sensitivity found in BPD. Reduced CSF and serum oxytocin levels have been found to be associated with BPD symptoms [39]; however, these findings are not specific to BPD. It may therefore be oversimplistic to consider BPD as a disorder uniquely characterized by low oxytocin levels. Studies of the impact of oxytocin in BPD indicate that while it downregulates stress responses to social threat [40], it is not associated with increased non-verbal affiliative behaviour observed in healthy controls [41]. In another study, BPD subjects given intranasal oxytocin were found to show less co-operative behaviour while playing the assurance game (a variant of the classic prisoner's dilemma) and described higher levels of attachment anxiety [42]. Striepens *et al.* have proposed a paradoxical effect of oxytocin in BPD; while oxytocin may downregulate amygdala reactivity to aversive stimuli [43], it may also increase insular responses to negative stimuli, enhancing the defensive impact of negative social cues [44]. It could be that individuals with BPD experience the prosocial effects of oxytocin as aversive, given the association of the insula with the processing of complex negative emotions.

Given the conflicting evidence about the effects of oxytocin in BPD, its role in treatment remains unclear. However, all studies to date have used single doses of oxytocin and explored the possibility that BPD may be associated with dysfunctional oxytocin regulation or that the prosocial effects of oxytocin may heighten entrenched anxieties and fears about trust and attachment. Despite these uncertainties, oxytocin represents a potential treatment for the core dysfunction in BPD. Some authors have suggested that oxytocin may facilitate the learning of new relational strategies in combination with psychological interventions [42], while others have proposed that it may allow the intergenerational cycle of dysfunction to be broken [36].

Opioids

Brain opioids play an important role in mediating the social impact of isolation and exclusion [45]. There is evidence to support the dysfunction of the endogenous opioid system (EOS) in both BPD [46] and ASPD [47], and it has been proposed that reduced EOS activity may underpin the chronic dysphoria associated with BPD [48]. It has also been suggested that self-harm represents an unconscious drive to increase EOS activity [48]. PET studies showed evidence of mu-opioid receptor binding dysfunction [46], and lower levels of endogenous opioids have been reported in the CSF of individuals with BPD [49]. To date, there have been no randomized controlled trials of opioid antagonists, but a small number of open-label studies [50, 51] in BPD suggested that targeting the EOS may be a potential treatment strategy.

The glutamatergic system has been proposed as a potential treatment target, given the role of *N*-methyl-*D*-aspartate (NMDA) in mediating a range of psychiatric symptoms and on the basis that excessive glutamatergic activity contributes to hypersensitivity of the limbic system associated with BPD [52]. There is little direct evidence directly linking personality disorders with glutamatergic dysfunction, but a randomized trial of an NMDA receptor antagonist in BPD is ongoing [53].

Symptom-based targets

Factor analysis of the diagnostic criteria for borderline personality disorder has consistently revealed three factors: affective dysregulation, behavioural dysregulation, and interpersonal disturbances.

Mood instability

Affective dysregulation has long been viewed as the core source of dysfunction in BPD. Recent technological developments enabling prospective real-time monitoring have confirmed this observation [54]. Although mood instability is common in other mental disorders, the high temporal frequency and characteristics observed in BPD appear to be distinct and specific to the disorder [54, 55]. Some of the most consistent neuroanatomical findings in BPD are those of reduced volumes in the amygdala, hippocampus, orbitofrontal cortex, and anterior cingulate cortex [56, 57]. These are all areas of the brain involved in emotional regulation. Multiple studies revealed decreased activation in prefrontal areas in response to emotional stimuli, suggesting that top-down emotional control may be impaired [58]. Psychophysiological studies also indicate abnormal emotional regulation in BPD [59]. Mood regulation forms one of the central components of a number of psychotherapies, and there is some limited evidence that existing treatments may reduce mood instability, although this is limited to single-study estimates of effect [60]. Specific emotion regulation training has not been found to be effective, although this may relate to short study duration [61]. While mood instability is often used as an outcome measure in trials of treatments for BPD, few studies have employed objective longitudinal measurement of mood; rather mood instability has been assessed using one-off questionnaires and items from the Structured Clinical Interview for DSM-IV Axis II personality disorders (SCID-II). Mood instability remains an important treatment target, and there is a need for large, high-quality studies using objective longitudinal measures of mood.

Interpersonal disturbance

Social dysfunction is a prominent and pervasive feature in BPD. Impairments in social functioning are well documented in BPD and persist despite remission of other symptoms, both in children who meet criteria for borderline pathology [62] and in adults [63].

Interpersonal difficulties have been linked to impairments in decoding social signals, such as facial expressions [64], and deeper problems with trusting the motives and behaviours of others [65, 66]. Individuals with BPD appeared to lack the capacity to sustain mutually beneficial interactions with playing partners in an investment-trust game [67] and showed patterns of reduced co-operation when compared to those with bipolar disorder or healthy controls in an iterated prisoner's dilemma game [68]. In this latter study, trait aggression, hostility, and impulsivity were not found to account for the failure to co-operate; instead it was proposed that in BPD, the experience of co-operation may not be coded or experienced as rewarding and consequently cannot provide a basis for sustained future co-operation. However, in real life, decisions rarely involve interactions with one individual. To date, no one has systematically studied the responses of individuals with BPD in a group context or which factors are most influential. Given that almost all

current treatment modalities involve group treatments, enhancing our understanding of group behaviour may assist in identifying potential specific treatment targets relating to social function.

Behavioural disturbance

Behavioural disturbance is common to all personality disorders but has been most widely studied in BPD and ASPD. Reactive aggression has been consistently described in ASPD and is associated with dysfunctional representation of the cost of aggressive behaviour and the failure of inhibitory mechanisms in response to the distress of the victim [69]. In BPD, prefrontal activation is diminished, when compared to non-aggressive healthy controls, and there is evidence of decoupling of orbitofrontal-amygdala responses in BPD, suggesting a failure of top-down control leading to more rapid escalation of angry responses to angry faces [70]. However, these findings are not specific to personality disorders, and to date, interventions specifically directly targeting aggression have been unsuccessful.

What can we learn from effective treatments?

While there is evidence for pharmacological targets in personality disorders, the rationale for the use of medications is largely based on observed symptom control, although this is not supported by any randomized controlled trials of adequate size, observational data are poor, and studies have generally been limited by short treatment duration and inadequate follow-up time. The one independent randomized trial of a reasonable size found no beneficial effect in the use of lamotrigine in BPD [71].

In contrast, there are a wide range of psychosocial interventions that appear to be effective, in particular in BPD. The majority of randomized studies have follow-up periods of <2 years, a drawback in the treatment of trait-based disorders. Of the three studies with longer follow-ups, only mentalization-based treatment (MBT) has demonstrated a robust effect [72]. This is a small study and the nature of the intervention is unclear [73], consisting of 5-days-per-week day hospital treatment and employing a range of interventions [74]. This result may mirror Antonsen *et al.*'s [75] finding at 6-year follow-up of a superior outcome for patients with BPD who participated in day hospital treatment, when compared to a group receiving individual therapy. A 6-year follow-up of cognitive behavioural therapy (CBT) for BPD gave mixed results [76].

Authors of the psychosocial treatments that appeared to have a beneficial effect in BPD proposed a variety of mechanisms which underpin their efficacy (Table 118.1).

The wide range of therapeutic targets is likely to be a result of the complex nature of BPD, involving a wide range of high-level functions, but may also reflect the lack of current knowledge of the active elements in effective therapies and the heterogenous nature of the population.

In ASPD, the evidence is too weak to support any specific treatment targets [95]. In cluster C conditions, exposure and behavioural experimentation have been proposed as the mechanism of action of CBT and the development of emotional insight in short-term psychodynamic psychotherapy (STPP) [96].

In addition to authors' assumption/models, other themes are emerging from the existing evidence base. The majority of successful treatments involve groups (all except individual schema-focused therapy (SFT), transference-focused psychotherapy (TFP), STPP, and cognitive analytic therapy) [97]. Group membership promotes

Table 118.1 Treatment targets/mechanisms of successful psychological treatments for BPD

Treatment target/mechanism	Therapy
Addressing underlying schema/cognitive distortions	SFT and CBT-PD address unhelpful cognitive schema explicitly, and 'loving kindness/self compassion' techniques are also likely to challenge putative schema [77]
Mentalizing capacity deficits/reflective function	MBT and DTC encourage mentalizing/reflective function explicitly, while SCM incorporates elements of the MBT theory, and TFP has been found to have a beneficial impact on reflective function [78]
Emotional regulation skills deficits	DBT and STEPPS incorporate group-based emotional skills sessions, which, in DBT, are then practised and reinforced in one-to-one sessions and telephone support. Mindfulness comprises an additional emotional regulation skill taught in DBT, although its applicability as a stand-alone intervention in personality disorder is not established [79]
Psychoeducation	Psychoeducation overlaps with emotional skills training, but in addition, STEPPS explicitly incorporates education on the nature of BPD, an approach that is also showing promise using the Internet [80]
Identifying recurring behavioural and emotional themes and patterns	STPP, DBT, and DTC all target problematic and recurrent behavioural and emotional patterns in order to explore their meaning (STPP and DTC) and encourage the development of alternative strategies (DTC and DBT)
Case management	Nidotherapy [81] and SCM both provide this as a core part of the intervention, but it is probably active in most of the approaches discussed here
Encouraging emotional expression and addressing emotional avoidance	A number of the models recognize the tendency of individuals with personality disorder to avoid strong emotions. STPP, DTC, MBT, and DDP all explicitly encourage the idea that this is an unhelpful coping strategy and encourage alternative ways of dealing with distress
Resolution of past trauma/construction of coherent narrative, development of emotional insight	Individuals with personality disorder have often experienced adverse events in childhood, and narrative reconstruction is a part of all exploratory approaches to personality disorder, including DTC, STPP, CAT, DDP, TFP, and SFT [82]
Social function and belongingness	Improvement in social function is probably targeted in all group-based approaches but has been specifically addressed in PEPS (although with disappointing results [83]) and interpersonal group psychotherapy [84]. Belongingness arises from frequent and positive contact with others and has a range of benefits [85], and is also likely to be active, to an extent, in group approaches but has been specifically identified in DTC
Deficiencies in responsible agency	Agency is the main therapeutic target in MI, and it is also targeted in DTC and MBT

SFT, schema-focused therapy [86]; MBT, mentalization-based therapy [72]; SCM, structured clinical management [87]; DTC, democratic therapeutic community [88]; DBT, dialectical behaviour therapy [89]; STEPPS, systems training for emotional predictability and problem solving [90]; STPP, short-term psychodynamic psychotherapy [91]; PEPS, psychoeducation with problem-solving [83]; MI, motivational interviewing [92]; DDP, dynamic deconstructive psychotherapy [93]; TFP, transference-focused psychotherapy [78]; CAT, cognitive analytic therapy [94].

social learning and a sense of belongingness, and there is evidence that this is associated with more prosocial behaviour in experimental settings [98]. Many interventions improve self-efficacy and responsible agency (the concept that individuals are motivated to change,

feel that they have the power to do so, and wish to exert this power to effect change). This is likely to be related to empowerment—an internal locus of control, knowledge of how to respond, and a sense of having something to offer to others. This is a particularly prominent element of democratic therapeutic communities (DTCs) where it is facilitated by support systems and member–member mentoring. All interventions probably improve social function when clinicians are empathic and reasonably skilled, but attempts to teach social problem-solving have proved disappointing [83]. Clinician attitude and faith in the model is likely to be an important ingredient in the success of any treatment [87].

Treatment strategies can also be derived from ineffective interventions. Crisis planning and motivational interviewing are too brief to be effective [99]. Failure of emotional regulation training to have any impact in adolescents with BPD may also relate to the brevity of the intervention [61]. Similarly, brief CBT seems not to help in people with personality dysfunction after self-harm [100].

The apparent effectiveness of a range of complex interventions illustrates the need for dismantling studies. The only approach in which this has been attempted to date is dialectical behaviour therapy (DBT) where Linehan *et al.* [89] found that skills training plus case management (DBT-S) showed significant advantages over DBT individual therapy plus activities group, whereas the full DBT programme was not clearly superior to DBT-S, indicating that group-based skills training constitutes an essential part of the DBT intervention and may represent the active element. Similarly, Soler *et al.* [101] found DBT skills training superior to standard group therapy. The apparent effectiveness of Systems Training for Emotional Predictability and Problem Solving (STEPPS) [90], a 20-week CBT programme that bears similarities to DBT skills training groups, provides further evidence to support this conclusion.

It has been proposed that the effectiveness of therapies for personality disorder relates to non-specific factors that all therapies share. While there are considerable overlaps between therapies, it is unlikely that this is a valid explanation, given the heterogeneity of approach and the fact that some studies have been able to differentiate between psychotherapies (for example, [102]). Nevertheless, the use of control conditions that incorporate non-specific factors such as case management and skills groups produces improvements in the control arm of trials, thus narrowing the gap with the active conditions both in trials that were still able to demonstrate some superiority for the active condition (in MBT [103] and TFP [104]) and in those that were not (in DBT [105] and cognitive analytic therapy [106]).

Future directions

Current neuroscientific evidence supported by the theoretical underpinnings of successful psychotherapeutic interventions converge on social functioning and mood regulation as key treatment targets in personality disorder, and specifically in BPD. Current treatments may be more efficacious than they appear, but the heterogeneity of the recruited samples and poor choices of outcome measures have created too much noise for much signal to be detected. Trans-diagnostic approaches may prove more informative, given the heterogeneity of presentations within each specific personality disorder and the extent of comorbidity.

Treatment outcome trials have suffered from a number of methodological flaws which limit their usefulness, and further research is required to address these. In trials of medication, most studies have suffered from being small and funded by drug companies and having short follow-ups. Although follow-up periods have, on the whole, been longer for psychosocial interventions, long-term follow-up over 5 years remains the exception; to date, there have been no published multi-centre trials, and randomized studies have not yet been carried out for cluster A disorders and are rare for cluster C disorders (although some studies have looked at all three clusters [88, 107]). The current uncertainty over the effectiveness of psychosocial interventions for personality disorders stems also from the small numbers enrolled in studies to date for all interventions other than DBT. Finally, the active elements of effective complex interventions will need to be investigated through dismantling and component studies [108].

To date, there are no animal models of personality disorder or an experimental medicine model against which to test new treatments, and there is no consensus on outcome measures in personality disorder research [109]. Developments in mobile and wearable technologies should be exploited in the development of new treatments and objective markers of treatment success.

Personality disorders

Epidemiology and clinical course

Renato D. Alarcón and Brian A. Palmer

Introduction

The conceptual, clinical, and nosological debates about personality disorders (PDs) as psychiatric entities reflect both the complexity of the diagnoses and the fragility of the agreements arrived at in different classification systems [1, 2]. Among the reasons, the absence of common or homogenous phenomenological and psychopathological bases for the different PD types, the multiple clinical variations or subtypes among the individual conditions, profuse comorbidity levels, and uncertain outcomes are frequently mentioned [3, 4]. Additionally, a relatively reduced prevalence of PDs in the general population, when compared with 'major' psychiatric disorders, leads to relatively scarce (and, at times, questionable) epidemiological data and to a colourful, but heterogenous, clinical course. On the other hand, the same debates and their many implications represent the growing relevance of PDs, not only as more or less permanent distortions of individual identities, but also as repositories of genetic, epigenetic, environmental, and socio-cultural factors in the construction of such identities [3–5]. Thanks to the rapidly developing field of molecular genetics, PD phenotypes may assist in better aetio-pathogenic, and therefore diagnostic, and epidemiological estimates [6]. Furthermore, in many modern approaches to the delineation of PDs, basic personality features or traits and personality functioning levels are the departure point of thorough and comprehensive clinical evaluations [7]. Different statistical methods and procedures (from multi-dimensional scaling to factor analysis through correlational analyses, to cite a few) assist in the structuring of PDs and the controversial acceptance of their three superordinate clusters in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5).

Historically, the maladaptive variants of normal personality traits, grouped in the well-known Five-Factor Model [8], provide a particularly compelling tool for the identification and assessment of the 11 DSM-IV's axis II PDs, still present in DSM-5 [1]; in spite of the unevenness of studies about these factors (many more on neuroticism and extraversion than on openness, agreeableness, and conscientiousness related to former axis I disorders) [9], it is clear that personality can decisively influence much broader

psychopathologies and, secondarily, epidemiological, follow-up, and outcome inquiries. Intrapersonal and interpersonal manifestations of PDs differ, and informant reports may be more valid than self-reports in both clinical evaluations and prevalence surveys, adding another important methodological layer to research in both areas. Higher-order internalizing and externalizing structural factors in different psychopathologies were correlated with 30 latent personality facets in a study by Uliaszek and Zinbarg [10]. An elevation of the neuroticism facets, along with low positive emotions, low actions, and low competence, was found for the higher-order internalizing factor entities (that is, major depression), whereas the higher-order externalizing ones were negatively associated with most conscientiousness and agreeableness factors and with an elevation of excitement-seeking impulsivity and angry hostility. These findings constitute a call for active search of PDs in different types of studies, epidemiological surveys included. In turn, environmental characteristics (including interpersonal transactions such as perceived discrimination) must be assessed in every type of study, as they have shown to be a main social pathway which, in addition to biological and developmental routes, is crucial for the establishment of the adult personality type and its detection and prognosis [11–12].

This section will examine, first, general epidemiological data on PDs through studies from different regions of the world, following immediately with studies on the prevalence and incidence of each of the PD types identified in the main world nomenclatures. Emphasis on the role and significance of socio-demographic variables, family history, and relevant comorbidities will precede the clinical course subsection, similarly focused on each PD type, with and without treatment, on pertinent risk and protective factors, and on their short- and long-term prognostic implications. Topics such as relapses and chronicity patterns will also be examined.

Methodological issues

The considerable heterogeneity and poor discriminant validity of DSM's PDs impede accurate diagnoses and therefore can make epidemiological findings questionable. Yun *et al.* [13] proposed

alternative assessment tools such as Kernberg's object relational model [14], on the basis of which develops a finite mixture modelling that harboured three components: Group 1, characterized by low levels of antisocial, paranoid, and aggressive features; Group 2, by elevated paranoid features; and Group 3, with the highest levels across the three variables. Various external measures supported the validity of this grouping structure, thus offering a substantive aid in refining PD classification and conferring additional solidity to prevalence, incidence, and clinical course studies.

Different clinical populations have been used in attempts to delineate more precisely normal personality types and actual PDs. This helps to consider pathogenic circumstances, that is, situations that contribute to the evolution of actual psychopathologies. For instance, coping styles (relevant personality-based features) and treatment preferences were evaluated by Contractor *et al.* [15] in 1266 trauma-exposed military veterans (89.6% male). The results were revealing: (1) post-traumatic stress disorder (PTSD)-free and emotionally stable probands were less likely to use self-distraction, denial, and substance consumption, and more likely to use active coping; (2) those less emotionally stable and with more re-experiencing and avoidance symptoms were less likely to use denial and active coping, but more likely to use behavioural disengagement; (3) those with subsyndromal PTSD were more likely to use self-distraction, active coping, and substance use, but less likely denial, instrumental coping, positive reframing, and acceptance; and (4) those with severe PTSD and combined internalizing-externalizing traits responded similarly to (3), but also used more substances, more denial, more emotional support, and less active coping. Interestingly, emotional stability was the most distinguishing feature, and all classes were more likely to seek mental health treatment.

Similarly, the assessment of personality traits becomes an important parameter for psychological evaluations among persons seeking cosmetic surgery. In a study from Iran, Golshani *et al.* [16], using three well-validated instruments, evaluated 274 randomly selected individuals seeking rhinoplasty, blepharoplasty, face/jaw implant, mammoplasty, and liposuction; a prevalence of 51% of psychiatric problems was found, with interpersonal sensitivity as the highest syndrome-like endorsed (the lowest, psychosis), and agreeableness and extroversion as the highest scored features (the lowest, openness).

Sexual problems (hypersexuality, excitation, and inhibition) constitute another area of discussions and studies of this kind. Rettenberger *et al.* [17] investigated the impact of different personality traits on data provided by two instruments in a sample of 1749 participants in an Internet-based survey. Six per cent of the probands were categorized as hypersexual, irrespective of gender and sexual orientation. Among male recidivist offenders, Barbosa *et al.* [18], based on the signal detection theory, evaluated sensitivity to emotional arousal and valence induced by pictures; offenders reported higher arousal than controls and showed lower sensitivity to changes in levels of arousal, but no differences vis-à-vis controls for valence. This modality of research broadens the narrow typological taxonomy and allows indirect, but valid, assessment of PDs in special populations.

Finally, issues such as reality-testing, developmental phases of the life cycle, and traumatic experiences make prevalence and incidence studies of PDs a difficult enterprise. The associations between PDs and other conditions have shown different degrees of consistency

when epidemiologically assessed by established nomenclature classifications. It can be said that the pervasive and relatively inflexible pattern of behaviours that reflect the individual's predominant mode of being is, in itself, a formidable challenge for epidemiological, field, and clinical studies.

General epidemiology

The instruments used in epidemiological studies of personality and other disorders are a critical component of this area of knowledge. In addition to the questionnaires used in the first historical studies, a multitude of instruments reflecting different modalities of conceptualization (categorical and dimensional, and among the latter, interpersonal, clinical, bio-psychological, etc.) have been developed. Names of authors such as Goldberg, Fonagy, Widiger, Costa and McCrae, Cloninger, Millon, Gunderson, Livesley, Silver and Davies, Oldham and Skodol, Krueger, and Clark provide a sound historical background for this field of inquiry [3].

There is some variability in the estimation of general prevalence of PDs in the general population. Torgersen *et al.* [19] examined the issue in depth, identifying different components of any epidemiological search (that is, sample selection) that impact the final estimates. In eight prevalence studies including all PDs and covering a total of 5081 persons, with >500 as the average sample size, the findings ranked between 3.9% and 22.7%, but in small samples, the variation was smaller between 10.0% and 14.3%. The median prevalence of all studies was 11.55%, and the pooled prevalence 12.26% [20]. These data are consistent with the major large, representative national epidemiological studies, including those from Great Britain [21], which estimated an overall prevalence of 10.1%, and the US National Comorbidity Survey Replication [22] with a rate of 9.1%.

Prevalence data

Grant *et al.*'s analysis of the National Epidemiological Survey on Alcohol and Related Conditions (NESARC) [23] presented nationally representative data (from a sample of 43,093 subjects) on the prevalence, socio-demographic correlates, and disability of seven of the ten DSM-IV PDs; overall, 14.8% of adult Americans (or 30.8 million) had at least one personality disorder. Another report of the same study found rates of PDs at the high end of previously published ranges (21.5% overall) [24]. Test-retest reliabilities between wave 1 (2001–2002) and wave 2 data (2004–2005), using the Alcohol Use Disorder and Associated Disabilities Interview Schedule-IV (AUDADIS-IV) were, however, low for some types [that is, 0.40 for histrionic PD (HPD)] [25]. Some have criticized the diagnostic approach, as the study required only one of the identified PD symptoms to have an association with distress or impairment. A re-analysis of the data that required an association with distress or impairment for *each* of the symptoms used to make the PD diagnosis [for example, five of nine borderline personality disorder (BPD) symptoms] yielded rates more in keeping with other samples (9.1%) [26].

As expected, prevalence figures increased up to 50% in studies conducted within specific clinical settings [20]. Widiger and Rojas [27] pointed out that the prevalence of PDs is generally underestimated in clinical practice due, in part, to the previously mentioned deficiencies in a comprehensive clinical assessment of the

corresponding symptomatology. Moreover, Beckwith *et al.* [28] conducted a systematic literature review of studies measuring the prevalence of PDs in community secondary care settings and identified only nine out of 269 papers deserving critical appraisal; they showed a high level of heterogeneity with regard to methods, inclusion criteria, source of information, times of assessment, instruments used, and overall quality of research. Prevalence estimates in Europe varied between 40% and 92%, showed a closer range (45–51%) in the United States, and differed significantly in two Asian studies (1.07% in India and 60% in Pakistan). The low prevalence in India confirmed a previous finding by Gupta and Mattoo [29], but once again, weak methodology (case records study) may have generated questionable results.

Socio-demographic variables

It is generally accepted that the prevalence rates are higher in urban populations and in lower socio-economic groups. Gender is probably the most controversial topic in this area. Some studies concluded that the prevalence levels of PDs in men and women are roughly equivalent, with some disorders more frequently present in each gender, whereas others seemed to indicate that only one type (borderline) is more prevalent among women. A variety of recommendations to reduce and avoid sampling, assessment, and criteria biases have been made. The differential socialization and life experiences of males and females have been used to explain the differences in personality and PDs between males' and females' innate behavioural tendencies, without excluding neurobiological (particularly physiological and endocrinological) factors. Nevertheless, the general agreement is that more than one in ten adult individuals has a PD. The average prevalence of specific PDs is a little above 1%, with variations per type. It is also important to remark that these correlations neither display one-directional causal relationships nor account for the total nature and characteristics of the individual's interpersonal experiences [30].

According to DSM-5 [1], features of a PD must have been present for at least 1 year if the diagnosis is to be made before age 18. Apparently, individuals with odd/eccentric PDs are older, and the dramatic/emotional trait dimensions decrease with age [19]. Subjects with PDs have more often been separated, unmarried, or divorced, even though there is agreement in that the real effect of marital status on PD occurrence is difficult to determine. Similarly, the trend of a negative correlation between PD prevalence and educational and income status is not uniformly agreed upon. Urban location seems more often linked to PDs, with subsequent lower quality of life and higher dysfunctional level [31]. Last, but not least, the few studies on PDs and ethnicity show methodological weaknesses, as analysed by McGilloway *et al.* [32]. Meta-analyses revealed significant differences in prevalence of PDs between black and white groups, but no differences between Asian or Hispanic groups compared with white groups; these heterogeneous results may be accounted for by methodological characteristics, ranging from a true lower prevalence among black patients to a clear neglect of PD diagnoses among other ethnic groups.

Risk and protective factors

We have touched also on risk and protective factors as important variables in the clinical evolution of PDs and their epidemiological correlates. While the genetic load seems to be unquestionable,

particularly, for example, in the DSM-5's Cluster A types [33], epigenetic variations and environmental factors, such as child-rearing issues, intra-family relationships, parental styles, educational milieu, and opportunities or cultural and religious concerns, can play either a risk or a protective role, depending on the kind, orientation, and weight of each in everyday life [4]. Childhood and adolescence are considered critical periods in the developmental cycle of every individual. A balanced use of modelling, independence fostering, decision-making, and social/relational skills will do a lot to favour a normal personality development. Contrariwise, gender-based violence is associated with at least 38% of all PD cases, and women who have experienced it have 8.5 times the odds of PDs, compared to non-victims [34]. Needless to say, the assessment of these factors is decisive in the epidemiological and clinical evaluation of the disorders.

Comorbidities

Another heatedly debated topic is that of the correlation (or coexistence, although some may call it comorbidity) between PDs and other psychiatric conditions—the main point of contention is the cause–effect equation, which is first, and how one can lead into the other. It must be clear that this type of studies does not refer to the clinical setting in which they take place; actually, most of them are community-based projects. A third phase of the NESARC study [23], conducted in 36,309 adults, found significant associations of 12-month and lifetime prevalence of drug use disorders (DUD) with a variety of PDs, including antisocial, avoidant, and borderline. In Denmark, Toftdahl *et al.* [35] found that 46% of 463,003 substance use disorder (SUD) patients had diagnoses of PDs.

A study in France [36] found PDs (independent of clusters) as significant risk factors for generalized anxiety disorder, and Cluster C types for major depressive disorder (MDD), in non-metastatic breast cancer patients. In a population-based 37-year follow-up cohort study of >29,000 Swedish Twin Registry members, Sieurin *et al.* [37] found neuroticism and introversion strongly associated with a risk of Parkinson's disease; smoking was a significant mediator in the relationship between personality traits and Parkinson's disease, partly accounting for the effect of introversion, while being a suppressor for the effect of neuroticism. Higher-than-normal body weight was associated with paranoid, antisocial, and avoidant PDs among women, whereas overweight men had lower rates of paranoid PD (PPD) and underweight women had higher odds of schizoid PD (SPD) [38]. An intriguing finding—among college men with purging-type eating disorders, symptoms were associated with constellations of personality traits that are typically reported among women [39]. The obvious conclusion is that, in general, PDs are highly associated with a variety of disabilities in different periods of the life cycle.

Thus, it is evident that personality and its temperamental and characterological components are always in the background of normal and ill people; among the latter, early and precise identification of such features is crucial as they can contribute, in many cases, to increased levels of severity and to a complicated clinical course of the comorbid condition. Of interest, the trait model of personality pathology in DSM-5 Section III [1] has been successfully applied to problematic alcohol use cases, with antagonism and disinhibition as the most relevant domains. It has been suggested that throughout life, higher coercion experiences are associated

with lower understanding and lower reasoning which, in turn, decrease the social engagement of individuals with severe PDs [40]. On the other hand, the course of PDs themselves will depend on the timing and scope of the professional intervention. In general, an early diagnosis and appropriate therapeutic interventions can certainly be effective, improve the patient's quality of life, and disrupt the chronicity pathway characteristic of untreated conditions; the pattern is similar in the case of comorbid medical or psychiatric pictures.

Special epidemiology, comorbidities, and clinical course

Primarily referred to data about each of the more or less established PDs in modern psychiatry, special epidemiology integrates concomitant issues such as comorbidities and risk and protective factors. At the same time, it offers much needed information for the formulation and understanding of the clinical course, prognosis, and outcomes of each of the disorders [41, 42]. **Tables 119.1 and 119.2** summarize the information from this and the previous section.

Paranoid personality disorder

Prevalence

Although distrust and suspiciousness, with subsequent misinterpretation of others' behaviours, may be present in 13% of adult males and 6% of females [8], the actual DSM-5 criteria for PPD seem to be met only by a population range of between 0.4% and 4.4%, according to a variety of prevalence studies [1], with a median rate of 1.6% [27]. In inpatient clinical settings, the range may increase to 10–30%, while in ambulatory services, it may oscillate between 2% and 10%. It may be worth mentioning that some studies show a 0% prevalence of PPD, which raises several of the questions examined in previous pages.

Table 119.1 Main epidemiological data about personality disorders

PD type	Prevalence range (%)	Avg community (%)	Clinical settings (%)
All	3.9–22.7	11.6	40.0–51.0
Paranoid	0.4–4.4	1.6	Inpt 10–30; outpt 2–10
Schizoid	0.4–4.9	0.6	Inpt 16
Schizotypal	0.1–5.6	0.8	Inpt 2–20
Antisocial	0.2–4.5	1.3	Outpt 3–30
Borderline	0.2–5.9	1.7	Inpt 20; Outpt 6.0
Histrionic	0.3–3.9	1.6	Outpt 10–15
Narcissistic	0.1–1.5	0.5	Outpt 6.2

Comorbidities

It has been demonstrated that the phenomenological structure of PPD can share some of its features with the other Cluster A types, all of Cluster B's, and Cluster C's avoidant PD (AvPD). The clinician must have a clear perspective about the global nature of the trait combinations, that is, the distinction between the affective distance and eccentricity of the schizoid or avoidant PD's fear of being ashamed or overwhelmed vs the hypervigilance or suspiciousness of PPD. Conversely, a careful evaluation must be pursued to rule out predictable 'paranoid-like' behaviours in members of immigrant, ethnic, or political groups.

Other forms of psychopathology may occur simultaneously (or more frequently) in individuals with PPD: psychotic conditions such as delusional disorder, schizophrenia, depressive and manic episodes, alcohol and substance dependence and abuse, criminal behaviours, and obsessive–compulsive, agoraphobic, and depressive disorders [43, 44].

Clinical course

During childhood and early adolescence, PPD features such as hypersensitivity, social anxiety, low school performance, and poor peer relationships can elicit bullying from other children, thus accentuating paranoid attitudes. Brief psychotic episodes have been reported in connection with stressful situations throughout the life of PPD patients. A consistent employment history is relatively infrequent, mostly due to hyperdefensiveness, litigiousness, and antagonistic, or even violent, behaviour. Last, but not least, clinicians must not forget the premonitory nature of PPD features in patients that later may develop psychoses such as schizophrenia.

Schizoid personality disorder

Prevalence

With two studies showing a 0% prevalence, the range in all the others goes from 0.4% to 4.9% and one study showed 7%, but the median in several tables is around 0.65%. Additional contradictions emerge from the statement that SPD is considered 'uncommon' in clinical settings, at the time that the same source (DSM-5) included prevalence levels of 4.9 and 3.1%, from Part II of the Comorbidity Survey-Replication (CMS-R) and NESARC samples, respectively [1]; in other clinical samples, the prevalence reaches 16%. Similar disagreements exist about the prevalence of SPD by gender [45, 46].

Comorbidities

There is limited documentation of comorbidity between SPD and major psychotic conditions, probably due to difficulties in differentiating the clinical presentations of both kinds of disorders. Actually, some authors have found little or no relationship between SPD and schizophrenia when family history or clinical course were compared. The same occurs in cases of mild autism spectrum disorder that may co-occur with SPD, even though in the majority of cases, the former may be installed earlier than SPD could be detected. These problems multiply when a trait distinction is attempted between SPD and schizotypal and avoidant PDs.

Clinical course

Usually long-lasting, but not necessarily life-long, SPD courses in a more or less 'stable' fashion, seldom exhibiting rapid or profound

Table 119.2 Comorbidities and clinical course of personality disorders

PD types	Main comorbidities	Clinical course
All	Other PDs; alcohol and SUDs; mood and anxiety disorders; eating disorders; medical illnesses	Strong tendency to chronicity
Paranoid	Clusters A and B and AvPD; schizophrenia and other psychoses; bipolar disorder; SUDs; OCD	Bullying victims, pre-psychotic states, unstable employment
Schizoid	Cluster A PDs; mood and phobic disorders; autism spectrum disorder	Marital and relational difficulties; reasonable adaptation
Schizotypal	Cluster A PDs; AvPD and BPD; brief psychotic episode; MDD, OCD, generalized anxiety disorder	More among men; social isolation; 10% suicidal behaviour; marginal employment; no frequent psychoses
Antisocial	Cluster B PDs; PPD; alcohol and SUDs; hypochondriasis; gambling; ADHD	More among men; family dysfunction; unemployment; conduct disorder and law/forensic problems; criminal behaviour; frequent use of medical services; some improvement with ageing
Borderline	MDD, bipolar disorder, PTSD, SUDs, generalized anxiety disorder, and panic disorder	Self-mutilation episodes and suicidal behaviour; 80% remission by 10 years, 40% with high functioning; infrequent relapses, but persistent social and occupational issues
Histrionic	Cluster B PDs and DPD; somatization, conversion and dissociative disorders; brief reactive psychosis	More among women; problems since adolescence; suicidal attempts; occupational fragility; frequent use of medical services; improves with age
Narcissistic	SUDs; anxiety disorders; bipolar disorder; BPD and AsPD	60% improve in 3 years; connection with evolution of comorbidities; prognosis worsens with AsPD
Avoidant	SAD, DPD	Variations in early periods; diagnostic 'stability'; many patients remain single
Dependent	AvPD; anxiety disorders; depressive mood	Few studies; limited reduction of symptoms
Obsessive-compulsive	Anxiety, mood and obsessive-compulsive disorders; Cluster C PDs	More among men; small long-term improvement of core symptoms

changes. This does not mean that patients will not have difficulties in different settings—their more or less severe social ostracism makes them have few close relationships, including sexual partners, and occasionally become homeless. If married and having children, they have limited capacity to provide warm, supportive, or endearing affection. Clinical complications, in addition to possible psychotic occurrences, include mood, phobic, and behavioural disorders. On the other hand, and differing from the other Cluster A PDs, a relatively good number of SPD patients, particularly those with mild manifestations, may reach reasonable levels of social adaptation, work, and quality of life [45].

Schizotypal personality disorder (StPD)

Prevalence

Studies that have found prevalent schizotypal personality disorder (StPD) showed a lowest level of 0.1% and a highest of 5.6% in community populations, with a median of 0.7–0.9%. In clinical populations, prevalence levels of between 2% and 20% have been found, and 14.6% among relatives of schizophrenic patients [46, 47], particularly those with a history of childhood onset and among monozygotic twins. According to Kendler *et al.* [33], StPD most closely reflects the genetic and environmental liability common to all three Cluster A disorders. No gender distinction appears to be unequivocal, but there seems to be more male than female StPD patients.

Comorbidities

About 30% of StPD patients present a comorbid pattern with SPD (with introversion as the common dominant feature), and 60% with PPD (with suspiciousness as the most shared trait). AvPD and BPD

are also frequently encountered in patients with StPD. The joint presence of paranoid, schizotypal, schizoid, and avoidant personalities among first-degree relatives of schizophrenic patients has led to the notion of schizophrenia-spectrum disorder and the identification of such PDs as psychometric high-risk groups [48]. In cases, these patients may be 'in and out' of brief psychotic episodes or present premorbid schizophreniform disorder or schizophrenia. As relevant as this, DSM-5 [1] points out that approximately half of StPD patients experience comorbid MDD and may also show evidence of obsessive-compulsive and generalized anxiety disorders [27].

Clinical course

Like the other Cluster A PDs, StPD patients show their main symptoms (social isolation, esoteric fantasies, peculiar thought, and language and school underachievement) early in childhood or adolescence. As adults, they may join in marginal groups with extreme socio-political or religious views which may increase their sense of alienation and interpersonal deterioration, a factor that can make them reach, according to some studies, up to 10% of suicidal behaviour. They do not seek treatment for their PD, but rather for associated depression, dysphoria, and/or anxiety. Nevertheless, only a minority falls into schizophrenia or other psychotic disorders, and a good number of patients remain marginally employed throughout their active life period [42].

Antisocial personality disorder

Prevalence

One of the two most studied PDs, the prevalence figures of antisocial personality disorder (AsPD) do not escape the levels of debate or disagreement seen in other types, in spite of large-size

studies and more sophisticated evaluation instruments. The highest incidence figures are seen in late adolescence and early adulthood. The range in community samples goes from 0.2% to 4.5%, with a median of between 0.9% and 1.7%, while figures in clinical populations (including prisons or other forensic settings) vary from 3% to 30%. High levels of sensation-seeking and low anxiety sensitivity indicate an increased risk for substance misuse in incarcerated male offenders [49]. In most studies, the role of socio-environmental factors has been elucidated: more often seen in men than in women (rates of 3:1) and among people of younger ages; living in urban, but deprived, areas [ergo, low socio-economic status (SES)]; members of dysfunctional families; and history of trauma, victimization, and neglect during childhood. AsPD patients also have been found to be frequent users of medical services [47]. All-cause mortality is twice as high among those imprisoned [50]. A genetic component is strongly considered by the majority of researchers [6, 33, 42, 51].

Comorbidities

In addition to a relatively frequent co-occurrence of other Cluster B PDs like borderline, narcissistic, and histrionic, AsPD patients show frequent comorbidity with PPD, alcoholism, hypochondriac behaviour, problem-gambling, and depression [42, 52], the latter exhibiting predominantly atypical features. Substance abuse may coexist with AsPD since childhood, and antisocial behaviour may be secondary to premorbid alcoholism; this association relies on underlying dimensions of impulsivity or externalization [53, 54]. Men with attention-deficit/hyperactivity disorder (ADHD) and patterns of use of nicotine, cannabis, and other illicit drugs since early age also show high presence of AsPD [49], and almost 15% of patients on methadone maintenance therapy fulfil the diagnostic criteria [55].

Clinical course

AsPD is probably one of the most complicated and clinically fascinating conditions, even when looking back at the childhood life period of the patients—conduct disorder diagnoses frequently precede AsPD detection by the second decade of life. Children with a history of severe conduct problems and callous-unemotional traits (that is, with limited prosocial emotions) can be identified by their peers as early as their preschool years [56] and are high on fearlessness but, like those on the other extreme of the same scales, may have the same antisocial phenotypic outcome. AsPD cannot be diagnosed before age 18, as its typical behavioural manifestations are most pronounced in early adult years [57]. In addition to serious problems with the law, other sequelae, such as unemployment, poverty, homelessness, risky driving, weapon-carrying, and increasingly brutal actions in and out of numerous and fragile marital relationships [56–58], may end up in a shorter life course. Non-domestic homicide offenders are four times more frequent users of firearms, and twice more likely than spontaneous domestic homicide's to be diagnosed as AsPD [58].

It is possible that AsPD behaviours may either gradually decrease with age in some patients, or a subgroup of them may be able to conduct seemingly acceptable social and occupational lives; thus, reduction or remission of criminal behaviour and decrease of the full spectrum of antisocial postures may occur around the fourth decade of life. On average, 20 years after the diagnosis is made, 12% of the patients are symptom-free, 27% show a notable improvement, but

60% remain unchanged [46]. Interestingly, the appearance of other conditions such as depression or hypochondriasis correlates with abandonment of rage and aggression as interpersonal life strategies, reflecting and fostering personality maturation.

Borderline personality disorder

Prevalence

According to DSM-5, the median population prevalence of BPD is estimated to be 1.6%, but other sources cite a range of 0.2–5.9%. The high end of this range is from the NESARC study [59], which may be inflated by oversampling young adults (prevalence decreases with age), thus requiring less robust associations with impairment. The samples have been more numerous than with any other PDs, and the clinical correlates with a variety of other conditions are abundant. The disorder is significantly more common among females, particularly widowed and unmarried women (though less clearly so in community samples), and its frequency increases in younger, non-white, urban, and poorer respondents. The presence of BPD patients in primary care settings seems to be about 6%, about 10% in outpatient mental health clinics, and 20% in inpatient psychiatric units [60]. A substantial genetic basis, 18–35 years as age of onset, and decreased incidence among older individuals are additional findings.

Comorbidities

BPD is highly comorbid with a number of other disorders. Up to 75% of patients have comorbid major depression [61], and patients with BPD report MDD symptoms that are subjectively more severe and more interpersonally driven [62]. Even though the presence of MDD does not impact the accuracy of the BPD diagnosis, the latter's symptoms are less responsive to treatment with drugs for depression and electroconvulsive therapy (ECT). On the other hand, bipolar disorder is overrepresented in BPD. In two large prospective studies of BPD, bipolar disorder co-occurred in 15–20% of patients [12% bipolar disorder type I (BPI) and 8% bipolar type II (BPPII) in one study [61]; 1% BPI and 14% BPPII in the other [63], though BPI was initially excluded from this second cohort).

PTSD co-occurs with BPD at rates of between 17% and 50%, depending on sample and methodology, whereas BPD is found in 7–25% of people with PTSD [22, 26, 59, 64, 65]. Substance use and anxiety disorders (including panic disorder) are also quite common in BPD (upwards of 50%) and tend to remit when BPD symptoms do [60].

Clinical course

Two large prospective, longitudinal studies inform most of what is known about the course and outcome of BPD. The McLean Study of Adult Development (MSAD), led by Zanarini [63, 66], followed 290 former inpatients for about 20 years; all met rigorous diagnostic criteria for study entry. The second study—the Collaborative Longitudinal Personality Disorders Study (CLPDS)—led by Gunderson [65] was a multi-site, more socio-economically representative inquiry and followed 175 patients with BPD (as well as patients with MDD and other PDs). Both studies demonstrated surprising levels of symptom remission. In fact, by the end of 10 years of follow-up, >80% of each sample no longer met diagnostic criteria. Moreover, when symptomatic remission was achieved, relapse was rare—cumulatively 12% in CLPDS and 15% in the MSAD study. Nonetheless, severe and persistent impairment in social

and occupational functioning remained, with only a third of patients obtaining full-time employment by the end of 10 years and only 40% of previously high-functioning patients regaining that performance level.

Histrionic personality disorder

Prevalence

Within ranges of 0.3–3.9% in general populations (median between 1.5% and 1.8%) and 10–15% in clinical settings, HPD is seen more frequently among women, particularly separated and divorced, but without other socio-demographic differences. This disorder seems to respond more to cultural aetio-pathogenic factors (that is, sex role stereotypes, emotional expressiveness, etc.), while some authors suggest that HPD in women is genotypically linked to AsPD in men [42, 45].

Comorbidities

Overlapping HPD cases and those of other clusters is a relatively frequent occurrence; borderline, narcissistic, and antisocial from Cluster B, and dependent from Cluster C are the most prevalent. As the features of the different disorders can be combined, once again, a clinically sound differential diagnosis must converge with a thorough assessment of authentic comorbidity. The most difficult comparison is with narcissistic personality disorder (NPD) and AsPD. In the former, the main distinction has to do with the narcissist's attention- and superiority-seeking vs the histrionic's inconsistent and dependency-seeking interpersonal transactions; about the latter, although both types show impulsive, manipulative, and seductive behaviours, the histrionic manipulates to capture others' attention and does not necessarily break the law to reach it, whereas the antisocial individual seduces others in search of absolute authoritarian power frequently nourished by illegal manoeuvres.

The evidence in favour of HPD's comorbidity with other psychiatric disorders is greater for somatization, conversion, and dissociative disorders, besides brief reactive psychosis and a few cases of hypomanic and manic states; the episodic nature of these, though, leads to a differential diagnosis more than to a real comorbidity process [45].

Clinical course

Blashfield *et al.* [67] characterized the HPD patient's adolescent period as playful, flamboyant, flirtatious, and attention-seeking. During their early adult life, superficiality, rapidly changing and inconsistent interpersonal patterns, poor sense of responsibility, competitiveness, emotional instability, and suggestibility lead them to, at times, risky or dangerous connections, theatrical and melodramatic explosions, and occupational fragility. Obviously, concomitant borderline and antisocial disorders generate severe levels of personal dysfunctionality. In these and other contexts, depressive symptoms, suicide attempts, and frequent use of medical services are common. Ageing may become a factor of sobering changes in the clinical course of a number of HPD cases.

Narcissistic personality disorder

Prevalence

Perhaps the most debatable and debated PD, with serious considerations of its elimination from DSM-5 due to reasons such as limited

credible research, excessive theoretical/ideological considerations, very low prevalence figures, and more dimensional or trait-related coverage and pertinence [68], NPD is, at best, a rich source of dialectics or a window into the relationship between self-esteem and emotional regulation [69] and, at worst, a questionable clinical disorder. It is the PD with the most 0% prevalence figures in the epidemiological literature (eight of 16), and with levels as low as 0.1% among general populations. It is commonly cited as having a rate of 0.5% [19–21], with a range of up to 4.4% [70] or a surprisingly high 6.2% in the NESARC study [71]. More frequently diagnosed in some female clinical populations, this gender difference becomes irrelevant, however, in most epidemiological inquiries.

Comorbidities

In the NESARC data, NPD was strongly associated with SUD (40% 12-month prevalence, 64% lifetime) and anxiety disorders (40% 12-month prevalence, 55% lifetime) [71]. Rates of NPD in BPI (24% lifetime) and BPI in BPD (20% lifetime) were surprisingly high, perhaps owing to the overlaps in constructs of grandiosity. Given the prevalence data being out of step with most other studies, interpretation or application of these results warrant caution. Finally, NPD can co-occur with other PDs, most commonly BPD. Estimates are that 15% of patients with BPD have NPD, and 25% of patients with NPD have BPD [60].

Clinical course

There are strikingly limited data about the course of NPD. One 3-year prospective study found that 60% of a sample of 20 patients improved over 3 years and that the remaining 40% showed no change; improvement was associated with achievements and new relationships, whereas disillusionments and remaining symptomatology were predicted by high narcissism in interpersonal relationships [72]. Furthermore, NPD worsens the course of comorbid BPD but will improve when BPD symptoms do, and comorbidity with AsPD worsens the prognosis of NPD [60].

Avoidant personality disorder

Prevalence

The clinical expression of an intense sensitivity to rejection and criticism with resulting social isolation, AvPD was first introduced as an independent entity in DSM-III. It is considered the most prevalent PD type in clinical populations, with figures of up to 5.7% in at least one epidemiological study [70], but still above 5% in two other surveys, a rate of 1.7% in general populations [20] and much higher in psychiatric outpatients. Forty-five per cent of people with AvPD are single (never married) [19, 20], but no strong gender differences have been found [73].

Comorbidities

Social anxiety disorder (SAD) is both the most common comorbid condition with AvPD and the most common diagnostic confounder. Co-occurrence with SAD is seen in 40% of patients with AvPD, and in patients with SAD, AvPD can be diagnosed in 46% [74]. Social fears are more associated with self-concept AvPD and therefore are more pervasive and interfere with more life domains [75]. High comorbidity with DPD is noted, and a connection with schizoid PD has also been postulated [76].

Clinical course

While carefully designed long-term studies of AvPD are rare, data do support the relative stability of the symptoms over time. An analysis of the CLPDS data showed that in a 10-year follow-up of AvPD patients, diagnostic stability was reasonably robust from years 6 through 10 (standardized effect 0.79 in men and 0.81 in women), with more variability earlier in the course [77]. It also seems that genetic factors contribute most robustly to AvPD's phenotypic stability [78].

Dependent personality disorder

Prevalence

In spite of relatively small numbers, prevalence data of DPD in different studies report significant oscillations (0.1–11%), with a median of between 0.5% and 1.4% and some predominance among women [21, 23, 78, 79]. This PD may be one of the most affected by cultural factors, as pointed out by Carrasco and Lecic-Tosevski [80], due to patterns of passivity, politeness, and submissiveness normally dominant and accepted in some societies.

Comorbidities

DPD has reasonably high comorbidity with AvPD, as outlined [75]. It is also commonly thought to have high comorbidity with anxiety disorders, but meta-analytic data have questioned this assumption by reporting a modest association ($r = 0.11$) [81]. The submissive nature of the disorder may contribute to an ambiguous presence of a comorbid anxiety, whereas reports of depressed mood are more common.

Clinical course

The clinical course of DPD is very poorly studied, a major gap in the epidemiological literature on PDs. Indirect evidence for diagnostic stability (vs its emergence in older age) comes from the fact that it only shows a 23.8% reduction in symptoms between ages 20 and 50 [82].

Obsessive-compulsive personality disorder

Prevalence

There seems to be agreement in that OCPD is, side by side with AvPD, one of the most prevalent PDs in the general population, with a range of 2.1–7.9% [1], depending in some cases on the preciseness and specificity of the instruments utilized. In clinical populations, prevalence may be as high as 10%. The most accepted median figure is 2.1%. Males may show five times higher rates than females, and the same happens among white, highly educated, married, older age, and employed subjects [83]. Clinical setting may be another differentiating factor, as the highest number of OCPD is seen in outpatient clinics and the lowest in inpatient units and private practice offices [27]. The issue of 'adaptive' (with a subtle or evident cultural input), not necessarily pathological, obsessive-compulsive personality traits has also been raised since the publication of the Epidemiologic Catchment Area (ECA) findings [41, 43, 68].

Comorbidities

OCPD is commonly comorbid with anxiety and mood disorders, occurring at rates of over 20% in both groups of patients [84]. Among the PDs, OCPD co-occurs with the other Cluster C disorders (particularly AvPD), as well as PPD and StPD. While obsessive-compulsive disorder (OCD) is clearly a separate disorder, symmetry

and hoarding symptoms can certainly co-occur, and the capacity to delay rewards contributes to this distinction [85].

Clinical course

Data from the CLPDS documented no change in OCPD functional improvement over 2 years. Small treatment studies have shown improvement in core PD symptoms, as well as anxiety and depression measures, but data are limited regarding long-term changes in OCPD.

Other personality disorders

Passive-aggressive (negativistic) personality disorder

Initially considered in DSM-I as a 'personality trait disturbance', this label was taken out of DSM-IV, and in DSM-5, it could be eventually ascribed to the so-called 'Personality disorder-trait specified' (PD-TS) category included in Section III as a resource for clinicians to describe and identify types different from the generally accepted ones [86]. In European psychiatry, the label is more used and recognized than in North America. According to studies, the general population prevalence ranges from 0.9 to 3.1, but in clinical settings, it moves up to 10% [80].

Additional PD types

There are several additional labels scattered around the existing literature. For example, some pre-DSM-5 classification instruments listed a *depressive personality disorder*, later incorporated to either 'Dysthymia', 'Major/moderate depressive disorder', or other clinical entities. In a recent study, it was found mostly associated with inattentive ADHD [87]. Similarly, *self-defeating (masochistic)* and *sadistic PDs*, with low prevalence levels (0.8% and 0.2%, respectively), have been studied primarily by Scandinavian researchers [19] and in forensic populations. Finally, a *mixed PD* could not be absent from attempts at a comprehensive clinical assessment [1].

DSM-5 [1] groups a series of personality-related conditions under the rubric of '*Personality change due to another medical condition*' (in the past also called 'Organic PD'), with specifiers that identify different types (labile, disinhibited, aggressive, apathetic, paranoid, other, combined, and unspecified) causing significant distress or impairment in social, occupational, and other areas of functioning. In this context, the issue and actual existence of defined *comorbidities* make the distinction between a pre-existing PD and personality changes secondary to medical conditions a delicate and complex clinical exercise. Furthermore, a growing variety of medical diagnoses can cause this disruption: neurological (that is, Huntington's, Parkinson's, Alzheimer's, and Pick's diseases, epilepsy and interictal status, frontal lobe syndrome, head or central nervous system trauma), neoplastic, infectious (that is, HIV), endocrinological (that is, hypo- and hyperthyroidism, hypo- and hyperadrenalism), and autoimmune conditions (that is, systemic lupus erythematosus). Thus, the *clinical course* of these variants is determined by the underlying cause and a subsequent tendency to chronicity and gradual clinical worsening.

Genetics of personality disorders

C. Robert Cloninger

Introduction

Substantial contributions have been made to understanding personality disorders through work in psychiatric genetics in a progressive way that can be summarized in five major steps. Initially twin, family, and adoption studies were conducted in order to test whether personality disorders were familial and heritable [1, 2], and also whether there was concordance for specific categorical diagnoses in families [3]. Personality disorders were found to be familial, but patterns of comorbidity within individuals and resemblance among relatives were found to be complex [4]. Personality disorders are not inherited as discrete entities, so there was a need to quantify the descriptive features of the disorders [5].

Secondly, reliable interviews were developed with checklists of features that quantified diagnosis, and the inheritance patterns of such descriptive features were studied. The number of features of disorders was found to be moderately heritable, and some progress was made to identify which features were common to all personality disorders and which to particular subtypes [6, 7]. However, there was still much overlap within individuals and within families, calling into serious doubt the reliance on categorical diagnosis [8]. Nevertheless, categorical diagnoses communicate much information concisely, so they continue to be popular with clinicians.

Thirdly, the relationship between normal and abnormal personality traits were thoroughly studied using quantitative interviews and/or self-report inventories with many scales and subscales [9]. The structure of personality was found to be the same whether people came from the general population or from clinical samples [10, 11], indicating that people with personality disorders or prominent abnormal personality traits were simple unusual configurations of traits that vary widely in the general population [12]. Extremes of individual traits or particular combinations of traits led to problems adapting in a healthy manner. In other words, what appeared to be fuzzy categories of disorder without discrete boundaries could well be specified as specific combinations of extreme (high or low) scorers on multiple dimensions of personality [13]. At least seven dimensions of personality, as measured by various alternative models, had some genes that were unique to each dimension, even though some systems used only 3–5 dimensions [14].

Fourthly, with the ability to measure personality and its disorders as multi-dimensional configurations or profiles of traits, it quickly

became clear that the inheritance of the dimensions of personality was highly complex, with resemblance in families influenced by genetics, socio-cultural learning, and environmental experiences throughout the lifespan, even though such complexity had been well described much earlier [15, 16]. Personality is a person's characteristic way of learning about, and adapting to, his or her life experiences. Human beings have multiple systems of learning and memory—procedural (behavioural conditioning for temperament traits), semantic (learning facts and propositions), and auto-noetic (self-aware learning or autobiographical memory of a life narrative). Such observations facilitated the integration of genetic, biological, social, and cultural contributions to understanding personality and its disorders. Although twin studies often seemed to suggest that heritability of personality was about 50%, in fact, most of the heritability is due to complex interactions among many gene loci acting in concert, which is called epistasis [17, 18]. The average effects of individual genes on personality are weak and inconsistent until their interactions with other genetic variants and environmental events are taken into account [19, 20]. There is much gene–gene and gene–environment interaction involved in the development of healthy and unhealthy personalities [21–23]. As a result, the field was stuck for more than two decades with what was called the ‘missing’ or ‘hidden’ heritability problem—despite resemblance for personality in monozygotic (MZ) twins being very much greater than in dizygotic (DZ) twins and other relatives, most of the genetic variability could not be explained by the average effects of genetic variants despite surveying dense maps of the entire genome [24, 25]. Less than 1% of variability in personality was explained by the average effects of individual genes, even in huge samples of over 60,000 subjects collected by the Genetics of Personality Consortium [19, 26].

Fifthly, it has recently become possible to identify systematically sets of many genetic variants that influence the risk of personality disorders [24]. Using genome-wide association studies (GWAS) in moderate-sized samples with detailed genotyping of the whole genome, the hidden heritability was found distributed in networks of many genes acting in concert, rather than individually. We now have well-validated clustering methods that allow a thorough description of both the genetic and phenotypic architecture of personality [24, 27, 28]. Most of the genome is expressed in the brain, and there is much regional variability in brain gene expression, as well as much individual variability in gene expression between individuals. The

genetic variants that influence personality are widespread across the genome, as illustrated later, and are found to regulate gene expression that contributes, in particular, to variability in neural development and neuroplasticity. These recent discoveries open a rich and promising field for understanding the complex genotypic networks and pathways by which personality develops and is self-regulated in human beings. Its applicability to even small and moderate samples means that the pathway from genotype to phenotype can be characterized with depth and precision in ways that are impractical in very large samples [24].

In this chapter, the basic observations along this progression in understanding the genetics of personality disorders will be described and discussed to provide an overview of the contributions of genetics to the diagnosis and treatment of personality disorders.

Genetic variation in risk of personality disorder is quantitative, not discrete

Antisocial personality is the most consistently recognized and most extensively studied personality disorder. Family, twin, and adoption studies have all shown that liability to antisocial personality disorders varies quantitatively and is moderately heritable, regardless of methods of assessment and diagnosis. Adoption studies of psychopathy [29], antisocial personality [2, 30], and criminality [31, 32] all moderate heritability of the quantitative risk of illness. The childhood experience of an unstable, hostile, or neglectful home acted synergistically to increase the risk of adult petty criminality or antisocial personality [30, 31]. MZ twins were much more often concordant for criminality than were DZ twins, with differences in prevalence according to gender and severity of impairment explaining the degree of familial loading or concordance in relatives in population-based samples for all of Denmark and its islands [33]. A meta-analysis of 51 twin and adoption studies estimated that there were moderate proportions of variance due to additive genetic influences (0.32), non-additive genetic influences (0.09), shared environmental influences (0.16), and non-shared environmental influences (0.43) [34], but the additive genetic influences may have been inflated by the neglect of cultural inheritance and assortative mating [15].

Sex differences in prevalence in the general population have a substantial impact on the degree of familial concordance [1, 33, 35]. For example, antisocial personality disorder is more rare in women than in men, and antisocial women carry a greater genetic loading (measured by more antisocial relatives) than do antisocial men [36].

Such findings show that liability to personality and its disorders varies quantitatively, not as a discrete disease or a set of diseases. Nevertheless, categorical classifications have remained popular for use in clinical practice, even when clinicians are warned that the clinical syndromes used for classification should be reified into discrete diseases, as was done in DSM-IV. The quantitative nature of variation in personality traits suggested the possibility that the number of diagnostic symptoms would be a good index of genetic risk.

Resemblance for personality disorder categories and symptoms in twins

Svenn Torgersen and his colleagues carried out a twin study of personality disorders using categorical diagnoses [3]. They ascertained

92 MZ and 129 DZ twin pairs, in which at least one proband had a diagnosis of personality disorder, and then classified subjects according to DSM clusters and categories. The concordances for any personality disorder were 58% for MZ pairs and 36% for DZ pairs, indicating moderate heritability (44%) (Table 120.1). When the diagnosis of personality disorder was definite, concordances for any personality disorder were 40% for MZ pairs and 29% for DZ pairs, which was highly significant ($P < 0.01$). However, the results could not be explained by a single heritable factor for personality disorder in general; there were heritable influences that further differentiated personality disorder clusters (Table 120.1). Torgersen's estimates of heritability for the clusters and specific categories were moderate (that is, between 40% and 60%), just as was found for quantitative measures of normal [16, 37] and abnormal personality traits [38]. The correlations between DZ pairs were usually less than half of those of MZ pairs, which suggests that gene–gene and gene–environment interactions are important for categorical diagnoses, as they are for personality dimensions in twins reared apart [17, 39–41].

Even stronger evidence for the moderate heritability of personality disorders has been provided by more recent studies of the inheritance of the number of symptoms in each of the ten categories of personality disorders in DSM-IV, which is conserved officially in DSM-5. The sample included 1386 pairs of twins aged 19–35, as assessed by Structured Interview for DSM-IV Personality Disorders (SIDP-IV) interviews. The data were compiled from separate reports about the heritability of the number of symptoms of disorders in personality Cluster A [6], Cluster B [42], and Cluster C [7] (Table 120.2). The total heritability of liability to the number of symptoms in each category varied from weak to moderate, ranging from 28% for paranoid personality symptoms to 38% for antisocial personality symptoms (Table 120.2).

The unique heritability in Table 120.2 indicates the specificity of the genetic determinants of each disorder. Low specificity means that the genetic determinants are non-specific for various diagnoses, so that there is much overlap of diagnostic features in the same individuals and in their relatives, as is true for most personality disorders. In contrast, obsessive–compulsive personality disorder has 85% unique heritability, indicating that its genetic determinants are largely distinct from those of avoidant and dependent personality disorders. This supports the proposal that obsessional traits constitute a fourth cluster with high persistence or anankastic traits [43]. Likewise, unique genetic determinants predominate for dependent personality disorder (52%) in Cluster C, and for schizoid personality disorder (74%) and paranoid personality disorder (54%) in Cluster A. Likewise in Cluster B, antisocial and borderline personality

Table 120.1 A study of categorical personality disorders (PDs) assessed by SCID-II interviews in 92 MZ twin pairs and 129 DZ twin pairs in Norway

Diagnoses	MZ correlation 100($r \pm SE$)	DZ correlation 100($r \pm SE$)	Broad heritability (% $\pm SE$)
Any PD	58 \pm 10	36 \pm 10	44 \pm 20
Any Cluster A	37 \pm 14	9 \pm 11	37 \pm 25
Any Cluster B	60 \pm 11	31 \pm 12	59 \pm 23
Any Cluster C	61 \pm 9	23 \pm 11	59 \pm 20

disorders are more closely related genetically to each other than to histrionic and narcissistic personality disorders.

The genetic and environmental architecture of all ten DSM-IV personality disorders has been evaluated using path analysis to estimate the number of common factors and unique determinants of all

ten DSM-IV personality disorders [44]. Three latent genetic factors were uncovered (Table 120.3). The first factor is a common determinant of all personality disorders. This common personality factor corresponds to what is measured as low self-directedness (that is, irresponsible, blaming) using the Temperament and Character Inventory (TCI) [10, 43]. The second genetic determinant contributes most strongly to antisocial and borderline personality disorders and most likely corresponds to low TCI Cooperativeness (that is, hostile, revengeful). The third genetic determinant contributes most strongly to schizoid and avoidant personality disorders and most likely corresponds to social detachment as a result of high TCI Harm Avoidance (that is, anxious, shy) and/or low TCI Reward Dependence (that is, aloof, detached).

The first two general factors provide support for proposals to use low Self-directedness and low Cooperativeness as indices of personality in general, as is done in the alternative criteria in DSM-5 [45] and elsewhere [46]. However, most of the disorders have additional genetic influences that are not accounted for by such character variables that define personality disorders in general. Subtypes of personality disorder are largely explained by variation in four temperament dimensions [5, 46], as proposed by Peter Tyrer for the eleventh edition of the *International Classification of Diseases* (ICD-11) [47]. Therefore, genetic evidence strongly supports classifying personality disorders on the basis of multi-dimensional inventories that distinguish character traits for identifying personality disorder in general or not, and temperament traits that distinguish subtypes in terms of their profile of emotional style [10, 43].

Same genes influence normal and abnormal personality

Multi-dimensional inventories for assessing components of personality disorders have been developed to measure both normal and abnormal traits. One of the most robust findings about personality, but

Table 120.3 Path coefficients ($\times 100$) for contributions to heritability of numbers of PD symptom groupings measured by the SIDP from three latent genetic factors (GFs) and unique contributions for each grouping of symptoms in 2794 Norwegian twins

Clusters of PD symptoms	Path from GF1 (? low Self-directedness)	Path from GF2 (? high Novelty Seeking/ low Cooperativeness)	Path from GF3 (? high Harm Avoidance/low Reward Dependence)	Path from Unique or Unexplained GF
Cluster A				
Schizotypal	11	22	22	31
Paranoid	30	13	22	28
Schizoid	2	7	37	34

one that is surprising to many psychiatrists, is that the same dimensions of personality are observed whether one begins with normal personality variation in the general community, with abnormal personality traits, or with symptoms of personality disorders in treatment samples.

There are three main lines of evidence indicating that the same genes and environmental variables account for variation in both normal and abnormal personality traits. Firstly, people with personality disorders or other forms of psychopathology have extreme values on one or more personality dimensions, but the correlational structure is the same in samples from the general community and from psychiatric treatment facilities [43, 48, 49]. If personality disorders were discrete diseases unrelated to normal personality variation, then the correlational structures of personality would differ in clinical and non-clinical samples (but they do not!). Secondly, the genetic–environmental architecture of normal personality traits is indistinguishable from that of abnormal personality traits. The finding that the genes and environmental influences for normal and abnormal personality are the same is found whether twins are reared together [49] or apart [50]. Thirdly, variability in normal personality traits that are descriptive of the general population are diagnostic of personality disorders [43, 51]. Therefore, normal personality traits share a common functional foundation with abnormal personality traits and most, if not all, mental disorders. Essentially, the same genetic and bio-psychosocial systems influence individual differences in normal personality and in its disorders.

In order to understand how personality disorders arise from particular configurations of traits that characterize normal variation in the general population, it is helpful to consider information from genetic studies of both normal and abnormal personality. Twin studies of personality dimensions in the general population demonstrated moderate heritability of normal personality traits. For example, the TCI was developed based on specific neurobiological and psychosocial data [5, 10, 52–54]. It measures four dimensions of temperament (that is, behavioural biases in response to basic emotional stimuli) and three dimensions of character (that is, higher cognitive processes influencing the maturity of a person's goals and values). Initial twin studies were carried out using only measures of temperament [55, 56]. More recent twin studies have used the TCI and showed that each of the seven TCI dimensions has a unique genetic variance that is not explained by the other dimensions [14].

The TCI is descriptive of normal variation in the general population and is also highly effective in distinguishing people with and without personality disorder and in doing differential diagnosis of all personality disorder subtypes [43, 46]. The distinction between character and temperament in the TCI allows its character dimensions to be a highly effective model in distinguishing healthy from unhealthy personality traits [51]. The three character dimensions of the TCI are Self-directedness (that is, resourceful, purposeful, and responsible), Cooperativeness (that is, tolerant, helpful, and principled), and Self-transcendence (that is, idealistic, selfless, and contemplative) [57]. These dimensions correspond to variability in the intrapersonal, interpersonal, and transpersonal aspects of the self. The distinction between character (what we make of ourselves intentionally) and temperament (emotional drives) is well supported by studies of unique genetic determinants [14], phylogenesis [58, 59], brain imaging [60, 61], self-awareness and mental time-travel [62], effects of parental child rearing and early home environment [63],

and generativity (that is, fertile and/or stable marriage, sperm donation) [64–67].

The heritability of each of the seven TCI dimensions in a sample of 2517 Australian twins is summarized in [Table 120.4](#). Total heritability varied from 27% to 45%, without correcting for the reduced reliability of the short form of the TCI used in this study. Both temperament and character traits were roughly equally heritable, and each dimension had genetic determinants unique to it (that is, not overlapping with the genetics of other dimensions).

Likewise, John Livesley and his colleagues developed the Differential Assessment of Personality Pathology (DAPP) to measure the self-report of abnormal personality traits as a hierarchy of dimensions. The questionnaire is composed of 560 items measuring 18 factorially derived dimensions, each with at least three specific facet scales [11, 38]. The heritability and concordances in 236 MZ twin pairs and 247 DZ twin pairs have been estimated for all 18 DAPP traits ([Table 120.5](#)). The heritability ranged from 35% for rejection sensitivity to 56% for conduct problems and callousness, once again showing that personality traits are moderately heritable.

Four higher-order traits have been identified that account for most of the variability in the 18 DAPP dimensions. These are described as: (1) 'emotional lability or dysregulation'; (2) 'antagonism or dissocial behavior'; (3) 'interpersonal responsiveness or inhibition'; and (4) 'compulsivity' [49]. These higher-order dimensions of abnormal personality resemble the unhealthy extreme of the dimensions of normal personality. The first three also correspond to the three factors identified in path analysis of personality disorders, as summarized previously in [Table 120.3](#). For example, emotional dysregulation is similar to high neuroticism in the five-factor model (measured by the NEO) [68] or low Self-directedness in the seven-factor model of temperament and character (measured by TCI) [10]. Antagonism or dissocial behaviour is similar to low agreeableness in the five-factor model and low Cooperativeness in the seven-factor model. Hence, these dimensions define healthy personality at one extreme (namely, high TCI Self-directedness and Cooperativeness, or low DAPP emotional dysregulation and dissocial behaviour, or low NEO Neuroticism and Agreeableness) and personality disorder at the other extreme (for example, low TCI Self-directedness and Cooperativeness, etc.) [43, 49, 68].

Table 120.4 Total heritability of each of the seven Temperament and Character Inventory (TCI) personality dimensions estimated in 2517 twins in Australia (unique effects exclude genetic contributions shared with other TCI personality dimensions)

Personality dimension	Total heritability (%)	Unique heritability (%)
Harm Avoidance	42	29
Novelty Seeking	39	32
Reward Dependence	35	20
Persistence	30	23
Self-directedness	34	25
Cooperativeness	27	16
Self-transcendence	45	26

Overall, twin studies showed that personality is moderately heritable whether measured as normal traits, abnormal traits, number of symptoms, or categorical diagnoses. Alternative measurement methods are highly convergent with one another.

The complexity of personality genetics

Twin studies indicated that between 30% and 60% of the phenotypic variance in personality and its disorders, as assessed by a variety of instruments, is genetic in origin [14, 18, 39, 69, 70]. However, adoption studies, studies of twins plus other family members, and GWAS have shown that common additive genetic variants account for little of the heritability of personality traits; most of the heritability of personality and its disorders, as assessed by a variety of instruments, depends on complex interactions among multiple gene loci (that is, epistasis) and possibly multiple alleles at a locus (that is, dominance), rather than the average effects of individual genes [17, 18, 20, 39, 70–72]. As a result, little (that is, <7.2% on average) of the expected genetic effects on personality can be attributed to the average effects of individual single-nucleotide polymorphisms (SNPs) [20].

The importance of gene–gene and gene–environment interactions can be illustrated by studies of association of TCI Novelty Seeking with polymorphisms for dopamine receptor type 4 (DRD4), first reported by Jonathan Benjamin. Initially, they observed the simple association between DRD4 and Novelty Seeking, and then extended their findings to show the association depends on the three-way interaction of DRD4 with catechol-O-methyltransferase (COMT)

and the serotonin transporter locus promoter's regulatory region (5-HTTLPR). Consequently, the association of Novelty Seeking with the average effects of DRD4 is weak and inconsistent. In the absence of the short 5-HTTLPR allele (5HTTLPR L/L genotype) and in the presence of the high-activity COMT Val/Val genotype, Novelty Seeking scores are higher in the presence of the DRD4 7-repeat allele than in its absence [73]. Furthermore, within families, siblings who shared identical genotype groups for all three polymorphisms (COMT, DRD4, and 5-HTTLPR) had significantly correlated TCI Novelty Seeking scores ($r = 0.4$ in 49 subjects; $P < 0.01$). In contrast, sibs with dissimilar genotypes in at least one polymorphism showed no significant correlation for Novelty Seeking. Similar interactions were observed between these polymorphisms and Novelty Seeking in an independent sample of unrelated subjects [73] and have been replicated by independent investigators [74]. Likewise, there is also substantial evidence for specific gene–environment interactions on personality development [21, 75–83]. For example, TCI Novelty Seeking scores in adulthood are associated with particular DRD4 polymorphisms only if the children were reared in a hostile childhood environment with measures during childhood of maternal reports of emotional distance and punitive discipline [21]. Such complex non-linear interactions present great challenges for the identification and replication of relationships in GWAS. As a result of such complexity, despite extensive past effort, for the past decade, GWAS of personality had found few significant associations between specific SNPs and personality traits despite using a variety of well-validated personality instruments [19, 26, 84]. This is not surprising because the GWAS methods failed to account for the complexity of personality. Such failure to account for most of the heritability of complex traits has been called the 'missing' [25] or 'hidden' [85] heritability problem.

Until recently [24], the missing heritability problem had been approached in GWAS by analysing the explained variance in individual personality traits in large individual samples or by using meta-analysis to combine data sets, such as the Genetics of Personality Consortium, with more than 60,000 subjects in 30 or more demographically diverse samples assessed with a variety of personality inventories [19, 20, 26, 86–89]. Efforts have also been made to harmonize measures from moderately correlated inventories using item-response theory and to consider the impact of demographic variables or allele frequencies on variation in individual traits. Nevertheless, most of the heritability of the traits has remained unexplained because even in large samples, the methods used are effective for detecting only the average effects of individual genes, but not the non-additive interactions among multiple genes and environmental events that are actually expected [24, 28, 90] (Table 120.6).

Genomic approaches to understanding temperament and character

Fortunately, the integration of well-validated clustering methods with GWAS has made it possible to address the complexity of personality systematically [24]. Different profiles of temperament and of character were associated with different sets of functionally interacting genes detected through SNPs. The broad heritability of the various traits of personality varies from 30% to 60%, but this

Table 120.6 Greater importance of non-additive than additive components of heritability for Cloninger's and Eysenck's personality traits in a study of 9672 MZ and DZ twins and 3241 of their siblings (twin plus sibling design)

Personality trait	Additive heritability (women)	Non-additive heritability (women)	Additive heritability (men)	Non-additive heritability (men)
TCI Harm Avoidance	0.15*	0.27*	–	0.29*
TCI Novelty Seeking	0.05	0.35*	0.05	0.35*
TCI Reward Dependence	0.07	0.31*	–	0.11*
TCI Persistence	0.00	0.35*	0.00	0.35*
EPQ-R Extraversion	0.23*	0.24*	0.23*	0.24*
EPQ-R Neuroticism	0.19*	0.23*	0.09*	0.12*

depends on substantial interactions among multiple genes and environmental variables. The average effects of individual genes explains <7.2% of the variability in personality, but allowing for gene–gene and gene–environment interactions accounted well for the broad heritability of temperament and character. The whole genome was screened for specific genes using about one million SNPs in >4000 people representative of the general populations of Finland, Germany, and Korea. Personality was found to be highly polygenic, with the associated genes distributed across all the human chromosomes in the Young Finns Heart Study [91], followed by replication in the other two independent samples. Fig. 120.1 shows the number of genes per chromosome that are strongly associated with clusters of people with particular temperament profiles (that is, temperament only), clusters of people with particular character profiles

(that is, character only), and clusters of people with profiles of both temperament and character traits (that is, temperament and character). Sets of multiple genes were identified, independently of information about the personality traits, and the clusters of people were identified without information about the genetic profiles. The gene sets therefore represent naturally occurring combinations of genes with distinct functional interactions [24]. The sets of genes and personality profiles were very strongly associated, but the relationships were complex in the sense that the same gene set could be expressed in multiple ways (that is, multifinality, pleiotropy) and different sets of genes could be expressed in the same way (that is, equifinality, heterogeneity).

The complex development of personality profiles from interacting sets of multiple genes and environmental variables will be described in more detail later. Now it is fundamentally important to recognize that most of the genes that influence personality have regulatory functions, rather than being protein-coding genes (Fig. 120.2). In older genetic studies of personality, nearly all attention has been focused on protein-coding genes related to neurotransmitter functions. However, it is the regulatory genes that help us to understand change and development of human personality.

Most of the regulatory genes are long non-coding ribonucleic acids (lncRNAs), other shorter non-coding RNAs (ncRNAs), and pseudogenes. These ncRNAs (long or short) are functional RNA molecules that are transcribed from deoxyribonucleic acid (DNA) but are not translated into proteins [92]. They can regulate gene expression at both the transcriptional and post-transcriptional levels. They are involved in epigenetic processes that can be divided into two main groups: the short ncRNAs of <30 nucleotides and the lncRNAs of >200 nucleotides. The major classes of short ncRNAs are microRNAs (miRNAs), short interfering RNAs (siRNAs), and piwi-interacting RNAs (piRNAs). Both long and short RNAs are known to play a role in heterochromatin formation, histone modification, DNA methylation targeting, and gene silencing. However, lncRNAs and the shorter ncRNAs act differently.

Nearly 30% of the genes associated with character only involve lncRNAs, whereas the percentage is only 20% in the other two

Fig. 120.1 Number of genes per chromosome for temperament and character identified and replicated in person-centred GWAS of Temperament and Character Inventory in the Young Finns Study.

Fig. 120.2 Genes distinguished by biotype for temperament only, character only, and both in person-centred GWAS of Temperament and Character Inventory in the Young Finns Study.

groups, as shown in Fig. 120.2. In contrast, protein-coding genes are more often associated with temperament only than with the groups involving character. The more prominent role of lncRNAs in character is consistent with the hypothesis that epigenetic change is more important for the development of character than for temperament [63, 91].

lncRNAs form extensive networks of ribonucleoprotein (RNP) complexes with numerous chromatin regulators. These chromatin regulators target these enzymatic activities to the appropriate locations in the genome. Apparently, lncRNAs can function as modular scaffolds to specify higher-order organization in RNP complexes and in chromatin states. lncRNAs have several functions in the regulation of gene transcription, including the regulation of specific gene transcription (either activation or repression), post-transcriptional regulation, differential splicing, and regulation of epigenetic modifications, including histone and DNA methylation, histone acetylation and sumoylation, and remodelling of chromatin domains. These findings suggest the hypothesis that character development involves epigenetic processes involving regulation of gene expression and chromatin modification, which, in turn, influence neural development and neuroplasticity. lncRNA dysfunction is also often observed in common chronic diseases related to stress and lifestyle regulation, including cancer, cardiovascular diseases, neurological diseases, and immune-mediated diseases.

In contrast, the shorter ncRNAs are mostly involved in distinct temporal expression patterns during embryogenesis, acting in specific tissues to regulate expression at a post-transcriptional level. miRNAs usually bind to a specific target messenger RNA with a complementary sequence to induce cleavage and degradation or to block translation, and they have crucial roles in epigenesis. Silent-interfering RNAs function in ways similar to miRNAs to mediate post-transcriptional gene silencing as a result of messenger RNA degradation and to induce heterochromatin formation. piRNAs are so named due to their interaction with the piwi family of proteins. They are involved in chromatin regulation and suppression of transposon activity during embryogenesis. The percentage of ncRNA

genes associated with personality is only 5% and do not distinguish the temperament clusters from the character clusters.

As shown in Fig. 120.2, the distribution of the types of genes associated with character differs from that of other groups. These findings suggest that the ability of the human character to self-regulate emotion may be related to the human capacity to self-regulate gene expression, which can be cultivated by enhanced self-awareness [93]. The prominence of regulatory functions associated with personality traits that influence neural development and neuroplasticity provides a mechanism for understanding the way learning and memory processes influence personality development as a complex adaptive process.

Imaging of personality disorders

Christian Paret and Christian Schmahl

Introduction

In this chapter, we will review the neuroimaging literature in personality disorders. Given its clinical importance and the rapidly grown literature on borderline personality disorder (BPD), we will focus on this condition, with some additional findings from studies on avoidant (AvPD), narcissistic (NPD), and obsessive-compulsive personality disorder (OCPD), where appropriate. Due to consistency and readability, we abstained from reviewing the large body of imaging literature on suspicious personality disorder types (paranoid, schizoid, schizotypal, antisocial), which has been covered elsewhere [1, 2].

Emotion processing and regulation

Emotion processing

Emotion dysregulation is a hallmark of BPD psychopathology [3]. A growing number of studies have used functional magnetic resonance imaging (fMRI) during emotional challenge (for example, presentation of emotionally arousing pictures or facial expressions) to investigate the neural correlates of emotional responding in individuals with BPD, compared to healthy individuals; the majority of fMRI studies have observed hyperreactivity of the amygdala in response to negative emotional stimuli in BPD patients, compared to healthy controls (for a meta-analysis, see [4]). In addition to an exaggerated amygdala response to emotional pictures, several studies in BPD patients found increased amygdala activation in response to pictures which have been rated as neutral in the general population (for example, [5, 6]). Both BPD and AvPD patients showed a lack of habituation to repeated presentations of emotional stimuli [7]. Increased dorsal anterior cingulate cortex (ACC) activity and amygdala–insula connectivity was observed in healthy controls, but not in BPD and AvPD [7]. This is in line with other studies revealing a lack of habituation in BPD [8–10] which may contribute to affective instability [7]. Findings of increased and prolonged amygdala activation are in line with the well-documented clinical feature of high sensitivity to emotional stimuli with intense and long-lasting reactions in patients with BPD [10–12]. Most interestingly, medication-free samples were characterized by limbic hyperactivity, whereas no such group differences were found in patients currently taking psychotropic medication [4].

In addition to amygdala hyperreactivity, increased activation in the insula has been observed in emotional challenge studies in BPD patients, compared to healthy controls, emphasizing the role of this brain area in disturbed emotion processing in BPD [5, 6, 13, 14]. In numerous studies in healthy individuals, the insula has been associated with the encoding of unpleasant feelings, interoceptive awareness (awareness of one's own bodily experiences), perceived social exclusion, and pain perception [15, 16].

Several neuroimaging studies have revealed frontal hypoactivation [17–19], especially blunted responses of the bilateral dorsolateral prefrontal cortex (dlPFC) [4], in response to emotionally arousing stimuli. Schmahl and colleagues [20] presented individualized auditory scripts of abandonment situations to their participants and found increased activation in the dlPFC and decreased activation in the medial prefrontal cortex (mPFC). Furthermore, when patients were confronted with their self-reported traumatic memories, they did not exhibit increased activity in the ACC or orbitofrontal cortex (OFC) and dlPFC, as did healthy controls. Instead, they showed unaltered or diminished activity [21]. The OFC and dlPFC are thought to be implicated in a top-down appraisal system that modulates activation in limbic and subcortical brain areas [22]. Hence, it is conceivable that the pattern of hypoactivation observed in frontal brain regions during emotional challenge in BPD might represent a neural correlate of altered processing of negative autobiographical memories and negative emotions.

Turning to studies of brain structures (for example, brain volume) in patients with BPD, compared to healthy controls, several studies have shown a reduced volume in limbic and paralimbic brain regions. A meta-analysis [23] even proposed that reduced volumes of the amygdala and hippocampus may be regarded as 'biological markers' or endophenotypes of BPD. In a recent meta-analysis on studies using voxel-based morphometry (VBM), most prominent volumetric changes in BPD were observed in the amygdala and dlPFC [4]. It is nonetheless controversial whether the observed alterations rather stem from experience of abuse in childhood [24] or might even be a substrate of comorbid post-traumatic stress disorder (PTSD), both of which are highly prevalent conditions in BPD [25, 26]. Kuhlmann and colleagues [27] further detected a reduced volume of the hypothalamus, which extends previous findings of alterations in the hypothalamic–pituitary–adrenal axis in BPD [28, 29]. The first multimodal imaging study in BPD published by Salvador

and colleagues [30] complements earlier work [31–33] showing converging abnormalities in subgenual and perigenual ACC.

While no differences were found between BPD and AvPD in brain structure, both patient groups showed reduced mPFC and ACC volumes, compared to healthy controls [34]. Further, both patient groups showed a positive correlation between amygdala volume and anxiety [34].

The research depicted here has led to the current conceptualization of BPD suggesting that emotion dysregulation results from deficient ‘top-down’ frontal control mechanisms involved in regulating activation in hyperactive ‘bottom-up’ emotion-generating limbic structures. Imbalance of control such that the lower brain regions generating emotion are untethered from prefrontal control areas is also observed in anxiety disorders [35] and is probably not specific to BPD. The white and grey matter abnormality, accompanied with altered resting-state brain connectivity [36], emphasizes alterations in fronto-limbic networks as a candidate neural substrate of symptoms concerning several functions, such as emotion processing, emotion regulation, and decision-making, that are impaired in BPD and other mental disorders.

Cognitive emotion regulation

Three studies investigated the cognitive regulation of emotions in BPD by presenting negative pictures with the instruction to regulate emotions in the MRI scanner [37–39]. The results converged to a reduced response of the dorsal mPFC and dlPFC in BPD patients when regulating emotions. More specifically, the study by Koenigsberg and colleagues [37] found diminished activity in the dlPFC and ventrolateral prefrontal cortices when patients with BPD tried to cognitively distance themselves from negative stimuli. Similarly, cognitive reappraisal yielded decreased recruitment of the OFC and increased activation of the insula in patients with BPD, relative to healthy participants [39]. In an attempt to clarify the role of trauma history on downregulation of emotional responses in BPD patients, Lang *et al.* [38] compared trauma-exposed BPD patients to trauma-exposed healthy subjects without BPD and non-traumatized healthy subjects. In this study, BPD patients, as well as healthy individuals with a trauma history, recruited brain regions associated with up- and downregulation of negative emotions (for example, ACC) to a lesser extent, which might reflect compensatory changes associated with trauma exposure.

Initial fMRI findings suggested changes in neural responding with psychotherapy. Goodman and colleagues [40] demonstrated a reduction of amygdala activity in a passive viewing paradigm after dialectical behaviour therapy (DBT) treatment. Testing patients receiving DBT vs patients receiving treatment as usual (TAU) and healthy controls, Winter *et al.* [41] found the inferior parietal lobe/supramarginal gyrus (IPL/SMG) to alter responding during emotion regulation. Decreased IPL/SMG responding predicted an improvement of symptom severity. Furthermore, DBT responders reduced perigenual ACC activation when viewing negative vs neutral pictures. Schmitt *et al.* [42] found decreased insula and ACC activity during reappraisal in patients with BPD. ACC connectivity to the medial and superior frontal gyri, superior temporal gyrus, and inferior parietal cortices increased after DBT. Treatment responders exhibited reduced activation in the amygdala, ACC, OFC, and dlPFC, together with increased connectivity within a

limbic–prefrontal network, during reappraisal of negative stimuli after psychotherapy.

One fMRI study testing neural responses of cognitive emotion regulation in AvPD revealed amygdala hyperreactivity in anticipation of regulation and in response to negative, compared to neutral, pictures [43]. Furthermore, amygdala reactivity was correlated with anxiety ratings [43] and may be interpreted as a neural correlate of exaggerated anticipatory anxiety of social situations.

Self-injury and altered pain processing

A very common dysfunctional behaviour, closely linked to emotion dysregulation in BPD, is non-suicidal self-injury (NSSI) [44]. Pain appears to have an important emotion-regulating effect in BPD [45]. A large body of experimental research investigating pain perception in individuals with BPD points to reduced sensitivity in BPD patients (for example, [46–49]). Schmahl and colleagues [48] showed that self-reported pain ratings were *lower* in BPD patients and that pain thresholds were altered. Interestingly, no differences were observed in discrimination task performance of laser-evoked brain potentials, which showed that the analgesic state in BPD is not explained by an impairment of the sensory-discriminative component of pain [48]. In a first neuroimaging study by Schmahl *et al.* [47], patients with BPD and NSSI underwent fMRI while heat stimuli were applied to their hands. BPD patients showed increased dlPFC activation, along with decreased activation of the posterior parietal cortex. Moreover, painful heat stimulation evoked neural deactivation in the amygdala and perigenual ACC in participants with BPD [47]. The observed interaction between increased pain-induced response in the dlPFC, coupled with deactivations in the ACC and amygdala, could be interpreted as an anti-nociceptive mechanism in BPD [47]. While sensory discrimination processes remain intact, this mechanism may modulate pain circuits primarily by an increased top-down regulation of emotional components of pain or an altered affective appraisal of pain [47].

Examining the neural mechanisms underlying the role of self-inflicted pain as a means of affect regulation in BPD more directly, Niedtfeld and colleagues [6] conducted an fMRI study using pictures to elicit negative affect and thermal stimuli to induce heat pain. Although the authors found an attenuation of activation in limbic areas (amygdala, insula) in response to sensory stimulation, it was specific neither to patients with BPD nor to painful stimulation. In order to identify brain mechanisms underlying the limbic deactivation observed [6], the authors measured functional connectivity between those regions that had been identified to be involved in emotional processing, namely the amygdala, insula, and ACC [50]. Results of their analyses indicated that painful sensory stimuli, as opposed to warmth perception, resulted in enhanced negative coupling between (para-) limbic and prefrontal structures in BPD, thus indicating inhibition of limbic arousal. Increased coupling between the amygdala and medial frontal gyrus (BA8 and BA9) may point to attentional distraction processes [51]. Additionally, in the patient group, the dlPFC showed enhanced coupling to the posterior insula, a brain region known to play a critical role in pain processing [52] and affective appraisal of pain perception [53].

To test the direct effect of tissue damage, two recent studies induced stress with the Montreal Imaging Stress Task, followed by either an incision into the forearm (tissue damage) or a sham condition [54, 55]. The incision resulted in a decrease in tension and heart rate in the BPD group, in contrast to a short-term increase in aversive tension in the

healthy control group [55]. A resting-state fMRI scan after the incision pointed to a decrease in amygdala activity, together with normalized functional connectivity of the amygdala and superior frontal gyrus, in the BPD group [54]. These results may point to a stress-reducing effect of tissue damage that affects subjective experience, psychophysiological reactions, and brain function in BPD.

In sum, the overall reported results on pain processing in BPD suggest that NSSI may be interpreted as an attempt to compensate for a deficient emotion regulation mechanism. More specifically, the reported findings implicate that the soothing effect of pain in BPD seems to be mediated by different emotion regulation processes (attentional shift and altered appraisal of pain).

Social interaction

Processing of social stimuli

Izurieta Hidalgo and colleagues [56] found a decreased late centroparietal P300 response in BPD patients that may reflect diminished categorical processing of happy faces. Several fMRI studies found increased amygdala responses to emotional facial expressions [57–60], and decreased subgenual and dorsal ACC responses were reported [60]. Further, increased functional connectivity of the amygdala with the dorsal and rostral ACC was observed in overt face processing [61]. Covert face processing increased the amygdala–thalamus connectivity in BPD patients [61], and an early enhancement in electroencephalogram (EEG) responses (P100, N170) was observed [56]. Although BPD patients tended to make more and faster initial eye fixations to the eyes of angry faces [58] and to misclassify predominantly happy faces as angry faces [56], amygdala hyperactivation was not enhanced comparing angry faces to other emotions [57, 60].

Empathy

Both increased interpersonal resonance and pervasive interpersonal disturbances are ubiquitous in BPD, possibly rooted in reduced mirroring of emotional reactions in parent–child dyads and childhood traumatic experiences [62]. Frick *et al.* [63] found that BPD patients were better and faster than healthy controls in inferring emotional states from eye gaze pictures. This was accompanied by increased amygdala, temporal cortex, and OFC responses to emotional eye gazes and ventromedial PFC (vmPFC), ACC, and parietal activations specifically to eye gazes in faces with negative emotional expression in BPD. Increased amygdala activation was also observed in BPD patients attributing intentions to emotional face expressions [59]. Similar to posterior insula hyperactivity in BPD patients who empathized with people on violence and threat photographs [64], amygdala hyperactivity may reflect increased emotional resonance and arousal. In contrast, reduced anterior insula activations [63] may reflect divergent social expectations in BPD [65]. Moreover, empathic mindsets increased superior temporal cortex activity in healthy subjects, but not in BPD patients [59, 63, 64]. Low superior temporal cortex activity was suggested to reflect reduced meta-cognitive processes [66], which may entail inadequate emotion regulation in social situations. Paired with enhanced emotional sensitivity and affective reverberation, this may promote interpersonal disturbances [62].

Reduced grey matter volume in patients with NPD was found in the anterior insula, rostral ACC, mPFC, and medial cingulate [67]. Another study found reduced grey matter volume in the mPFC/

ACC and fusiform, temporal, and occipital cortices [68]. Higher anterior insula volume predicted higher emotional empathy [67]. These findings were further supported by diffusion tensor imaging findings, showing altered structural connectivity involving frontal lobe and thalamic regions [68]. Neural alterations were discussed to underlie decreased empathy, which is characteristic for NPD [67]. Somatosensory gating (SG) during the anticipation and observation of pain, measured with EEG, was found increased in NPD subjects [69]. According to the authors, this finding may reflect an increased somatic representation of observed pain. A positive correlation of SG with impulsivity–egocentricity ratings suggests an increased somatic representation of observed pain despite lower empathy [69]. The NPD sample consisted of patients with high psychopathic traits, limiting the generalization of results. Though the database is sparse, imaging data so far support malfunction in the frontolimbic and paralimbic systems to underlie NPD psychopathology.

Co-operation and social exclusion

Perceived exclusion in a virtual ball-tossing game was associated with hyperactivation of the dlPFC and precuneus in patients with BPD [70]. Furthermore and independent of actual exclusion by the co-players, hyperactivation of the dorsal mPFC/ACC, parietal cortex, occipital cortex, and insula was found [70]. Unlike healthy controls, BPD patients felt excluded, even when they were actually included. Furthermore, they also felt excluded and showed neural hyperactivation when players followed predefined rules [70]. The observed pattern was discussed to possibly reflect ‘hypermentalizing’, that is, the tendency to attribute intentions to co-players when behaviour is actually not guided by intentions. Abnormal anterior insula activation may reflect decreased expectations of co-operative behaviour in BPD [65], a potential precursor of break-ups in interpersonal co-operation. Additionally, increased anterior PFC activation during exclusion [71] may relate to altered emotion regulation in social interactions [72]. In summary, divergent social expectations appear to promote feelings of exclusion and impede the maintenance of relationships. This is reflected by divergent neural responding to social interaction in BPD.

With regard to interpersonal aggression, patients increased both OFC and amygdala activation in an experimental manipulation provoking aggressive tendencies, while controls decreased amygdala activation [73]. As the latter study assessed patients with comorbid intermittent explosive disorder (IED), results may not generalize to BPD without IED. Mancke, Herpertz, and Bertsch [74] suggested a multi-dimensional model linking neuropsychology and neurochemistry data to the bio-behavioural dimensions of affective dysregulation, threat hypersensitivity, reduced cognitive empathy, reduced self–other differentiation, and impulsivity. The authors assumed a prefrontal–limbic imbalance to underlie impulsivity, affective dysregulation, and hypersensitivity to social threat cues, mediating aggressive tendencies often observed in BPD [74].

Behavioural regulation

Decision-making

Decisions are ubiquitous in daily life and ‘commit the organism to one out of several possible behaviors’ [75]. It is assumed that decisions are guided by the processing of subjective value that critically

involves the vmPFC and OFC (reviewed, for example, in [76]). Brain volumetry analyses revealed differences in mPFC/OFC grey matter volume in BPD patients vs healthy controls [77–83] and in BPD patients vs other clinical populations [77, 84]. A meta-analysis found reduced grey matter volume in the ventral mPFC/OFC of patients with BPD [4].

fMRI studies demonstrated that BPD patients' vmPFC response did not differentiate between reward and no-reward expectations; in contrast, this pattern was observed in healthy controls [85, 86]. Notably, effects were most pronounced for reward anticipation in face of emotional pictures [85]; in the presence of emotional pictures, BPD patients did not discriminate between anticipated reward and no-reward conditions. Group differences were also observed in upstream brain regions of the reward system such as the ventral striatum, ventral tegmental area, and amygdala. Generally, healthy participants, compared to BPD patients, showed stronger deactivations in these regions if no reward was expected [85]. In line with this, reduced neural discrimination between reward and punishment in BPD was found in a simple gambling task [87, 88]. Andreou *et al.* [87] localized this group interaction effect to the mPFC/ACC. In addition, they observed group differences in mPFC and OFC responses to high vs low magnitudes of monetary reward and punishment. In concert with the findings reviewed in this chapter, Schuermann and colleagues [89] demonstrated reduced frontal EEG discrimination between reward and punishment in a more complex decision-making task. In addition, they observed an increased P300 response to punishments in BPD patients that may relate to delayed processing of feedback [89]. Alternatively, an increased P300 response may indicate differences in BPD patients' expectations about receiving punishment [89]. In accordance with these findings, BPD patients did not adjust their choices and kept drawing from disadvantageous card decks [89].

In summary, neuroimaging studies document a lack of discrimination between reward and punishments in the neural reward system of BPD patients.

Learning

Classical conditioning is used as a paradigmatic task for fear learning. In turn, the unlearning of fear is studied by investigating how well subjects extinguish an established conditioned response. BPD patients reported stronger affective responses in fear extinction [9]. However, on the neural level, no significant group differences emerged comparing BPD patients and healthy controls [9].

Fear can also be learnt by verbal instruction. In research, this phenomenon is investigated in 'instructed fear' studies where investigators inform subjects about a possible negative stimulus (for example, an electrodermal pain stimulus) that might be delivered upon a certain cue but is actually never given during the experiment. BPD patients showed a prolonged amygdala response to instructed fear, while healthy controls decreased amygdala activation over time [10]. In addition, BPD patients showed altered connectivity patterns in the prefrontal–limbic regions in this paradigm [10]. While patients' amygdala activation failed to habituate, this was not represented in skin conductance responses [10].

Turning to another learning process, Soloff *et al.* [90] investigated episodic memory encoding and retrieval. BPD patients observed affective and neutral pictures a first and later a second time where they should identify those already known pictures among unfamiliar

pictures. Comparing with healthy control patients, differential activations in the hippocampus, ACC, dorsal PFC, and parietal cortex were seen for negative vs positive pictures. This suggests less differential recruitment of brain areas associated with episodic memory formation in BPD. Despite neural differences, patients recognized items equally well as healthy controls during retrieval.

To our knowledge, imaging studies in other personality disorders (excluding antisocial personality disorder, which are not addressed in this chapter) focusing on memory functions are not existent. Coutinho and colleagues demonstrated altered precuneus network connectivity in OCPD [91]. The authors speculated that altered precuneus connectivity may reflect over-involvement in anticipatory processes, leading to rumination in future-oriented planning at the cost of present moment experience and an attentional bias to minor details [91].

Cognitive conflict management

Winter *et al.* [92] did not find a group difference comparing BPD patients to healthy controls in an fMRI study with the 'emotional Stroop' task. However, when dissociation was evoked by personalized autobiographical memory scripts, significant emotional interference was observed comparing these patients to non-dissociated BPD patients and controls [92]. Moderate activation differences in the inferior parietal cortex and inferior temporal gyrus may reflect impaired inhibition of task-irrelevant information caused by dissociation [92]. Dissociation involves disruptions of usually integrated functions such as consciousness, memory, attention, pain perception, and perception of the self and environment, and is frequently reported by patients with BPD [93–95]. Compared to healthy controls, non-dissociated patients were found to increase responses to positive words in temporal, frontal, and cingulate regions, but no differences were observed with regard to negative words [92]. In contrast, Malhi *et al.* [96] found increased ventrolateral PFC and decreased dlPFC and amygdala activation in BPD patients in the 'emotional Stroop' task, although lacking behavioural group differences. In their analyses, both PFC regions showed correlations with self-assessments of emotion dysregulation, which is supportive of increased involvement of the PFC in emotional interference resolution. In contrast, another study found decreased dlPFC activation [97]. Wingenfeld and colleagues [98] reported activations of a more posterior lateral PFC area when comparing the responses to negative vs neutral words in healthy controls to responses in BPD patients, in addition to temporal cortex and ACC activations.

Beyond word identification, emotional conflict can also be introduced to other cognitive processes. Krause-Utz *et al.* [5] found BPD patients to be more distracted by negative emotional pictures that were presented during a working memory task, evidenced by slowing of reaction times. Neurally, this was complemented by increased amygdala and anterior insula, as well as decreased dlPFC, activation [5]. Furthermore, stronger functional connectivity of the amygdala with the dorsomedial prefrontal cortex (dmPFC) was found, and stronger coupling of these regions was related to increased reaction times [99]. In addition, amygdala connectivity with the dorsal ACC was increased and amygdala activation decreased when patients reported higher dissociation [99]. These findings suggest that BPD is associated with an increased demand of cognitive resources to counteract intense emotional interference.

Presenting emotional face distractors in a flanker-task, Holtmann *et al.* [100] found stronger dorsal ACC responses to fearful vs neutral faces in BPD patients, compared to healthy controls. A negative correlation of dorsal ACC response to incongruent vs congruent trials with anxiety ratings suggests involvement of this region in conflict resolution, modulated by anxiety. Behaviourally, no effect of distraction on reaction times or accuracy was detected by the authors. As reviewed previously, emotional content is also suggested to interfere with neural representations of reward processing [85].

In contrast to emotional conflict, semantic conflict is provoked, for example in the colour-word Stroop or the face-word Stroop task [101], where semantically relevant distractors (that is, colour words or emotion words) compete with target stimuli (that is, print colour or faces with emotional expressions, respectively). To the best of our knowledge, there is currently no published study on the neural correlates of semantic conflict resolution in BPD. Though there is limited evidence for significant slowing in the colour-word Stroop task [102], we are not aware of a study testing interference with task-relevant emotional stimuli in BPD patients (utilizing the face-word Stroop task).

In summary, though several studies found neural differences in emotional conflict processing in BPD, no consistent picture can be derived from the literature. Behaviourally, though significant interference of emotional material with working memory was found, BPD patients did not show distraction effects in the majority of tasks. Negative findings may also relate to low robustness of the 'emotional Stroop' effect [89].

Response control

The ability to inhibit a prepotent response can shed light on impulse control. Impulsivity is not assumed to be a unitary construct; thus, different facets of impulsivity have been investigated, using both behavioural experiments and self-assessment instruments, in BPD (for a review, see [103]). Subjects are required to withhold a prepotent behavioural response (usually a button press) to perform a correct action, while neural responses are measured. Jacob *et al.* [104] reported lower inferior frontal cortex (IFC) and higher subthalamic nucleus activation in BPD patients, compared to controls, after anger induction. The authors discussed this in terms of increased neural inhibitory activity of the IFC and compensatory subthalamic activity in BPD. However, behavioural data did not reveal group differences. When BPD patients were confronted with face stimuli showing affective expressions, increased brain activations were observed in task-related (parietal, basal ganglia, middle inferior OFC, hippocampus) and emotion-related (amygdala) brain areas [90]. This reflects task-dependent differences in the recruitment of neural circuits, perhaps due to increased proneness to cognitive interference from emotional distraction. In face of affective vs neutral words, which were used as distracting stimuli while subjects performed a response control task, BPD patients decreased responses in the subgenual ACC, posterior medial OFC, and posterior ACC, relative to healthy controls [97]. Conversely, patients increased responses in the lateral OFC and dlPFC, among others. There are major differences in methods and stimulus material in the latter two studies, limiting comparability. Nonetheless, they both support altered brain activations in response control in BPD patients when confronted with emotional material. With a stress induction procedure, which might more potently affect information processing

systems in BPD, Cackowski and colleagues [105] found patients to make more response errors relative to a no-stress condition.

With EEG, Ruchow *et al.* [106] observed a reduced late positivity (P300) in BPD patients to events when subjects had to withhold a prepotent response. Conversely, no differences, compared to healthy controls, were found in the earlier N200 component. In addition, a negative correlation of the P300 component was found with cognitive impulsiveness and depressiveness in patients. The authors concluded that P300 findings point to altered response inhibition in BPD related to impulsivity and depression. On the other hand, unchanged N200 responses are in favour of intact conflict resolution. Behaviourally, no differences between patients and controls were observed. The most recent neuroimaging work found neither neural nor behavioural differences between unmedicated BPD patients and matched healthy controls in tasks probing action withholding, response interference resolution, and stop signal reactions [107]. Further, no correlations with self-assessments of impulsivity and task data were found.

In conclusion, the literature does not reflect a general impairment in the ability to control or stop actions in BPD (for reviews, see [103,107]). Cumulative evidence demonstrates that emotional provocation can deteriorate response withholding on the behavioural and neural levels in BPD.

Closing remarks

Neuroimaging work has contributed to a better understanding of the psychophysiological correlates of personality disorders. Existing research has resulted in a comprehensive picture of the neurobiology of altered emotion processing and emotion regulation. This is fundamental for understanding BPD psychopathology, although the neural mechanisms are probably not unique to this disorder.

Hyper-responsiveness to social cues in BPD is underscored by neuroimaging studies, providing support for altered activations in the brain's attention and salience systems. Research has started to illuminate the neural basis of empathy, cooperation, and aggression in BPD. Current findings are congruent with socio-psychological models; however, neuroimaging studies in social interaction research in BPD are still sparse. As discussed previously, integration of these findings into bio-behavioural models of dysfunctioning may result in a more complete picture to guide future research.

Diverse areas of executive functioning have been explored by BPD researchers such as decision-making, learning, cognitive conflict management, and response control. Taken together, many studies using tasks that are thought to tap into aspects of BPD psychopathology (for example, impulsivity, disinhibition, risky choice behaviour, emotional learning) lack positive behavioural findings, although they produce neural effects. In addition, the latter sometimes seem inconsistent in the aggregate. Furthermore, neuroimaging research in many areas of executive functioning in BPD is rare. In light of this, we currently do not have a clear picture on how neuroimaging findings relate to behavioural dysregulation in general in BPD.

Treatment and management of personality disorder

Giles Newton-Howes and Roger Mulder

Introduction

The management of personality disorder remains a complex and challenging, but increasingly recognized and potentially rewarding, area of psychiatric practice. Our understanding of personality, personality disorder, and its interactions with mental state disorders continues to develop, and alongside this, understanding of mechanisms of management has also developed. Personality disorder is discussed in multiple places in this textbook, and some of the interventions described here are developed in greater detail elsewhere, being general interventions for a wide array of presentations, as opposed to personality disorder itself. Nonetheless, collating these into one chapter provides an overview of the current state of the evidence in the management of personality disorder and the influence of personality pathology in those with comorbidities. Before we examine the current state of the literature, it is important to consider its potential shortcomings. This allows for a balanced understanding of the evidence base and its applicability to day-to-day clinical practice.

Difficulties with clinical interpretation of the literature

All medical evidence is open to criticism. However, as the complexity of problems being addressed increases, the need to understand the limitations of the evidence without discarding it increases. The difficulties in interpreting the evidence base for the treatment of personality disorders is considered under four headings: population studied, treatment duration, comorbidity, and outcome measures used.

Population studied

Ideally, to allow translation of clinical trials to standard clinical practice, it is important for the study population to mirror the clinical population to which it is to be applied. This presents difficulties in the interpretation of personality disorder trials for numerous

reasons. Importantly, there are no long-term, robust studies of the epidemiology of personality disorder in a general population. This makes the interpretation of trials difficult. We do not know what the natural progression of personality disorder is in the community. This is not to say there are no data to act as a guide, but simply the data that exist require interpretation with caution. The Children in the Community study [1], based in New York state and initiated in 1975, has tracked the course of around 800 children over longer than a 20-year period. However, the inclusion of personality considerations occurred late with a 'constructed' measurement of uncertain validity, and no data were published from this study in relation to personality disorder for 18 years after its initiation [2]. The McLean Study of Adult Development (MSAD) [3] provides valuable information on the trajectory of borderline personality disorder (BPD). The Collaborative Longitudinal Personality Disorders Study (CLiPS) [4] follows the course of avoidant, obsessive-compulsive, borderline, and schizotypal personality disorders, but again broader issues as to the value of categorical diagnoses and the capacity to translate these data into other cultural settings provide at best a coarse backdrop from which to compare intervention studies.

Treatment duration

For most mental state disorders, it is relatively clear about the duration over which to demonstrate the efficacy of a particular intervention, largely due to an understanding of the natural development of the disorder. In the case of personality disorder, since chronicity is a core feature of the condition, much longer time frames are needed than in many other disorders. Previously, periods of 2–3 years have been suggested. However, it is not clear how long is really needed. This problem is made more difficult by the relative instability of the categorical personality disorder diagnoses over time [5]. It is also clear that, in following those with categorical diagnoses longitudinally, there is a natural progression of the disorder, with many no longer reaching diagnostic criteria without targeted interventions [6]. It is not clear whether this translates into problem resolution [7]. This evidence suggests that larger numbers will be required for

trials to show an effect (taking into account the potential natural resolution of some participants) conducted over a time frame that takes this natural variation into account. It also suggests studies should examine treatment effect over variable time frames, to assess the duration of treatment needed to accelerate symptom remission. Therapy studies of one [8] or more [9] years have been conducted; however, few brief interventions have been considered. For those that have, they have not reported benefit, although understanding the reasons for this is complex. What is clear is that for a treatment to be considered useful, it needs to show improvement greater than would be expected from the natural history of the disorder; the improvement needs to be sustained, and follow-up should be able to find evidence of continued effectiveness in a real-world clinical setting.

Consideration also needs to be given to the natural history of personality development and the place of extremes of personality that cause distress, namely personality disorder. It is clear that personality develops and continues to do so throughout the life course, and this needs to be considered when the outcomes of trials on management are considered. This is most clearly highlighted by work that identifies personality disorder in adolescence and its specific treatment [10]. The personality disorders that garner the most clinical (and research) attention are externalizing, and these disorders tend to peak in mid life where the bulk of the literature into interventions is focused, improving from the fourth decade onwards. Later in life, paranoid, schizoid, and schizotypal presentations become increasingly apparent. The literature is starting to recognize this better [11], as well as the problems associated with it [12], although there has been little work on the management and treatment of later-life personality disorder.

Comorbidity

Comorbidity is 'the presence of any distinct clinical entity that has existed or that may occur during the clinical course of a patient who has the index disease under study' [13]. The key word here is 'distinct', identifying two separate disorders that are distinct and not causally related in any way. Co-occurrence ranges from comorbidity to the presence of the same disorder in two or more differing forms [14]. Historically, personality disorder itself has been questioned as a diagnostic entity, with some suggesting it is 'an adjective in search of a noun' [15]. Frustratingly, comorbidity (or consanguinity) is the norm in personality disorders, both with other personality disorders [16] and with mental state disorder [17]. This may relate to the categorical constructs used to artificially separate normal from abnormal personality. In deciding the efficacy of a treatment for personality pathology, it would be useful to examine the intervention in a population without comorbidity. However, this is difficult, with a rate of BPD without comorbidity of as low as 5% [18] and no clear indication of the rates of comorbidity for other personality disorders. This comorbidity implies undertaking efficacy studies for the management of personality disorder is difficult to impossible, and the trials described in the following sections are, in effect, effectiveness trials. While this has the advantage of clinical applicability, it leaves open the question as to whether the intervention is impacting primarily on the personality disorder or the comorbid condition. It may be more sensible to consider personality function in this

regard—an intervention may not lead to a change in personality *per se*; however, the functioning of the individual may markedly change on the basis of changes in the environment, mental state changes, or cognitive consideration of the person's internal world [19].

Outcome measures

Understanding the most appropriate outcome measure in personality disorder trials is also problematic. Personality disorders that come to the attention of psychiatric services cause problems for an individual in their internal world, in their relationships with others and society in general. These are all potentially outcome targets to measure. Forensic clinicians generally consider social measures of the most importance (for example, reoffending), and this measure is often considered the most important by the general public. Although such measures offer a clear outcome target, there are so many potential confounders that it may well not reflect personal or personality change at all. Change in psychopathology is the most common measure in most psychiatric trials but may be inappropriate due to the likely presence of comorbid mental state disorder, as well as the reorientation of psychiatric services towards a recovery focus of care that minimizes the importance of symptoms over improvement in psychosocial functioning [20]. Direct use of repeated measures using personality assessment tools is also beset by problems related to the instability of these tools over time and the natural development of personality through the life course [21]. Currently, there is no agreed outcome measure in personality disorder trials, requiring careful consideration of each trial on its own. This problem needs to be kept in mind when considering meta-analyses or overviews that combine multiple trials in an effort to overcome the power problems described previously. It is probably best to have a range of outcome measures, being mindful of their shortcomings and examining for areas of convergence that may reflect more closely actual change.

Taxonomic issues

Overarching all of the issues described previously when considering the literature related to the treatment of personality disorder is the issue of diagnosis and the use of the term 'personality disorder'. The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) and the *International Classification of Diseases*, tenth revision (ICD-10) take a categorical approach to the definition of personality disorder. This is not based on in a single theoretical construct, the empirical literature, or clear divisions in the epidemiological data to suggest a set number of discrete entities. These problems may go some way to explaining the difficulties in the utility of categories that experts agree neither are helpful nor reflect empirical understandings of personality [22]. Trials of interventions are heavily skewed towards BPD and antisocial personality disorder, and care is needed not to assume the heuristic that the weight of evidence (of varying strength and quality) implies these categories are more biologically based or amenable to intervention than other conceptualizations of personality. Rather these categories cause the most social distress and the greatest economic burden for society, focusing research on them for these reasons. The recently published ICD-11 has moved away from traditional personality disorder

categories [23]. Clinicians can now describe the severity of core personality dysfunction (mild, moderate, or severe) when describing personality disorders. The ICD-10 specific personality disorders are abandoned entirely in favour of five broad trait domains based on the scientific literature on personality: negative affectivity, disinhibition, dissociality, detachment, and anankastia. A borderline specifier was also added to enhance clinical utility and continuity. The utility of assessing core personality functioning is supported by research showing that severity is more predictive of clinical outcomes than specific personality disorder categories [23a]. The range of behaviours described by the domains may encourage treatment studies to venture beyond BPD into patients with detachment or anankastic symptoms.

Psychotherapies

Psychological treatment is now clearly recognized as the most appropriate primary intervention for the treatment of BPD, and this is identified in national guidelines [25]. The evidence discussed later in this chapter is related to BPD unless stated otherwise. Although the evidence is much weaker, a similar approach is recommended for other personality pathologies. A broad spectrum of psychotherapeutic approaches have been tried, from strict behavioural approaches, through psychoeducation and supportive therapy, to analytic therapy. A recent Cochrane review identified more than 15 modalities of therapy trialled in BPD alone [26]. These have been trialled in inpatient, outpatient, and partial hospitalization settings. Length of therapy and therapy mix (individual, group, and mixed individual and group) are also variable and often based on therapist choice or model adherence, as opposed to robust clinical evidence. The UK's National Institute for Health and Care Excellence (NICE) recommends a mixed-therapy approach for patients with BPD, but little other guidance is available. Often the key determinant is resource provision, heavily working against high cost services, such as traditional therapeutic communities, and significantly advancing treatments that reduce hospital presentations or admissions, as opposed to functional recovery. It is worth noting that the overall evidence for the effectiveness of psychotherapies is low, with the likelihood that well-designed randomized controlled trials (RCTs) in the future may lead to significant changes in clinical practice. A recent systematic review and meta-analysis concluded that psychotherapies are effective for BPD. However, effect sizes were small, inflated by risk of bias, and unstable at follow-up [26a].

Cognitive therapies

Cognitive behavioural therapy for personality disorder (CBT-PD) [27, 28], dialectical behaviour therapy (DBT) [29], and schema-focused therapy (SFT) [30] are the three largely cognitively based psychological interventions that are most researched. They have in common an attempt to integrate biological and social factors, linking past experience and relationships with current difficulty and testing out mechanisms in the 'here and now' to normalize dysfunctional behaviours and emotional responses.

Cognitive behavioural therapy (CBT) was originally developed for the treatment of depressive disorder, designed to help the

patient identify and modify dysfunctional thoughts and beliefs through the use of specific techniques such as Socratic questioning. Although therapy relies on an understanding of development, the focus of therapy is 'here and now', with symptomatic relief of central importance. CBT-PD expands this narrow window regarding problems as originating in the temperament of the child, development, and early experience. These experiences, particularly early attachment experiences, shape the style of interpersonal relatedness in adulthood and ongoing emotional and behavioural responses. With this in mind, one of the primary tasks of CBT-PD is to gain a solid understanding of childhood experience and the development of a shared formulation to link past difficulties with present problems. This understanding is then used to identify core beliefs and consequent behavioural patterns and emotional responses that are maladaptive. The meaning and content of these beliefs are explored, as well as their basis in negative early experience, possible neglect, and abuse. These experiences are likely to have led to difficulties in self-esteem, hypersensitivity to criticism, and difficult interpersonal relationships. Once these patterns are identified, the therapist and patient develop strategies to test them out in the present and learn new, more adaptive patterns of response. The emphasis may be cognitive (for example, 'How can I think about myself in positive terms and collect evidence that supports this perspective?') or behavioural ('When I feel criticized, I will not retreat and cut but ask the question, "Can you explain that to me?" to gain a better understanding of the other person's perspective') [31]. Compared to CBT for mental state disorders, CBT-PD generally takes longer, places significantly greater importance on the maintenance of the therapeutic relationship, and uses experiences occurring in the therapeutic relationship as 'microcosmic' examples of experiences occurring in the real world. The logic behind this is the more ingrained and pervasive cognitive and behavioural patterns found in personality pathology would be expected to take longer to work through and are pervasive enough to be expected to occur in the therapeutic relationship. There is evidence of effectiveness in this approach [32].

DBT is a form of CBT linked to skills training and detached (or radical) acceptance conceptualized as mindfulness. DBT was one of the first therapies formally tested for its benefits in patients with BPD [33] and has been the subject of more RCTs than any other treatment for BPD. Working from a basis of assuming BPD is primarily a dysfunction of emotion regulation based on biology and early environment, patients become emotionally vulnerable, struggling to regulate patterns of responses associated with emotional states. This leads to maladaptive behaviours and maladaptive problem-solving strategies. As the name implies, DBT has an implicit embracing of opposites, for example an acceptance of how things are and a drive to change, directed through therapy. From a working perspective, the essentials of DBT include: (1) manualized weekly individual therapy sessions; (2) group psychoeducational behavioural skills training; and (3) telephone coaching. The focus is on problem-solving skills, emotion regulation techniques, distress tolerance, validation, and mindfulness. Therapists also meet weekly to discuss therapy progress, share problems, and ensure therapy adherence [29]. Nine RCTs have examined the effectiveness of DBT and summarized in a Cochrane review [26]. These showed DBT is beneficial in reducing anger and self-harm and generally improving overall functioning for patients with BPD.

SFT has been trialled in two RCTs, one of which importantly is a head-to-head trial against transference-focused therapy (TFT) [30]. Building on CBT, SFT expands the basic notions of cognitions affecting behaviours and affects to include considerations from object–relations theory, in particular. There are assumptions of maladaptive schemas developed early in life that lead to maladaptive interpersonal relatedness in adulthood. This leads to individual therapy sessions, with a focus on understanding and redressing maladaptive schemas and elements of CBT (and gestalt) to adapt or replace maladaptive coping styles. Techniques focus on the patient–therapist relationship with SFT, describing a ‘limited reparenting’ role for the therapist. Some describe SFT as an integrative psychotherapy, as opposed to a predominantly cognitively based therapy. The study of Giesen-Bloo and colleagues showed advantages of SFT over TFT in most domains related to BPD.

Dynamic therapies

Transference-focused therapy [34] and mentalization-based therapy (MBT) [35] are the two dynamically oriented therapies that have been trialled for the management of BPD. Although very different in approach, both are based on an understanding of the influence of the unconscious on the presentation of patients in their therapy. They utilize this understanding of the unconscious to enable the patient to develop insight into their difficulties, enabling change.

MBT [35] was specifically designed as therapy for patients with BPD, conceptualized as a problem of disorganized attachment and subsequent failure to mentalize. Mentalization is the capacity to interpret action and derive an internal meaning for it. This is the basis of relationships (and understanding of self), and developing this enables normalization of the emotional difficulties (neither too intense nor too detached) and behaviours of those with BPD. Having stabilized emotional expression in the initial stages of therapy, the primary aim of all therapy is to increase mentalization, this being more important than the ‘task’ orientation of cognitively based therapies (be they cognitive or behavioural tasks). This requires a ‘not knowing’ stance that accepts the various positions of the patient and focuses on description (‘What is going on for you now?’), as opposed to understanding (‘Why are you doing that?’). It is important for the therapist to be mindful of their own mentalizing stance throughout therapy. MBT has been trialled in both partial hospitalization [36] and outpatient [37] settings and shown to be effective in BPD.

TFT is also designed to manage the problems of BPD and developed from the object–relations model of borderline personality organization [38]. It assumes internal and unconscious conflict exists between internal representations of both self and others, and this leads to emotionally unstable relationships. These distorted internal representations emerge in the process of therapy in a classic transference style of understanding and interpretation. This is a major intervention designed to lead to internal change and also (ultimately) behavioural change. The end-goal of TFT, like all psychotherapy for BPD, is amelioration of symptoms, reduction of non-suicidal self-harm, and improved relationships. TFT is a long-term individual therapy, as long as twice-weekly sessions for 3 years, and works at containing dangerous behaviours, managing behaviour that impairs therapy, and synthesizing the ‘split-off’ part of self into an integrated whole. Although there is evidence of effectiveness, this is a

time-intensive treatment and has been shown to be inferior to SFT in a head-to-head trial.

Other structured therapies

Interpersonal therapy (IPT) has been modified for application in patients with BPD on the basis of efficacy of IPT in patient with depression and comorbid BPD. A small trial has suggested this may be of benefit [39] but needs replication. Systems Training for Emotional Predictability and Problem Solving (STEPPS) is aligned with cognitive therapies, but largely psychoeducational. It is a structured programme of 20 2-hour weekly group sessions, with a learning goal to be derived from each session. Evidence of effectiveness exists [40]. Cognitive analytic therapy has also shown weak evidence of effectiveness in adolescents with personality disorder and traits [41], and this well-constructed trial is important not only for its evidence of effectiveness, but also for clearly displaying the utility of a BPD diagnosis in adolescence.

Social therapies

Social therapies were the traditional mainstay for the management of personality disorders, bridging the time of development of pharmacotherapies and implementation of modern psychotherapies. Personality disorders do, by definition, cause significant distress to the community, and it is perhaps not surprising that efforts to consider alternative community settings were thought to be the best approach. In general, they recognize the influential elements of natural communities and aim to use these communities and the environment into the tools for change. Although these approaches are used considerably less today, they remain an important element of the overall bio-psychosocial management armory and should be considered for the most severe and disruptive patients with personality disorder. Notably, the therapeutic communities described in the following paragraphs are not those utilized by correctional services in the United States, although they have at times been considered in this light.

Therapeutic communities have been described variously, although their modern context was defined and described by Maxwell Jones [42], who created a structure that ran counter to the traditional mental hospital. This can be defined as a socially cohesive structure, depending on intensive group treatments carried out by the residents who are involved in treatment in a democratic way. These communities have a strong historical basis for their effectiveness but are complex, long-term interventions and, as such, are expensive to run and difficult to assess, particularly compared to manualized psychotherapy or pharmacotherapy. Nonetheless, there is some evidence for their effectiveness in personality disorder, although there are no RCTs that have been completed.

Nidotherapy is a novel social therapy described as ‘the collaborative systematic assessment and modification of the environment to minimise the impact of any form of mental disorder on the individual in society’ [43]. It was developed and trialled with personality disorder as a central focus, in association with other comorbid mental state disorders [44]. Interestingly, this ‘add-on therapy’ does not aim to directly change psychopathology; rather it focuses on developing a better ‘fit’ between an individual and their environment. It is normally

carried out by a nidotherapist working independently from other clinical services, while liaising with them. There is some RCT evidence this form of therapy may lead to cost savings and improvements in social functioning, the therapy's natural target endpoints [45].

Pharmacotherapies

The rationale for using drugs in the treatment of personality disorders is that some of the behaviours associated with personality disorders may reflect disordered neurochemistry [46]. The poor empirical basis for the creation of the individual personality disorders in DSM-III, their heterogeneity, and the absence of evidence to support drug treatment of specific personality disorders have led researchers to largely ignore the DSM categories and to focus on dimensions of psychopathology. The algorithm generally used to study drug effects was proposed by Siever and Davis [47] and further developed by Soloff [48]. It suggests that four dimensions— affective instability, anxiety inhibition, cognitive-perceptual disturbances, and impulsivity aggression—cut across all personality disorder categories and that drug treatment effects on these dimensions should be studied, rather than on individual personality disorders. Although heuristically appealing, little evidence exists to support their validity. The dimensions have never been tested in hypothesis-driven studies [49]. In addition, although the algorithm was designed to study behaviours across all personality disorder categories, most clinical trials have used participants with BPD. A systematic review reported that over 70% of all drug trials used subjects with BPD [50]. The review also noted that most trials were underpowered, with a mean of 22.4 participants in the treatment group and 19.3 in the control group, were of short duration, averaging 13.2 weeks, and had a wide range of outcome measures [50]. Finally, we should note that many studies were sponsored by the pharmaceutical industry.

Cluster A personality disorders

Studies have focused on the drug effect on cognitive perceptual disturbances in this population. Patients with schizotypal personality disorder have been studied in a few small, usually open-label studies using dopamine antagonists [51]. Patients showed some improvement in overall symptom severity, but the risk-to-benefit ratio appears poor. No RCTs for patients with schizoid or paranoid personality disorders have been undertaken, and therefore, no robust evidence about the efficacy of drugs in these patients is available at present.

Cluster B personality disorders

As previously noted, most evidence for the use of drugs in patients with Cluster B personality disorders have been derived from studies on subjects with BPD, using the Siever and Davis algorithm [47]. This has led to a number of recommendations which are confusing and, at times, contradictory. Some guidelines advocate symptom-targeted pharmacotherapy, based on Siever and Davis' dimensions, while others state drug treatment should be avoided generally in patients with BPD.

The American Psychiatric Association (APA) guideline [52] states that symptom-targeted pharmacotherapy is an important adjunct treatment. It suggests that affective instability is treated with selective serotonin reuptake inhibitors (SSRIs) or monoamine oxidase inhibitors (MAOIs), impulsive aggression with SSRIs or mood stabilizers, and cognitive-perceptual disturbances with low-dose dopamine antagonists. The World Federation of Societies of Biological Psychiatry guidelines [53] state that moderate evidence exists for dopamine antagonist drugs being effective for cognitive-perceptual and impulsive-aggressive symptoms, some evidence exists for SSRIs being effective for emotional dysregulation, and there is some evidence for mood stabilizers being effective for emotional dysregulation and impulsive-aggressive symptoms. The most recent Cochrane review [54] partially contradicted these guidelines, reporting no evidence for the efficacy of SSRIs, but did report that mood stabilizers could diminish affective dysregulation and impulsive-aggressive symptoms in patients with BPD and antipsychotics could improve cognitive-perceptual symptoms and affective dysregulation.

In contrast, the UK NICE guidelines [55] state that drug treatment should generally be avoided, except in a crisis, and then given for no longer than 1 week. More recent guidelines for the treatment of BPD from the Australian National Health and Medical Research Council (NHMRC) [56] again reviewed the literature, including conducting a series of meta-analyses. It concluded that pharmacotherapy did not appear to be effective in altering the nature and course of BPD.

These apparently contradictory recommendations may reflect the weight given to risks, as well as benefits, of drug treatment. Both NICE and NMHRC Committees acknowledged evidence existed that some dopaminergic drugs (notably aripiprazole and olanzapine) and mood stabilizers (notably topiramate, lamotrigine, and valproate) may reduce BPD symptoms over the short term. They concluded that substantial long-term risks did not justify recommending these drugs when alternative psychosocial interventions do not carry such risks.

A pragmatic compromise may be to acknowledge the real concerns about using drugs in this population and be guided towards using drugs with at least some evidence of efficacy, using them sparingly and for short periods. The current evidence [57] would suggest using dopamine antagonists/partial agonists and mood stabilizers, rather than SSRIs, tricyclic antidepressants, and benzodiazepines. However, a recent large, well-conducted RCT testing lamotrigine for BPD reported no evidence for its efficacy or cost-effectiveness [57a]. A more radical view, articulated in the NICE guidelines [55], is that if patients have no comorbid illness, efforts should be made to reduce or stop pharmacotherapy.

Drug treatment of antisocial personality disorder has almost no evidence base [50]. The NICE guidelines for antisocial personality disorder concluded that pharmacological interventions should not be used routinely for the treatment of antisocial personality disorder or its associated behaviours. However, NICE states that drugs can be used for comorbid mental disorders. A recent meta-analysis by Khalifa and colleagues [58] reached similar conclusions.

Cluster C personality disorders

No RCTs have been published of drug treatment for patients with Cluster C personality disorders. However, the World Federation

of Societies of Biological Psychiatry guidelines [53] suggests that studies in patients with social phobia, which reported that drugs for depression are superior to placebo, might be evidence that these drugs are effective in patients with avoidant personality disorder.

In summary, the evidence base for psychopharmacology in patients with personality disorders is poor. Drug treatment should be used sparingly for short periods, with careful consideration of risks and benefits. Hopefully, more useful drugs may become available. For example, targeting *N*-methyl-*D*-aspartate signalling pathways, which have effects on disinhibition, social cognition, and dissociative symptoms, has potential [59]. There is a suggestion that opioid modulation is a possible mechanism for treatment [60, 61] and oxytocin is associated with prosocial behaviour [62]. However, small open trial results have been mixed [62, 63]. We still have a long way to go.

Managing risk or managing needs?

In addition to interventions designed to alter the trajectory of personality disorder, a service orientation towards recognizing this problem and ensuring a seamless service is considered important. This needs to take into account the risks presented, while recognizing the limitations in the evidence for effective interventions, and not inadvertently positively reinforcing unhelpful or dangerous behaviours. For example, if hospitalization is the default response to non-suicidal self-injury and a patient with severe personality disorder is struggling in the community, there is a risk that they will self-harm in order to gain access to an inpatient ward. Developing a plan with the patient, which recognizes these difficulties, is important to ensure the patient, services, and the wider community that may be involved (for example, police and paramedical staff) are clear as to the best approach in difficult situations. Providing a consistency of response allows for a patient with personality disorder to develop an understanding of boundaries and balances long- and short-term risks. Constancy in personnel further allows for an understanding of behaviour driven by long-term traits and the more acute psychopathologically driven behaviours. This sort of conceptualization and understanding of the purpose of behaviour reflects what is known of personality disorder in regard to its structure [3, 64].

Conclusions

Although the management of personality disorder remains in flux, much progress has been made over the last decade. Increased clarity associated with an improved understanding of taxonomy has opened the door to the development of novel trait-based psychotherapeutic interventions. The importance of psychotherapy as the primary intervention of value, particularly in BPD, has been strengthened and the relatively limited place of pharmacotherapy is clearer. The potential for 'add-on' therapy, such as STEPPS or nidotherapy, is also clearer. Having said this, there remains little evidence to guide any but BPD treatment. The evidence for antisocial personality disorder treatment suggests little leads to long-term change. Almost nothing is known as to the effectiveness of interventions for other categorical diagnoses. Added to this, it is likely that ICD-11 will take a radically different approach to diagnosis from that of DSM-5, and this

opens the door to both confusion and improved study of personality problems. In the future, well-designed large randomized or complex trials with novel findings are likely to lead to significant changes in clinical practice, suggesting the current evidence is at best weak. Despite the significant steps forward, clarity about the limits of the evidence and the need for $n = 1$ trials with our patients remain important. Acknowledging the changes in personality through the life course [21] and the need to be cognizant of our limits and expertise ensures we will be able to help patients with personality disorder, without overstating the current state of the evidence.

Impulse-control and its disorders, including pathological gambling

Donald W. Black

Introduction

The hallmark of impulse-control disorders (ICDs) is difficulty with emotional and behavioural self-regulation, as manifested by difficult, disruptive, or aggressive behaviour. Recognized in *Diagnostic and Statistical Manual of Mental Disorders*, third edition (DSM-III) [1] as ‘disorders of impulse control not elsewhere classified’, the category included pathological gambling, kleptomania, pyromania, and both intermittent and isolated explosive disorders. All were unified by the failure to resist an impulse to perform an act harmful to the individual or others, increasing tension before the act, and the experience of pleasure, gratification, or release at the time of the act. They were believed ego-syntonic at the ‘moment of discharge’, but accompanied by guilt or regret afterwards [2]. The chapter continued in DSM-III-R, DSM-IV, and DSM-IV-TR [3]. Trichotillomania was added in DSM-III-R, while isolated explosive disorder was dropped after DSM-III.

The chapter was reorganized in DSM-5 [4], with intermittent explosive disorder (IED), kleptomania, and pyromania continuing in a new chapter called ‘Disruptive, impulse-control, and conduct disorders’. Pathological gambling was moved to the chapter on ‘Substance-related and addictive disorders’ and renamed *gambling disorder*, while trichotillomania was moved to the chapter on ‘Obsessive-compulsive and related disorders’. Oppositional defiant disorder (ODD) and conduct disorder, previously included in the chapter on childhood disorders, were brought into the new chapter, reflecting the view that they too are disorders of self-regulation.

ICDs received limited recognition in *International Classification of Diseases*, ninth revision (ICD-9) [5]. The category ‘Disturbances of conduct not elsewhere classified’ included conditions characterized by aggressive and destructive behaviour. Kleptomania was given as an example of a ‘compulsive conduct disorder’. In ICD-10 [6], the renamed category ‘Habit and impulse disorders’ was expanded to include gambling disorder, pyromania, pathological stealing (kleptomania), and trichotillomania (with IED listed under ‘Other habit and impulse disorders’). These disorders were characterized by repeated acts having no clear rationale.

Despite their historical roots, ICDs were not officially recognized until DSM-III. In the nineteenth century, the French psychiatrist Jean Étienne Esquirol used the term monomania to describe a group of conditions in which people had irresistible urges without apparent motivation [7]. Pyromania was recognized by the nineteenth-century German psychiatrist Griesinger as a ‘morbid impulse’, which drives the person to commit destructive acts. In the early twentieth century, Bleuler wrote about *reactive impulses* that borrowed from Kraepelin’s *impulsive insanity* [8, 9]. Included were pyromania, kleptomania, and compulsive shopping (*oniomania*). More recently, many of these conditions have been described as *behavioural addictions*, characterized by the presence of unrestrained or poorly controlled behaviours arising in the absence of alcohol or drugs of abuse [10].

This chapter discusses the following DSM-5 disorders: ODD, IED, pyromania, kleptomania, and gambling disorder. Trichotillomania is discussed in Chapter 93 on obsessive-compulsive and related disorders. For completeness, the chapter will include a discussion of three non-DSM conditions that involve poorly regulated behaviours: compulsive shopping (CS), Internet addiction, and compulsive sexual behaviour (CSB). Despite its reclassification in DSM-5, conduct disorder is discussed in Chapter 124.

Oppositional defiant disorder

ODD is a diagnosis for persons who exhibit negativistic, hostile, defiant, and disobedient behaviours towards others. ODD is mostly a diagnosis for children and adolescents but may also be used in adults. The diagnosis is made on the basis of angry or irritable, defiant, or vindictive behaviour of at least 6 months’ duration, with a minimum of four of eight symptoms in three categories: angry/irritable mood, argumentative/defiant behaviour, and vindictiveness. DSM-5 [4] considers ODD to be a developmental antecedent for some youth with conduct disorder, thereby suggesting that they may reflect different stages of a spectrum of disruptive behaviours.

ODD was introduced in DSM-III [1] as ‘oppositional disorder’ to characterize those with a negative and disobedient opposition

to authority. The diagnosis received its current name with DSM-III-R. The diagnosis had many commonalities with DSM-II's [11] unsocialized aggressive reaction, a diagnosis used to describe loners with a pattern of hostile disobedience, aggressiveness, stealing, and lying, behaviours thought to result from inconsistent discipline and parental rejection.

The prevalence of ODD has ranged in studies from 1% to 11%, with an average of 3.3% [4]. The disorder is more common in boys than girls prior to adolescence [12]. ODD has a mean age of onset of 6 years and may precede the onset of conduct disorder. Youth with ODD are also at risk for developing mood and anxiety disorders [12, 13]. The defiant, argumentative, and vindictive symptoms carry most of the risk for conduct disorder. Angry/irritable mood symptoms carry most of the risk for internalizing disorders. While all children show oppositional behaviour from time to time, the diagnosis is given to those with frequent, recurrent, and problematic behaviours, for example temper outbursts, arguments with parents or other authority figures, and a refusal to obey orders.

The disorder tends to be stable over time [12]. Boys who develop conduct disorder have higher numbers of ODD symptoms than those who do not. There appears to be a genetic overlap of ODD with other disruptive disorders, including conduct disorder and attention-deficit/hyperactivity disorder.

Other disorders need to be ruled out. Unlike conduct disorder which specifies that the child must have violated personal rights and social rules, ODD is defined on the basis of difficult and disruptive behaviour. Attention-deficit/hyperactivity disorder may be comorbid with ODD but is a diagnosis used in those with problems of sustained effort and attention. ODD shares many features with disruptive mood dysregulation disorder, such as negative mood and temper outbursts, but the severity, frequency, and chronicity of temper outbursts are more severe in children with disruptive mood dysregulation disorder than in those with ODD. (In DSM-5, the diagnosis of disruptive mood dysregulation disorder takes precedence over ODD, if the criteria for both disorders are met.) IED also involves high rates of anger, but people with this disorder show serious aggression towards others that is not part of the definition of ODD.

There has been little neurobiologic research with regard to ODD. One study showed elevated levels of dehydroepiandrosterone sulfate in children with ODD, in contrast to children with attention-deficit/hyperactivity disorder and controls, suggesting to the authors that stress or genetic factors have led to a shift in adrenocorticotrophic hormone (ACTH)- β -endorphin functioning in the hypothalamic-pituitary-adrenal axis. Another study found a specific pattern of single-nucleotide polymorphisms associated with attention-deficit/hyperactivity disorder comorbid with ODD, compared with attention-deficit/hyperactivity disorder alone, especially for measures of argumentative and defiant behaviours.

There is no standard treatment for ODD, but common sense suggests that because most patients with ODD are children, clinical management should emphasize individual and family therapy, with treatment of co-occurring attention-deficit/hyperactivity disorder or other disorders with medications, as needed, such as stimulants, guanfacine, or clonidine [12]. Family-based interventions include parental management training and child problem skills training. The former aims to teach parents to better manage their child's behaviour, as well as to promote desired behaviours. The latter is

cognitively based and aims to help children learn to manage anger, improve problem-solving ability, delay impulsive responses, and improve social interactions. School-based programmes, such as those aimed at resisting negative peer influences and reducing bullying and antisocial behaviour, may also be helpful.

Intermittent explosive disorder

IED was new to DSM-III [1] and included as a diagnosis for those with episodes of verbal or physical aggression grossly out of proportion to the stressor. IED was considered roughly equivalent to DSM-II's [11] explosive personality. A related diagnosis—isolated explosive disorder—was also included in DSM-III and was meant to be used in persons with a single, discrete episode of uncharacteristic aggression. It was dropped from later editions.

In DSM-5 [4], IED is defined by the presence of recurrent behavioural outbursts that are grossly out of proportion to the provocation or stressors, are not premeditated, occur in an individual aged 6 or older, cause distress or functional impairment, and are not better explained by another mental disorder, medical condition, or the effects of a substance. ICD-10 [6] lists IED under 'Other habit and impulse disorders' but does not provide criteria.

People with IED describe their aggressive episodes as brief, explosive, uncontrollable, and unpremeditated, and typically provoked by minor events [14]. They may experience changes in mood, awareness, and autonomic arousal before the outburst. The frequency of episodes depends, in part, on how the disorder is defined. In the National Comorbidity Survey-Replication (NCS-R) [15], whereby DSM-IV criterion A was operationalized as ≥ 3 lifetime attacks, persons with IED had a mean of 43 lifetime attacks. Many people with IED have a history of chronic anger or irritability accompanied by frequent minor episodes. Subthreshold episodes are similar to the anger attacks (sudden episodes of intense anger with autonomic arousal) often described in patients with mood disorders.

Before making the diagnosis, IED needs to be distinguished from Cluster B personality disorders associated with anger outbursts (antisocial and borderline personality disorders), neurocognitive disorders characterized by verbal or physical outbursts, substance abuse and intoxication causing behavioural disinhibition, and the childhood-onset disorders disruptive mood dysregulation disorder, autism spectrum disorder, attention-deficit/hyperactivity disorder, ODD, and conduct disorder. In the case of the childhood-onset disorders, the additional diagnosis of IED may be warranted when outbursts are deemed in excess of those usually seen in the disorders and warrant independent clinical attention.

IED is common in clinical and general population samples, with an estimated lifetime prevalence in the general population of 7.3% [14]. IED is more common in men than women. IED begins in childhood or adolescence and rarely occurs after age 40. The disorder follows a chronic or episodic course and is associated with distress, morbidity (for example, accidents), and social and occupational impairment. In the NCS-R [15], IED had a mean age at onset of 14 years, was persistent over the life course (with averages of 6.2–11.8 years with attacks), and was associated with substantial role impairment. The prevalence of the disorder was much lower in persons aged 60 years and older.

Psychiatric comorbidity is common in persons with IED. In the NCS-R [15], 82% of respondents with IED met criteria for at least one other lifetime disorder, in particular depressive, anxiety, and substance use disorders. It was also significantly comorbid with ODD, conduct disorder, and attention-deficit/hyperactivity disorder.

Family studies suggested that first-degree relatives of people with IED have high rates of impulsive violence, substance misuse, and possibly mood and other ICDs [14]. A blinded, controlled family history study using broadly defined IED criteria found a significantly increased morbid risk of the condition in relatives of affected probands (26%), compared with relatives of control probands (8%).

In terms of neurobiology, people with emotion dysregulation and aggression have been shown to have disturbed serotonergic function [14] and functional abnormalities in both the limbic system and the orbitofrontal cortex. In a functional magnetic resonance imaging (MRI) study of response to social threat [16], ten subjects with IED showed exaggerated amygdala reactivity and diminished orbitofrontal cortex activation to faces expressing anger, compared with controls. The authors noted these findings were similar to other disorders characterized by impulsive aggression, including borderline personality disorder and bipolar disorder, and that they supported a link between a dysfunctional frontal-limbic network and aggression.

There are no standard treatments for IED. Cognitive behavioural therapy has been used, with a focus on anger management [17]. Patients learn to recognize when they are becoming angry and to identify and defuse the triggers that lead to outbursts. One study showed that cognitive behavioural therapy was superior to a wait list in reducing anger and hostility in persons with IED. The programme employed relaxation training, imagery, rebreathing, use of time-outs, and cognitive restructuring.

Medication has been used to reduce or eliminate aggressive impulses [17] in persons with impulsive aggression. The strongest evidence supports the use of selective serotonin reuptake inhibitors (SSRIs) in the treatment of IED. There is some evidence that mood stabilizers and drugs for psychosis may also play a role in reducing anger outbursts in persons with behavioural dyscontrol. Benzodiazepines should be avoided because of their tendency to cause behavioural disinhibition.

Pyromania

Pyromania was first recognized in the nineteenth century, its name coined in 1833 by Marc, a French psychiatrist [3]. He described the disorder as a form of instinctive and impulsive monomania. Griesinger, Bleuler, and Kraepelin, all active at the turn of the twentieth century, considered pyromania a 'morbid impulse' [8, 9, 18]. The disorder was briefly mentioned in DSM-I [19] as a supplementary term but was not mentioned in DSM-II. Pyromania was included in DSM-III [1] and has continued to the present.

DSM-5 [4] defines pyromania as the deliberate and purposeful fire-setting on more than one occasion; tension or affective arousal before the act; fascination with, interest in, curiosity about, or attraction to fire and its contents and characteristics; and pleasure, gratification, or relief when setting fires or when witnessing or participating in their aftermath. Importantly, those who set fires for political motives, out of anger or to seek vengeance, to conceal

crimes, or to improve one's living situation (for example, by claiming insurance benefits) do not have pyromania. Likewise, the fire-setting cannot be in response to a psychosis or to impaired judgement from a neurocognitive disorder or drug of abuse. Thus, an arsonist who sets fires for monetary gain or for political or criminal purposes would not merit the diagnosis. In ICD-10 [6], pyromania is defined as multiple acts of, or attempts at, setting fire to property or other objects, without apparent motive and by a persistent preoccupation with subjects related to fire and burning.

Data show that around 1% of the general population report a lifetime history of fire-setting, though this is only one component of pyromania [20]. A study of psychiatric inpatients found that about 6% had a lifetime history of pyromania [21]. Pyromania is probably more common in men than women and usually begins in adolescence or early adulthood. Mood, substance use, and other ICDs are common in people with pyromania. Fire-setting is considered a poor prognostic sign for children with conduct disorders and is associated with adult aggression [20]. The course of pyromania is unknown, but clinical descriptions suggest that the course of pyromania is episodic and tends to wax and wane.

Before making the diagnosis, the clinician should rule out other causes of intentional fire-setting, including normal developmental experimentation (for example, playing with matches), antisocial personality disorder, and adult antisocial behaviour. Accidental fire-setting, as might occur in a person with a neurocognitive disorder, substance abuse or intoxication, and psychosis, should be ruled out.

There are no standard treatments for pyromania [22]. Much of the literature on the use of psychological treatments has focused on children and includes behavioural therapies, family therapy, and fire education. Case reports have suggested benefit from SSRIs, lithium, topiramate, olanzapine, and valproate.

Kleptomania

Kleptomania has been recognized for nearly 200 years [3]. Bleuler provided one of the first clinical descriptions: 'The kleptomaniacs in the old sense cannot even otherwise resist the impulse of appropriating things ...' ([8], p. 539). The disorder was listed as a supplementary term in DSM-I and was formally included in DSM-III. The disorder has continued to the present.

In DSM-5 [4], kleptomania is defined as the 'recurrent failure to resist impulses to steal objects that are not needed for personal use or for their monetary value'. In addition, there is an increasing sense of tension immediately before committing the theft, followed by pleasure, gratification, or relief at the time of the theft. Importantly, individuals do not steal to express anger or vengeance, or steal in response to hallucinations or delusions. In ICD-10 [6], kleptomania (or pathological stealing) is defined as the repeated failure to resist impulses to steal objects that are not acquired for personal use or monetary gain.

Kleptomania prevalence is unknown, perhaps because individuals rarely report their symptoms. A survey of the adult general population in the United States found shoplifting to have a lifetime prevalence of 11% [23], though stealing is only one component of kleptomania. A survey of nearly 800 college students reported a 0.4% current prevalence for kleptomania [24]. Grant *et al.* [21] reported a 9% lifetime prevalence rate in psychiatric inpatients.

People with kleptomania describe irresistible impulses or urges to steal that build until satisfied [25]. They understand their impulses are senseless and intrusive and that their behaviour is wrong. Many try to resist the impulses with varying degrees of success. Stealing itself is accompanied by a 'rush' or 'high', although that feeling dissipates as the potential consequences of the act become apparent. While most stealing is impulsive, some is premeditated. People with kleptomania tend to steal items that they otherwise could afford such as toiletries, make-up, or jewellery. Triggers include feelings of depression, anxiety, or boredom, or sometimes the particular sights, sounds, and objects found within a store. Lying to conceal the stealing is common. Some stop stealing temporarily following an arrest for shoplifting, but the behaviour resumes unfettered for most. A small number of individuals report that they have no memory of the stealing or that it occurs in a dream-like (or dissociative) state. For these individuals, stealing may become automatic.

Clinicians should rule out other causes of stealing before making the diagnosis of kleptomania. Other possible diagnoses include antisocial personality disorder, crime occurring in the context of adult antisocial behaviour, and stealing that may occur in the course of a neurocognitive disorder, mania, or psychosis.

Kleptomania appears more common in women than in men [25]. Many cases begin in the late teens to early 20s and often follow an episodic or a chronic course. By the time patients seek treatment, women are typically in their mid- to late 30s, while men are in their 50s. Clinical studies show that kleptomania often co-occurs with other mental psychiatric disorders, including mood, anxiety, substance use, and eating disorders (particularly bulimia). Kleptomania may also be associated with compulsive shopping.

Family study data are limited, but studies suggested that people with kleptomania have first-degree relatives with high rates of mood disorders, obsessive-compulsive disorder, and substance use disorders [25].

Kleptomania may be associated with serotonergic and frontal lobe dysfunction, as evidenced by reduced [3H] paroxetine binding (a peripheral marker of serotonin function) found in a mixed group of 20 people with obsessive-compulsive-related disorders, including five with kleptomania [26]. In another study, ten women with kleptomania were more likely than controls to have decreased white matter microstructural integrity in the inferior frontal brain regions when evaluated with diffusion tensor imaging [27].

While there are no standard treatments for kleptomania [25], various forms of cognitive behavioural therapy have been recommended. Case reports and open-label studies have reported on the use of SSRIs, topiramate, and naltrexone. Interestingly, there are also case reports of persons treated for depression with SSRIs who subsequently developed kleptomania [28]. In a randomized controlled trial (RCT) [29], naltrexone produced significant reductions in stealing urges and behaviours, compared with placebo. Common wisdom suggests that a self-imposed ban on shopping in an attempt to head off potential thefts may help curb stealing, but this may not be sustainable.

Gambling disorder

Recognized by both Kraepelin [10] and Bleuler [8], uncontrolled gambling was included in DSM-III [1] as pathological gambling

within the chapter 'Impulse-control disorders not elsewhere classified'. In DSM-5 [4], the disorder was moved to the chapter on 'Substance related and other addictive disorders', a change made because of growing evidence of its relationship with alcohol and drug use disorders. The name was changed to *gambling disorder* (GD), in part, because of the stigma from the word 'pathological' [3]. ICD-10 [6] includes pathological gambling, which is defined as frequent and repeated episodes of gambling that dominate the person's life to the detriment of their functioning.

GD prevalence is estimated at 1.6% of the general population, but the prevalence of subclinical GD ('at-risk' gambling) is much higher at nearly 4% [30]. Gambling behaviour typically has an onset in adolescence, with GD developing by the late 20s for men and early 40s for women [31]. GD affects more men than women and progresses more rapidly in the latter, a phenomenon also observed in alcoholic persons [32]. Risk factors include a history of mental illness or substance misuse, lower levels of education, and ethnic and racial minority populations. Family and twin data show that GD is familial and has a heritable component shared with substance addictions. In a large family study involving over 1200 subjects, rates of lifetime pathological gambling were significantly greater among the first-degree relatives of people with pathological gambling (11%) than among control relatives (1%) [33].

Substance use, mood, and anxiety disorders are common in persons with GD [31]. Personality disorders are frequent, particularly the antisocial and borderline types. Compulsive shopping commonly occurs in women with GD, and the disorders run in the same families [34].

The most widely discussed clinical distinction among gamblers is that of 'escape-seekers' and 'sensation-seekers' [35]. Escape-seekers are often older persons who gamble out of boredom, to alleviate depression, or to fill time. They tend to choose passive forms of gambling such as slot machines. Sensation-seekers are younger and prefer the excitement of card games or table games that involve active input. Another model posits the existence of three subgroups of GDs: (1) behaviourally conditioned gamblers without predisposing psychopathology but who make bad judgements regarding gambling; (2) emotionally vulnerable gamblers with premorbid depression or anxiety, and a history of poor coping; and (3) impulsive gamblers who are highly disturbed with features of antisocial personality disorder [36].

GD is described in DSM-5 as chronic and progressive, though recent data have challenged the notion that GD is intractable. Instead, most GD subjects improve during follow-up, as evidenced by fewer gambling behaviours and less preoccupation [37].

Functional MRI and other technologies showed that the neurocircuitry mediating GD is similar to those seen in substance addictions [38]. The involvement of reward circuitry has also been strongly suggested by research showing that dopamine agonist medications for Parkinson's disease have led to the development or exacerbation of GD in some persons [39]. Dopamine is widely considered the neurotransmitter most involved in reward-based neurocircuitry.

While few persons with GD seek treatment, cognitive behavioural therapy and motivational interviewing are effective [40]. Gamblers Anonymous (GA), a 12-step programme patterned after Alcoholics Anonymous, is often helpful and chapters are widely available. Self-exclusion programmes in which gamblers agree not to enter a casino

can be helpful. RCTs have shown naltrexone and nalmefene (not available in the United States) to be effective in reducing gambling behaviours and urges. SSRIs have also been studied, but RCTs have shown little effect [41].

Compulsive shopping

Compulsive shopping (CS) has been recognized for over 100 years, including descriptions from Kraepelin [10] and Bleuler [8]. Despite this rich history, CS attracted little attention until interest was revived in the late 1980s and early 1990s by consumer behaviour researchers and clinicians interested in compulsive behaviours [42–44]. CS is not included in DSM-5 or ICD-10.

McElroy *et al.* [43] have published diagnostic criteria that have become standard in the research community. They require the presence of cognitive and behavioural aspects of CS and impairment from both subjective distress and interference in social or occupational functioning or from financial or legal problems. The criteria require that the disorder does not co-occur with mania or hypomania.

The prevalence of CS has been estimated at nearly 6% [45]. The disorder has shown a female preponderance in nearly all clinical and epidemiologic studies. CS has an onset in the late teens or early twenties that appears to correspond with emancipation from the nuclear family and establishing credit [46]. CS occurs mainly in developed countries, probably due to the availability of consumer goods and disposable income. Interestingly, after Germany reunified in 1989, the prevalence rate of CS increased, presumably due to the influx of goods into the former East Germany, combined with increased income [47].

Psychiatric comorbidity with substance use, mood, anxiety, personality, and eating disorders and other ICDs is common. Research suggests that CS is familial and co-aggregates with mood, anxiety, and substance use disorders [46]. CS has been considered chronic or episodic, but a recent study showed that CS behaviours diminished during a 5-year follow-up [48].

The hallmark of CS is a preoccupation with shopping and spending [46]. People with CS spend many hours each week engaged in shopping and spending behaviours, often preceded by increasing tension or anxiety relieved with a purchase. Compulsive shoppers are mainly interested in consumer goods such as clothing, shoes, crafts, jewellery, and make-up. The impact of the Internet on CS behaviour is unclear but could be considerable.

Neurobiologic theories of CS have focused on disturbed serotonin neurotransmission, because of hypothetical similarities between CS and obsessive-compulsive disorder, a disorder treated with SSRIs. Dopamine has been theorized to play a role in 'reward dependence', which has been linked to behavioural addictions, including CS. Functional abnormalities in limbic regions and the prefrontal cortex have been hypothesized to account for the impulsivity and poor decision-making that characterize CS. Using fMRI, Raab *et al.* [49] reported on differences between 23 women with CS and 26 controls. They found greater nucleus accumbens activity during product presentation in women with CS, compared to those without, and lower insula activation during the presentation of prices for the products the CS women decided to purchase. These investigators concluded that the expected loss of money led to a stronger negative emotional response in healthy controls than in women with CS.

There are no standard treatments for CS, but various forms of cognitive behavioural therapy have been shown to be effective [50]. Benson *et al.* [51] have developed a comprehensive programme combining cognitive behavioural therapy and elements of dialectical behaviour therapy. In an RCT, 11 subjects randomized to the group treatment had significantly greater improvement than wait list controls and the benefit was maintained at 6-month follow-up. Medication studies have had mixed success, with open-label trials showing positive results not confirmed in RCTs. SSRIs have been the most frequently used drugs in these trials. Other treatments are 12-step programmes, financial counselling, and self-help books. Common sense suggests that people with CS should avoid carrying credit cards or shopping alone.

Internet addiction

Internet addiction is characterized by excessive and/or inappropriate use of personal computers and other electronic devices, combined with personal distress or impairment in important life domains. Young [52] has proposed criteria patterned after those used to diagnose GD. She only counts non-essential computer/Internet usage (for example, non-business or non-academic use), and Internet addiction is present when five or more symptom criteria are present during the past 6 months and mania has been ruled out. The concept of Internet addiction has been criticized because, unlike other behavioural addictions, the focus is on the medium, and not the behaviour, so that if an addiction exists, it likely pertains to the activity engaged in (for example, gaming, gambling, viewing pornography) [53]. The condition is not listed in DSM-5 or ICD-10.

The prevalence of Internet addiction is unknown, in part because surveys have produced figures that range from 0.9% to 38% [54]. In a random telephone survey of adult Americans, Aboujaoude *et al.* [55] reported prevalence rates ranging from 0.3% to 0.7%. The widely varying figures suggest that more work is needed to develop uniform definitions of Internet addiction. Cases of Internet addiction have been reported in many countries, showing its universality.

Data suggest that Internet addiction is more prevalent in males than females, perhaps because males are more likely to use the Internet for activities that may fuel addiction such as games, pornography, and gambling [54]. Age of onset is unknown, but Internet addiction has been reported in children as young as age 6 [55].

Psychiatric comorbidity is common, particularly for mood, anxiety, and substance use disorders and other ICDs [54]. Using a dimensional approach to assess the psychological status, increased use of the Internet was associated with higher ratings on measures of depression, loneliness, and social isolation.

Neurobiological theories of Internet addiction focus on disturbed neurotransmission, particularly serotonin and dopamine [55], but there is no direct evidence to support the role of these or other neurotransmitter systems in Internet addiction. Pallanti *et al.* [56] hypothesized that immaturity of the frontal cortical and subcortical monoaminergic system during normal neurodevelopment underlies adolescent impulsivity and perhaps Internet addiction. One study employing diffusion tensor imaging concluded that Internet addiction was associated with widespread reductions in fractional anisotropy in major white matter pathways that the authors believed

may be linked to the abnormal behaviours exhibited by their subjects [57].

There are no standard treatments for Internet addiction [55, 58]. Young [58] has developed a guide for therapists working with Internet addicts, employing cognitive behavioural methods. SSRIs have been used to treat Internet addiction [58], but there have been no RCTs. Because Internet affects many youth, family therapy has been recommended. Support groups are available in some areas and are available online as well.

Compulsive sexual behaviour

CSB involves excessive preoccupation and/or behaviour that causes distress or impairs one's functioning. The concept of a hypersexual disorder dates back to the work of the German psychiatrist Krafft-Ebing [59]; yet the concept of a *sexual addiction* was first recognized by Orford [60]. Diagnostic criteria have been proposed that incorporate the concepts of inappropriate or excessive sexual cognitions or behaviours, subjective distress, and impaired functioning [61]. CSB is not listed in DSM-5 or ICD-10.

CSB encompasses various problematic sexual behaviours that can roughly be divided into paraphilic and non-paraphilic subtypes [61]. The former involves pathological sexual behaviours (for example, exhibitionism, voyeurism), while the latter involves conventional sexual behaviours taken to extremes (for example, compulsive masturbation, promiscuity, pornography dependence). While hypersexual behaviour is the hallmark of CSB, it can be found in mania, substance use disorders, and neurocognitive disorders, all of which need ruling out.

The prevalence of CSB is estimated to range from 3% to 6% of the general adult population in the United States [61]. Kafka [62] has suggested that data on total sexual outlet (TSO) (or total number of orgasms achieved through any means during a designated week) may more accurately reflect CSB prevalence, at least in men. He concluded that ≥ 7 weekly orgasms over 6 consecutive months could be used to define hypersexual behaviour, a figure that corresponds to 3–15% of the adult male population in the United States. Grant *et al.* [21] reported a 4.9% lifetime prevalence for CSB in adult psychiatric inpatients. Whether high-frequency sexual behaviour is inherently pathological has been questioned. In one study, high-frequency sexual behaviour with a stable partner indicated *better* psychological functioning [63].

CSB is primarily a disorder of men, and there may be gender-specific differences in the way CSB manifests [61]. Men are more likely to report compulsive masturbation, to engage in paraphilias, to pay for sex, or to engage in anonymous sex. Women are more likely to engage in fantasy sex (for example, seductive behaviour leading to multiple affairs/relationships) or sadomasochism, to use sex as a business, or to see themselves as 'love addicts'. CSB has an onset in adolescence, with paraphilic behaviours frequently occurring earlier than non-paraphilic behaviours [61]. CSB appears to be chronic, though waxing and waning in frequency and severity. Psychiatric comorbidity is common in persons with CSB, particularly mood, anxiety, and substance use disorders. Some experts have suggested that CSB begins with childhood sexual abuse, but not all persons with CSB have experienced maltreatment [64].

Typical symptoms include preoccupation with one's sexual urges and fantasies and/or being overly sexually active, often spending considerable time in pursuit of sexual experiences [64]. Many will report feeling out of control and being subjectively distressed by their sexual thoughts or urges. The behaviour eventually causes impairment in important life domains such as affecting their marriage or significant relationships or one's work or school life (for example, through intrusive thoughts or from frequent lateness). Persons with CSB often try unsuccessfully to resist sexual thoughts and urges.

In terms of neurobiology, Kafka [65] has focused on the possible contribution of disturbed neurotransmission, noting that noradrenaline, serotonin, and dopamine all serve to modulate sexual behaviour and other dimensions of human and animal pathophysiology. In a functional MRI study [66], sexual-cue reactivity led to greater activation in brain regions linked to drug craving and emotion processing (ventral striatum, amygdala, and dorsal anterior cingulate cortex) in 19 persons with CSB, compared to 19 controls. The authors suggested that CSB shares neural mechanisms with addictive disorders.

There are no standard treatments for CSB. Many forms of psychotherapy have been recommended, including imaginal desensitization, aversion therapy, group therapy, and psychodynamic and cognitive behavioural therapies [67]. Twelve-step programmes are available in some areas and can be helpful. SSRIs have been used in one controlled study and several open studies, leading to a reduction in sexual preoccupations and behaviours [67]. Case reports and small case series have also suggested that nefazodone, naltrexone, and anti-androgens may be effective in treating CSB. A placebo-controlled trial of the gonadotrophin-releasing hormone analogue triptorelin in men with severe paraphilias suggested that it is effective [68]. A meta-analysis of 118 patients suggested that luteinizing hormone-releasing agonists were effective in treating patients with severe paraphilias [69]. Anti-androgens should probably be reserved for men with aggressive and/or dangerous forms of CSB.

Conduct disorders and antisocial personality disorder in childhood and adolescence

Stephen Scott and Melanie Palmer

Introduction

The term conduct disorder refers to a persistent pattern of antisocial behaviour in which the individual repeatedly breaks social rules and carries out aggressive acts. It is the most common psychiatric disorder of childhood across the world. Antisocial behaviour has the highest continuity into adulthood of all measured human traits, except intelligence. A high proportion of affected children and adolescents grow up to be antisocial adults with impoverished and destructive lifestyles; some will develop antisocial personality disorder. The disorder places a large personal and economic burden on individuals and society. Juvenile delinquency is a legal term, referring to an act by a young person that breaks the law. Most recurrent juvenile offenders have conduct disorder. In this chapter, the term ODD/CD is used to denote oppositional defiant disorder (ODD) and conduct disorder (CD) together, since although they are essentially the same underlying condition of persistent antisocial behaviour expressed at different ages, in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM 5), unlike in the *International Classification of Diseases*, tenth revision (ICD-10), they are separated. The term conduct problems will be used for less severe antisocial behaviour; when the term child is used, it refers to both children and adolescents, for brevity.

Clinical features

Aggressive and defiant behaviour is an important part of normal child and adolescent development which ensures physical and social survival. Indeed, parents may express concern if a child is too acquiescent and unassertive. The level varies considerably among children, and it is a continuously distributed trait. Picking a particular level of antisocial behaviour to call ODD/CD is therefore necessarily arbitrary. For all children, the expression of any particular behaviour also varies according to child age; for example, physical hitting is at a maximum at around 2 years of age but declines over the next few

years. Therefore, any judgement about the significance of the level of antisocial behaviour has to be made in the context of the child's age. Before deciding that the behaviour is abnormal, other clinical features have to be considered:

- Level: severity and frequency of antisocial acts, compared with children of the same age and gender.
- Pattern: the variety of antisocial acts and the setting in which they are carried out.
- Persistence: duration over time.
- Impact: distress and social impairment of the child; disruption and damage caused to others.

Change in clinical features with age

The type of behaviour seen will depend on the age and gender of the individual.

Younger children, from 3 to 7 years of age, usually present with general defiance of adults' wishes, disobedience of instructions, angry outbursts with temper tantrums, physical aggression to people, especially siblings and peers, destruction of property, arguing, blaming others for things that have gone wrong, and a tendency to annoy and provoke others.

In *middle childhood*, from 8 to 11 years, these features are often present, but as the child grows older and stronger and spends more time out of the home, other behaviours are seen. They include: swearing, lying, stealing of others' belongings outside the home, persistent breaking of rules, physical fights, and bullying of other children.

In *adolescence*, from 12 to 17 years, more antisocial behaviours are often added: cruelty and hurting of other people, assault, robbery using force, vandalism, breaking and entering houses, stealing from cars, driving and taking away cars without permission, running away from home, truanting from school, and misuse of drugs.

Girls

Severe antisocial behaviour is less common in girls who are less likely to be physically aggressive and engage in criminal behaviour, but more

likely to show spitefulness, emotional bullying (such as excluding children from groups, spreading rumours so others are rejected by their peers), frequent unprotected sex leading to sexually transmitted diseases and pregnancy, drug abuse, and running away from home.

Classification

The ICD-10 classification has a category for CDs—F91. The *ICD-10 Classification of Mental and Behavioural Disorders: Clinical Descriptions and Diagnostic Guidelines* [1] states that any one of the behaviours on which a diagnosis is based (for example, excessive levels of fighting or bullying, cruelty to animals), if marked, is sufficient for diagnosis, but isolated acts are not. An enduring pattern of behaviour should be present, but no time frame is given and there is no impairment or impact criterion stated.

ICD-10 has conduct disorder as an overarching term, which can be divided into two subtypes—ODD and CD, thus making it closely compatible with DSM-5 [2] which treats ODD and CD as completely separate conditions. There is considerable debate about the validity of this division, with many authorities considering it to be a unitary disorder, with different phenomena chiefly due to different ages of presentation. In contrast to the clinical guidelines, the *ICD-10 Classification of Mental and Behavioural Disorders: Diagnostic Criteria for Research* [3] takes a menu-driven approach that is virtually identical to DSM-5. In line with the underlying philosophy of DSM-5, ODD and CD could theoretically be used at any age, but in practice, ODD is usually used for younger children and CD for adolescents up to the age of 18. Neither term tends to be used in adults.

To diagnose ODD (313.81/F91.3), there should be four of the following eight symptoms over at least 6 months:

Angry/irritable mood

1. Has unusually frequent or severe temper tantrums for his or her developmental level.
2. Is often touchy or easily annoyed by others.
3. Is often angry or resentful.

Argumentative/defiant behaviour

4. Often argues with adults.
5. Often actively refuses adults' requests or defies rules.
6. Often deliberately does things that annoy other people.
7. Often blames others for their own mistakes or misbehaviour.

Vindictiveness

8. Has been spiteful or vindictive at least twice in the last 6 months.

The behavioural problems should be associated with distress in the individual or others around them, or affect social, educational, or other areas of function.

For the diagnosis of CD, three of the following 15 behaviours should have occurred in the last 6 months:

Aggression to people and animals

1. Often bullies, threatens, or intimidate others.
2. Frequently initiates physical fights.
3. Has used a weapon that can cause serious physical harm to others (for example, knife, gun).

4. Exhibits physical cruelty to people.
5. Exhibits physical cruelty to animals.
6. Has stolen with confrontation of victim (including purse-snatching, extortion, mugging).
7. Has forced someone into sexual activity.

Destruction of property

8. Deliberately sets fires with a risk or intention of causing serious damage.
9. Deliberately destroys the property of others.

Deceitfulness or theft

10. Has broken into someone else's house, building, or car.
11. Often lies to obtain goods or favours to avoid obligations (that is, 'cons' others).
12. Has stolen objects of significant value without confronting the victim (for example, shoplifting, burglary).

Serious violations of rules

13. Often stays out after dark despite parenting prohibition, beginning before age 13 years.
14. Has run away from home at least twice overnight.
15. Is frequently truant from school, beginning before age 13 years.

In DSM-5, there should be significant impairment in social, academic, or occupational functioning, whereas in ICD-10, there is no impairment criterion. Age of onset should be specified, with *childhood-onset type* (312.81) manifesting before age 10 and *adolescent-onset type* (312.89) after. Severity should be categorized as *mild*, *moderate*, or *severe*, according to the number of symptoms or impact on others.

New in DSM-5 is recognition of the subtype characterized by callous-unemotional traits (discussed further under 'Aetiology' p. 1268) called *with limited prosocial emotions*, which is effectively a personality trait. Two of the following four features should be persistently and pervasively present:

- *Lack of remorse or guilt*: does not feel bad or guilty when they do something wrong; unconcerned about the negative consequences of their actions, for example no remorse after hurting someone or harmful effect of breaking rules.
- *Callous—lack of empathy*: disregards, and is unconcerned about, the feelings of others; cold and uncaring. The person appears more concerned about themselves, even when their actions result in substantial harm to others.
- *Unconcerned about performance*: does not show concern about poor/problematic performance at school, work, or other important activities. Puts in insufficient effort needed to perform well, typically blames others for poor performance.
- *Shallow or deficient affect*: does not express feelings or show emotions to others, except in ways that seem shallow, insincere, or superficial or are used for gain (for example, emotions displayed to manipulate or intimidate others).

Where there are sufficient symptoms of a comorbid disorder to meet diagnostic criteria, the ICD-10 system discourages the application of a second diagnosis and instead offers two combined categories: mixed disorders of conduct and emotions where

Depressive Conduct Disorder (F92.0) is the best researched; and *Hyperkinetic Conduct Disorder* (F90.1). There is good evidence to suggest these combined conditions differ in the longitudinal course from the pure form, in a manner that would be expected. Comorbidity in DSM-5 is handled by giving as many separate diagnoses as necessary.

Differential diagnosis

Making a diagnosis of CD is usually straightforward, but comorbid conditions are often missed. The differential diagnosis may include:

1. *Hyperkinetic syndrome/attention-deficit/hyperactivity disorder (ADHD)*. These are the names given by ICD-10 and DSM-5, respectively, for similar conditions, except that the former is more severe. For convenience, the term *ADHD* will be used here. It is characterized by impulsivity, inattention, and motor overactivity. Any of these three sets of symptoms can be misconstrued as antisocial, particularly impulsivity which is also present in ODD/CD. However, none of the antisocial symptoms of ODD/CD are a part of ADHD, so excluding CD should not be difficult. A frequently made error, however, is to miss comorbid ADHD. Standardized questionnaires are very helpful here, such as the Conners or the Strengths and Difficulties Questionnaire, which is brief and just as effective at detecting hyperactivity as much longer alternatives [4].
2. *Adjustment reaction to an external stressor*. This can be diagnosed when onset occurs soon after exposure to an identifiable psychosocial stressor such as parental divorce or bereavement, trauma, abuse, or adoption. The onset should be within 1 month for ICD-10, and 3 months for DSM-5, and symptoms should not persist for >6 months.
3. *Mood disorders*. Depression can present with irritability and oppositional symptoms, but unlike typical ODD/CD, mood is usually clearly low and there are vegetative features; more severe conduct problems are absent. It is common—around a third of adolescents with ODD/CD have depressive or other emotional symptoms, severe enough to warrant a diagnosis. Low self-esteem is the norm in ODD/CD, as is a lack of friends or constructive pastimes, so it is easy to overlook more pronounced depressive symptoms. Early manic/bipolar depressive disorder can be harder to distinguish, as there is often considerable defiance and irritability, combined with disregard for rules and behaviour that violates the rights of others, but there should be clear evidence of elevated mood, racing thoughts, etc. [5].

A new disorder appeared in DSM-5, called *Disruptive Mood Dysregulation Disorder* (296.99). This condition does not have a solid research underpinning and has a comorbidity rate approaching 90% with ODD, so its validity as a separate entity is questionable. The motivation for introducing the new condition was to stop some psychiatrists misdiagnosing ODD with prominent temper tantrums in young children as juvenile bipolar disorder and using potentially harmful medications.

4. *Autistic spectrum disorders*. These are often accompanied by marked tantrums or destructiveness, which may be the reason for seeking a referral. Enquiring about other symptoms of autistic spectrum disorders should reveal their presence.

5. *Subcultural deviance*. Some youths are antisocial and commit crimes but are not particularly aggressive or defiant. They are well adjusted within a deviant peer culture that approves of recreational drug use, shoplifting, etc. In some localities, a quarter or more of teenage males fit this description and would meet ICD-10 diagnostic guidelines for socialized CD. Some clinicians are unhappy to label such a large proportion of the population with a psychiatric disorder. Using DSM-5 criteria would preclude the diagnosis for most youths like this, due to the requirement for significant impairment.

Multi-axial assessment

ICD-10 recommends that multi-axial assessment be carried out for children and adolescents. A benefit of having a multi-axial system is that at least it forces the clinician to consider aspects beyond the presenting symptoms. In ICD-10, Axis I is used for psychiatric disorders; Axis II and Axis III cover specific and general intellectual disabilities, respectively; and Axis IV, Axis V, and Axis VI cover general medical conditions, psychosocial problems, and the level of social functioning, respectively. DSM-5 has abolished the first three axes as separate entities but keeps psychosocial problems and level of social functioning.

Both specific and general learning disabilities need to be assessed in individuals with conduct problems. Over a quarter of children with ODD/CD also have specific reading impairment/dyslexia [6], defined as a reading level two standard deviations below that predicted by the person's intelligence quotient (IQ). This is not just due to a lack of adequate schooling; there is good evidence that the cognitive deficits often precede the behavioural problems. The rate of ODD/CD rises several-fold as the IQ gets below 70, and general intellectual disability is often missed in children, so if school performance is markedly behind, IQ and attainment testing should be carried out.

Epidemiology

Most surveys find ODD + CD to have a prevalence of around 5–7% when an impairment criterion is applied [7, 8]; a meta-analysis of epidemiological studies estimated that the worldwide prevalence of CD alone among children and adolescents aged 6–18 years is 3.2%, with little variation across countries or continents [9]. A modest rise in diagnosable ODD/CD over the second half of the twentieth century has also been observed, comparing assessments of three successive birth cohorts in Britain [10]. There is a very marked social class gradient, greater than for almost any other disorder, with five times the prevalence in the lowest, compared to the highest, socioeconomic group [8]. With respect to ethnicity, youth self-reports of symptoms of CD and crime victim survey reports of perpetrators' ethnicity (both of which are less likely to be influenced by racial prejudice than parent or teacher reports of CD symptoms or police arrests) show an excess of offenders of black African ancestry, whereas Hispanic Americans in the United States and British Asians in the UK do not show an excess of offending, compared to their white counterparts. The sex ratio is approximately equal with respect to ODD in younger children but then rises to 2- to 3-fold more

in males than females after around 7 years. The causes of conduct problems appear to be the same, but males have more ODD/CD because they experience a greater number and intensity of individual-level risk factors (for example, hyperactivity, neurodevelopmental delays).

Developmental subtypes

Life course persistent versus adolescence onset

DSM-5 distinguishes between conduct problems that are first seen in early childhood versus those that start in adolescence. Early onset is a strong predictor of persistence through childhood and into adult life (Fig. 124.1) [11]. Those with early onset differ from those with later onset in that they have lower IQ, more attention and impulsivity problems, poorer scores on neuropsychological tests, greater peer difficulties, and they are more likely to come from adverse family circumstances [12]. Those with later onset become delinquent predominantly as a result of social influences such as association with other delinquent youths; they have fewer neurodevelopmental risk factors, but they are not absent [12]. Longitudinal studies support poorer adult outcomes for the early-onset group, but the doom-laden prognosis of 20 years ago has been moderated by the discovery of an early-onset group that subsequently desist, called childhood limited. Distinguishing between this group and the life course-persistent group has proved difficult, although a family history of criminal behaviour predicts persistence [13]. While many of the adolescence-onset group still engage in offending as adults and often have problems with alcohol and drugs, the level is lower than in the early-onset group.

Progression to antisocial/dissocial personality disorder

In both ICD-10 and DSM-5, a person should be aged 18 or older before a personality disorder can be diagnosed, but it is a requirement that they should have a history of CD from before age 15. The diagnostic criterion is generous, since only one of the following seven symptoms is needed:

1. Failure to obey laws and norms by engaging in behaviour warranting criminal arrest.
2. Lying, deception, and manipulation for profit or self-amusement.
3. Impulsive behaviour.
4. Irritability and aggression, manifested as frequent assaults or fighting.
5. Blatantly disregards safety of self and others.
6. A pattern of irresponsibility.
7. Lack of remorse for actions.

Perhaps not surprisingly, given these wide criteria, prevalence rates vary from 0.2% to 3.3%; using clinical impairment criteria, the prevalence is around 1% [2]. Antisocial personality disorder is a natural progression over time in children with CD who display the subtype with limited prosocial emotions. They have difficulty learning from mistakes, are rigid in decision-making, and are typically unresponsive to punishment [14].

Aetiology

The causes of ODD/CD vary considerably according to subtype and are multifactorial. After consideration of implicated factors, a synthesis model will be offered.

Individual-level characteristics

Genetic contribution

While in former times, ODD/CD was reckoned to arise from bad socialization and a lack of self-control, it is now evident that overall, genetic factors account for around 60% of the variance [15]. Within this overall figure, for some subtypes, the genetic contribution is even stronger. Twin studies showed both substantial genetic influences and also a substantial shared environmental component [16]. The genetic contribution is higher when inattention and hyperactivity are present [17], and extremely high when there are callous-unemotional traits, when the heritability typically reaches 80% [18]. Conversely, where these factors are absent, the genetic contribution can be as low as 30% [18].

Identified genotypes

Genome-wide approaches looking for main effects have been disappointing so far for ODD/CD, typically accounting for at most 2% of the variance; no consistent linkage regions have been identified [19, 20]. The most studied candidate gene in relation to conduct problems is the MAOA promoter polymorphism. The gene encodes the MAOA enzyme, which metabolizes neurotransmitters linked to aggressive behaviour. Replicated studies showed that maltreatment history and genotype interact to predict antisocial outcome [21]. Recently, the impact of environmental influences on epigenetic processes has become prominent whereby identifiable chemical changes, such as acetylation and methylation of genes, are affected. For example, a study has shown differentially increased methylation in adolescents whose parents reported they were exposed to stress as infants [22].

Perinatal complications and temperament

Recent large-scale general population studies have found associations between life course-persistent type conduct problems and perinatal complications, minor physical anomalies, and

Fig. 124.1 Subtypes of antisocial behaviour by longitudinal course (data synthesis from several longitudinal studies).

low birthweight. Most studies support a biopsychosocial model in which obstetric complications might confer vulnerability to other co-occurring risks such as hostile or inconsistent parenting. Smoking in pregnancy is a statistical risk predictor of offspring conduct problems. Several prospective studies have shown associations between irritable temperament and conduct problems.

Brain structure and function

Whereas ADHD has been recognized as having specific brain differences for over 20 years, it is only in the last decade that it has become clear that ODD/CD has its own and different set of brain anomalies. These are in terms of both structure, with reduced white matter connectivity with default mode regions that subsume cognitive functions about understanding self [23], and function where a recent meta-analysis of 24 studies found consistent differences in the rostral-dorsomedial, fronto-cingulate, and ventral-striatal regions that mediate reward-based decision-making, which is typically compromised in ODD/CD. Youths with callous-unemotional traits, on the other hand, had dysfunctions associated with the ventromedial prefrontal cortex and limbic system, together with dorsal and fronto-striatal hyperfunctioning, which may reflect poor affect reactivity and empathy in the presence of hyperactive executive control. In particular, these youths have a hypofunctioning amygdala, which is consistent with their fearlessness [24].

Autonomic reactivity and intellectual and information processing deficits

A slow heart rate has been consistently associated with ODD/CD [25]. Indicators of heart rate variability and skin conductance confirm that the callous-unemotional subtype tend to be hypoaroused, whereas the subtype with mood/internalizing problems is hyperaroused [25].

Children with ODD/CD have increased rates of deficits in language-based verbal skills. The association holds after controlling for potential confounders such as race, socio-economic status, academic attainment, and test motivation. Children who cannot reason or assert themselves verbally may attempt to gain control of social exchanges using aggression; there are likely also to be indirect effects in which low verbal IQ contributes to academic difficulties, which, in turn, mean that the child's experience of school becomes unrewarding. Children with ODD/CD also have poor executive functions such as skills in learning and applying contingency rules, abstract reasoning, problem-solving, self-monitoring, sustained attention and concentration, relating previous actions to future goals, and inhibiting inappropriate responses. These functions are largely, although not exclusively, associated with frontal lobe function. A meta-analysis with nearly 15,000 participants found that individuals with conduct problems had poorer executive functioning by an effect size of 0.54 standard deviations [26].

Dodge [27] proposed the leading information-processing model for the genesis of aggressive behaviours within social interactions. The model has good evidence that children prone to aggression focus on threatening aspects of others' actions, interpret neutral actions as hostile, and are more likely to favour aggressive solutions.

Risks outside the family

Risks in the neighbourhood

It has long been assumed that bad neighbourhoods promote youth antisocial behaviour. It is difficult to make direct links between neighbourhood characteristics and child behaviour, since several risk factors often coexist such as demographic factors like percentage of ethnic minority residents or single-parent households, unemployment levels, and parental mental illness. Many neighbourhood influences are mediated by supportive parenting, notably high warmth and close monitoring [28].

Peer influences

Children with conduct problems have poorer peer relationships than non-disordered children. It often starts off with failure to have the social skills to befriend more socially successful children, so that they then tend to associate with other antisocial children and, in turn, take pleasure in being defiant and breaking rules. In adolescence, a high proportion of delinquent acts are committed in the company of other antisocial youths [29].

Risks within the family

Concentration of crime in families

Fewer than 10% of families in any community account for >50% of its criminal offences, reflecting the co-occurrence of genetic and environmental risks. However, knowing that conduct problems are under some genetic influence is less useful clinically than knowing that this genetic influence appears to be reduced or enhanced, depending on the quality of the child's environment. Several genetically sensitive studies have allowed interactions between family genetic liability and rearing environment to be examined. Thus, for example, genetic risk, indexed by having a criminal or an alcoholic parent, leads to tripling or so of ODD/CD in their children, compared to controls. However, if the upbringing is benign, this is reduced, whereas if it is harsh, the rate can be 8- or 10-fold greater. In short, genetic vulnerability provides a form of susceptibility to adverse child-rearing conditions [30].

Family poverty

There is an association between severe poverty and early childhood conduct problems. Early theories proposed direct effects of poverty. Subsequent research has indicated that the association between low income and childhood conduct problems is indirect, mediated via family processes such as marital discord and parenting deficits.

Parent-child attachment

Parent-child relationships provide the setting for the development of later social functioning, and disruption of these attachment relationships, for example through institutional care, is associated with subsequent difficulties in relating. One study found that ambivalent and controlling attachment predicted externalizing behaviours after controlling for baseline externalizing problems [31]; disorganized child attachment patterns seem to be especially associated with conduct problems. Although it seems obvious that poor parent-child

relationships in general predict conduct problems, it has yet to be established whether attachment difficulties have an independent causal role in the development of behaviour problems or if classifications are markers for poor parenting.

Discipline and parenting

Patterns of parenting associated with conduct problems were delineated by Patterson [32] in his seminal work *Coercive Family Process*. Parents of antisocial children were found to be more inconsistent in their use of rules, to issue less clear and more commands, to be more likely to respond to their children on the basis of their own mood, rather than the characteristics of the child's behaviour, to be less likely to monitor their children's whereabouts, and to fail to acknowledge or reward their children's prosocial behaviour. Patterson provided observational evidence for negative coercive cycles worsening antisocial behaviour as follows. A parent responds to mild child oppositional behaviour with a prohibition; the child responds by escalating his or her behaviour; the parent, in turn, gets angry and mutual escalation continues until exasperated and tired, the parent backs off. This has the inadvertent effect of teaching the child that if they argue and swear and are defiant, they get their way, thus reinforcing the child's behaviour and making it more likely that the child will be antisocial next time. There is ample evidence that conduct problems are associated with hostile, critical, punitive, and coercive parenting [33].

In considering the role of coercive processes in the origins or maintenance of conduct problems, we need to consider possible alternative explanations: (1) that the associations reflect familial genetic liability towards children's psychopathology and parents' coercive discipline, so they would happen whether or not they lived together; (2) that they represent evocative effects of children's behaviours on parents; and (3) that coercive parenting may be a correlate of other features of the relationship that influence children's behaviours, for example noisy living conditions that make them both more irritable. There is considerable evidence that children's difficult behaviours do indeed evoke parental negativity. The fact that children's behaviours can evoke negative parenting does not, however, mean that negative parenting has no impact on children's behaviour. The E-Risk longitudinal twin study of British families examined the effects of fathers' parenting on young children's aggression [34]. As expected, a prosocial father's *absence* predicted more aggression by his children, but the presence of an antisocial father predicted even greater aggression and his harmful effect was exacerbated the more times each week he spent taking care of the children.

Exposure to adult marital conflict and domestic violence

Family processes other than parenting skills and the quality of parent-child attachment relationships have a role. Many studies have shown that children exposed to domestic violence between adults are subsequently more likely to themselves become aggressive. Marital conflict influences children's behaviour because of its effect on their regulation of emotion. For example, a child may respond to frightening emotion arising from marital conflict by downregulating his or her own emotion through denial of the situation. This, in turn, may lead to inaccurate appraisal of other social situations and ineffective problem-solving. Repeated exposure to family conflict is thought to lower children's thresholds for psychological dysregulation, resulting in greater behavioural reactivity to

stress. Children's aggression may also be increased by marital discord because children are likely to imitate aggressive behaviour modelled by their parents [35].

Maltreatment

In the Christchurch longitudinal study, child sexual abuse predicted conduct problems, after controlling for other childhood adversities [36]. Overall, associations between physical punishment and conduct problems are well established; however, links are not straightforward. The risk for conduct problems does not apply equally to all forms of physical punishment. The E-Risk longitudinal twin study was able to compare the effects of corporal punishment (smacking, spanking) versus injurious physical maltreatment, using twin-specific reports of both experiences [37]. Results showed that children's genetic endowment accounted for virtually all of the association between their corporal punishment and their conduct problems. This indicated a 'child effect', in which children's bad conduct provokes their parents to use more corporal punishment, rather than the reverse. Findings for injurious physical maltreatment were the opposite; significant effects of maltreatment on child aggression remained after controlling for any genetic transmission of liability to aggression from antisocial parents.

From risk predictor to causation

Associations have been documented between conduct problems and a wide range of risk factors. A variable is called a 'risk factor' if it has a documented predictive relation with antisocial outcomes, whether or not the association is causal. The causal status of most of these risk factors is unknown; we know what statistically predicts conduct problem outcomes, but not how or why. Establishing a causal role for a risk factor is by no means straightforward, particularly as it is unethical to experimentally expose healthy children to risk factors. The use of genetically sensitive designs and the study of within-individual change in natural experiments and treatment studies have considerable methodological advantages for suggesting causal influences.

Prognosis

Many of the risk factors which predict poor outcome are associated with early onset (Table 124.1).

Table 124.1 Factors predicting poor outcome

Onset	Early onset of severe problems, before age 8
Phenomenology	Antisocial acts which are severe, frequent, and varied
Comorbidity	Hyperactivity and attention problems
Intelligence	Lower IQ
Family history	Parental criminality, parental alcoholism
Parenting	Harsh and inconsistent parenting, with high criticism, low warmth, low involvement, and low supervision
Wider environment	Low-income family in poor neighbourhood with ineffective schools

Protective factors

To detect protective factors, children who do well, despite adverse risk factors, have been studied.

These so-called 'resilient' children, however, have been shown to have lower levels of risk factors, for example a boy with antisocial behaviour and low IQ living in a rough neighbourhood, but living with supportive, concerned parents. Protective factors are mostly the opposite end of the spectrum of the same risk factor. Nonetheless, there are factors which are associated with resilience, independent of known adverse influences. These include a good relationship with at least one adult who does not necessarily have to be the parent, a sense of pride and self-esteem, and skills or competencies.

Adult outcome

Studies of groups of children with early-onset CD indicated a wide range of problems not only confined to antisocial acts, as shown in Table 124.2.

What is clear is that not only are there substantially increased rates of antisocial acts, but also the general psychosocial functioning of children with CD when they have grown up is strikingly poor. For most of the characteristics shown in Table 124.2, the increase, compared to controls, is at least double for community cases who were never referred, and 3–4 times for referred children [27].

Pathways

The path from childhood CD to poor adult outcome is neither inevitable nor linear.

Different sets of influences impinge and shape the life course as the individual grows up. Many of these can accentuate problems. Thus, a toddler with an irritable temperament and short attention

span may not learn good social skills if he or she is raised in a family lacking them and where he or she can only get his or her way by behaving antisocially and grasping for what he or she needs. At school, he or she may fall in with a deviant crowd of peers where violence and other antisocial acts are talked up and give him a sense of esteem. His or her generally poor academic ability and difficult behaviour in class may lead him to truancy increasingly, which, in turn, makes him fall further behind. He or she may then leave school with no qualifications and fail to find a job, and resort to drugs. To fund his or her drug habit, he or she may resort to crime and, once convicted, find it even harder to get a job. From this example, it can be seen that adverse experiences do not only arise passively and independently of the young person's behaviour; rather, the behaviour predisposes them to end up in risky and damaging environments. Consequently, the number of adverse life events experienced is greatly increased [38]. The path from early hyperactivity into later CD is also not inevitable. In the presence of a warm, supportive family atmosphere, it is far less likely than if the parents are highly critical and hostile.

Other influences can, however, steer the individual away from an antisocial path. For example, the fascinating follow-up of delinquent boys to age 70 by Laub and Sampson [39] showed that the following led to desistence: being separated from a deviant peer group; marrying to a non-deviant partner; moving away from a poor neighbourhood; and military service which imparted skills.

Treatment

Evidence-based treatments

Proven treatments include those which singly or in combination address: (1) parenting skills; (2) family functioning; (3) child interpersonal skills; (4) difficulties at school; (5) peer group influences; and (6) medication for coexisting hyperactivity.

1. Parenting skills.

Parent management training aims to improve parenting skills. There are scores of randomized controlled trials showing that it is effective for children aged up to about 10 years. They address the parenting practices identified in research as contributing to conduct problems. A more detailed account is given by Scott and Gardner [11]. Typically, they include five elements:

- i. *Promoting play and a positive relationship.* In order to cut into the cycle of defiant behaviour and recriminations, it is important to instil some positive experiences for both sides and begin to mend the relationship. Teaching parents the techniques of how to play helps them recognize their child's needs and respond sensitively. The child, in turn, begins to like and respect their parents more and becomes more secure in the relationship.
- ii. *Praise and rewards for prosocial behaviour.* Parents are helped to reformulate difficult behaviour in terms of the positive behaviour they wish to see, so that they encourage wanted behaviour, rather than criticize unwanted behaviour. For example, instead of shouting at the child not to run, they would praise him whenever he or she walks quietly; then he or she will do it more often. Through hundreds of such prosaic daily interactions, child behaviour can be substantially modified. Yet some parents find it hard to praise and fail to recognize positive behaviour when it happens, with the result that it become less frequent.

Table 124.2 Adult outcome

Antisocial behaviour	More violent and non-violent crimes, for example mugging, grievous bodily harm, theft, car crimes, fraud
Psychiatric problems	Increased rates of antisocial personality, alcohol and drug abuse, anxiety, depression and somatic complaints, episodes of deliberate self-harm and completed suicide, time in psychiatric hospitals
Education and training	Poorer examination results, more truancy and early school leaving, fewer vocational qualifications
Work	More unemployment, jobs held for shorter time, jobs lower in status and income, increased claiming of benefits and welfare
Social network	Few, if any, significant friends, low involvement with relatives, neighbours, clubs, and organizations
Intimate relationships	Increased rate of short-lived, violent cohabiting relationships, partners often also antisocial
Children	Increased rates of child abuse, conduct problems in offspring, children taken into care
Health	More medical problems, earlier death

- iii. *Clear rules and clear commands.* Rules need to be explicit and constant; commands need to be firm and brief. Thus, shouting at a child to stop being naughty does not tell him what he or she *should* do, whereas, for example, telling him to play quietly gives a clear instruction, which makes compliance easier.
- iv. *Consistent and calm consequences for unwanted behaviour.* Disobedience and aggression need to be responded to firmly and calmly by, for example, putting the child in a room for a few minutes. This method of 'time-out from positive reinforcement' sounds simple but requires considerable skill to administer effectively. More minor annoying behaviours, such as whining and shouting, often respond to being ignored, but again parents often find this hard to achieve in practice.
- v. *Reorganizing the child's day to prevent trouble.* There are often trouble spots in the day which will respond to fairly simple measures. For example, putting siblings in different rooms to prevent fights on getting home from school and banning electronic devices in the morning until the child is dressed.

Treatment can be given individually to the parent and child, which enables live feedback in light of the parent's progress and the child's response. Alternatively, group treatments with parents alone have been shown to be equally effective [40]. Trials showed that parent management training is effective in reducing child antisocial behaviour in the short term, with moderate to large effect sizes of 0.5–0.8 standard deviations, and there is little loss of effect at 1- or 3-year follow-up [41].

2. Family functioning.

Functional family therapy, multi-systemic therapy, and treatment foster care aim to change a range of difficulties which impede effective functioning of teenagers with CD. Functional family therapy addresses family processes which need to be present such as improved communication between parent and young person, reducing interparental inconsistency, tightening up on supervision and monitoring, and negotiating rules and sanctions to be applied for breaking them. Functional family therapy has been shown to reduce reoffending rates by around 50% [42]. Other varieties of family therapy have not been subjected to controlled trials for young people with CD or delinquency, so they cannot be evaluated for their efficacy.

In multi-systemic therapy [43], the young person's and family's needs are assessed in their own context at home and in their relations with other systems such as school and peers. Following the assessment, proven methods of intervention are used to address difficulties and promote strengths. Multi-systemic therapy differs from most types of family therapy such as the Milan or systemic approach as usually practised in a number of regards. Firstly, treatment is delivered in the situation where the young person lives, for example at home. Secondly, the therapist has a low caseload (4–6 families) and the team is available 24 hours a day. Thirdly, the therapist is responsible for ensuring appointments are kept and for making change happen—families cannot be blamed for failing to attend or 'not being ready' to change. Fourthly, regular written feedback on progress towards goals from multiple sources is gathered by the therapist and acted upon. Fifthly, there is a manual for the therapeutic approach and adherence is checked weekly by the supervisor.

Several randomized controlled trials have attested to the effectiveness, with reoffending rates typically cut by half and time spent in psychiatric hospitalization reduced further [43].

Treatment Foster Care is an approach developed in Oregon in the United States as a way to improve the quality of encouragement and supervision that teenagers with CD receive. The young person lives with a foster family specially trained in effective techniques; sometimes it is ordered as an alternative to jail. Outcome studies have shown useful reductions in reoffending [44].

3. Anger management and child interpersonal skills.

Most of the programmes to improve child interpersonal skills derive from cognitive behavioural therapy. A typical example is the *Coping Power Programme* [45]. This, and other programmes have in common, involves training the young person to:

- i. Slow down impulsive responses to challenging situations by stopping and thinking.
- ii. Recognize their own level of physiological arousal and their own emotional state.
- iii. Recognize and define problems.
- iv. Develop several alternative responses.
- v. Choose the best alternative, based on anticipation of consequences.
- vi. Reinforce himself or herself for use of this approach.

Over the longer term, they aim to increase positive social behaviour by teaching the young person skills to make and sustain friendships, turn taking and sharing, and express viewpoints in appropriate ways and listen to others.

Typically, given alone, treatment gains with interpersonal skills training are good within the treatment setting but only generalize slightly to 'real-life' situations such as the school playground. However, when they are part of a more comprehensive programme which has those outside the young person reinforcing the approach, they add to outcome gains [46].

4. Difficulties at school.

These can be divided into learning problems and disruptive behaviour. There are proven programmes to deal with specific learning problems such as Reading Recovery; however, few of the programmes have been specifically evaluated for their ability to improve outcomes in children with CD, although trials are in progress.

There are several schemes for improving classroom behaviour, which vary from those which stress on improved communication such as 'circle time' and those which work on behavioural principles or are part of a multimodal package. Many of these schemes have been shown to improve classroom behaviour, and some specifically target children with CD [47].

5. Peer group influences.

A few interventions have aimed to reduce the bad influence of deviant peers. However, a number attempted this through group work with other conduct-disordered youths, but outcome studies showed a *worsening* of antisocial behaviour due to forming more ties with antisocial peers. Current treatments therefore either see youths individually or work in small groups (say 3–5 youths) where the therapist can control the content of the sessions. Some interventions

place youths with CD in groups with well-functioning youths, and this has led to favourable outcomes [48].

6. Medication for coexisting hyperactivity.

Where there is comorbid hyperactivity, in addition to CD, several studies attested to a large (effect size of 0.8 standard deviations or greater) reduction in both overt and covert antisocial behaviour, both at home and at school [49]. However, the impact on long-term outcome is unstudied.

Management

Engagement of the family is particularly important for this group of children and families, as dropout from treatment is high at around 30–40%. Practical measures, such as assisting with transport, providing childcare, and holding sessions in the evening or at other times to suit the family, will all help. Many of the parents of children with CD may themselves have difficulty with authority and officialdom and be very sensitive to criticism. Therefore, the approach is more likely to succeed if it is respectful of their point of view, does not offer overly prescriptive solutions, and does not directly criticize parenting style. Practical homework tasks increase changes, as do problem-solving telephone calls from the therapist between sessions.

Parenting interventions may need to go beyond skills development to address more distal factors which prevent change. For example, drug or alcohol abuse in either parent, maternal depression, and a violent relationship with the partner are all common. Assistance in claiming welfare and benefits and help with financial planning may reduce stress from debts.

A multimodal approach is likely to get larger changes. Therefore, involving the school in treatment by visiting and offering strategies for managing the child in class is usually helpful, as is advocating for extra tuition where necessary. Avoiding antisocial peers and building self-esteem may be helped by getting the child to attend after-school clubs and holiday activities.

Where parents are not coping or an abusive relationship is detected, it may be necessary to liaise with social services to arrange respite for the parents or a spell of foster care. It is important during this time to work with the family to increase their skills, so the child can return to the family. Where there is permanent breakdown, long-term fostering or adoption may be recommended.

Opportunities for prevention

CD should offer good opportunities for prevention since:

1. It can be detected early reasonably well.
2. Early intervention is more effective than later intervention.
3. There are a number of effective interventions.

In the United States, a number of comprehensive interventions based on up-to-date empirical findings are being carried out. Perhaps the best known is Families and Schools Together [50]. Here the most antisocial 10% of 5- to 6-year olds in schools in disadvantaged areas were selected, as judged by teacher and parent reports.

They were then offered intervention which was given for a whole year in the first instance and comprised:

1. Weekly parent training in groups with videotapes.
2. An interpersonal skills training programme for the whole class.
3. Academic tutoring twice a week.
4. Home visits from the parent trainer.
5. A pairing programme with sociable peers from the class.

Almost 1000 children were randomized to receive this condition or controls, and the project has cost over \$100 million. By age 25, children in the treatment group had less antisocial behaviour and criminality and psychopathology, but only if they were in the more severe part of the sample to begin with.

In the United States, preschool education programmes for disadvantaged children have shown good outcomes in small demonstration projects, but replication on a larger scale has generally proved rather disappointing. In the UK, the government stressed the importance of helping parents of children in the first 3 years of life and put substantial resources (£540 million) into *SureStart* centres in specifically targeted high-risk neighbourhoods to support parenting. Early evaluation of outcome showed no change on 24 of 25 variables; maternal acceptance of the child was the only measured outcome to change, and child antisocial behaviour did not change [51]. However, more intensive high-quality parenting programmes started when children are young (aged 4–7 years) do have some evidence of longer-term effects, including prevention of antisocial personality traits in adolescence [52].

Conclusions

Much is known about the risk factors leading to CD, and effective interventions exist. The challenge is to make these available on a wide scale and to develop approaches to prevention which are effective and can be put into practice at a community level.

Understanding suicide

Ever since the work of Charles Darwin established that the struggle for existence plays a major role as scientific explanation of diversification in nature [1], the striving to live has been considered fundamental for all living creatures, also among human beings. Therefore, suicidal impulses and suicidal behaviour must be understood as disturbances of this fundamental condition. But suicide statistics clearly demonstrate that the will to live can be broken. While the strength of the force threatening to break the will to live is crucial, individual resilience play an important role too. When suicidal behaviour occurs, it must be considered as an indication that the strain on the individual is exceeding his or her capability to cope with the situation. The diathesis–stress model can be used as a framework for understanding suicidal impulses and suicidal behaviour. In 2003, van Heeringen presented a slightly modified version of the diathesis–stress model related to suicidal behaviour [2]. The model suggests that suicidal behaviour might be explained through factors related to trait (determined by genetics, personality, intellect, and other factors) and factors related to state (which can be influenced by, for instance, depression or substance use disorder). Stressors and protective factors, as well as threshold factors (for instance, access to lethal means, alcohol intoxication, crisis, and access to help), might further act as facilitators or barriers for suicidal behaviour. Destructive forces, that is, stressors, can be manifold and diverse and modified by protective factors hosted by the individual. Humans react differently to the same condition; thus, a situation perceived stressful for one individual may not be distressing for another individual. Different individuals have different levels of resilience. This may depend upon individual trait factors, genetics, or being grounded during childhood, but it can also be influenced by more recent factors such as the support to which he or she has access. Similarly, the perception of options for help is likely to vary from one individual to another, as well as by cultural factors. Protective factors and stressors either from early life experiences or from the current context may impact traits or the state of the individual, while genetic factors are mainly thought to influence traits. Threshold factors, such as alcohol intoxication, crisis, or access to help, can act either as drivers or as barriers for suicidal behaviour.

Prevention strategies

Suicide cannot be understood as a disease or an accident; suicidal acts should be considered as severe and preventable complications to a range of diseases and conditions in which social aspects play an important role. The understanding of suicidal acts as complications emphasizes that, like other complications, suicidal acts can be prevented.

The most frequently used model for suicide prevention is the Universal, Selected and Indicated preventive model (USI-model), which was suggested by Gordon [3] and later accepted by the Institute of Medicine [4]. This model provides a relevant and applicable framework for suicide prevention. Universal prevention strategies aim to address an entire population and is designed to influence everyone. *Universal* interventions include programmes such as: public education campaigns, restricting access to suicide means, and education programmes for the media on reporting practices related to suicide. There are several examples of universal interventions that could be considered suicide-preventive but were not launched as such, mainly because the primary focus of the intervention is not suicide—for instance, school-based programmes aiming at reducing bullying and campaigns to reduce mental health stigma. An example of successful universal suicide prevention is the restriction of pack sizes on paracetamol, which has been linked to less severe suicide poisoning [5]. *Selective* prevention strategies aim to prevent the onset of suicidal behaviours among specific subpopulations. Important high-risk groups are the mentally ill, alcohol and drug misusers, those with a newly diagnosed severe physical disorder, prisoners, and the homeless, as well as other socially marginalized groups. Crisis plans for patients with mental illness is an example of application of selective prevention strategies [6]. Another example is better education of general physicians for recognition and treatment of depression, which has been shown to reduce suicide rates [7]. *Indicated* prevention strategies are focused on high-risk groups, that is, persons who have attempted suicide or have presented themselves to health services because of suicidal ideation. An example of a promising indicated strategy is the psychosocial therapy provided to people after suicide attempt [8]. In addition, help lines, psychiatric emergency rooms, psychiatric emergency outreach, and other crisis interventions can play a role in preventing suicide attempts among persons in a suicidal crisis.

National action plans for suicide prevention generally include all three types of strategies.

Definitions

The World Health Organization (WHO) defines *suicide* as the act of deliberately killing oneself [9]. This definition underlines that the death is caused by a deliberate act, thereby separating suicide from accidents. The definition does not mention suicidal intent, which, in some cases, can be difficult to determine after death. The number of suicides is recorded and suicidal rates are available for most high-income countries.

The WHO [9] defines *suicide attempt* as any non-fatal suicidal behaviour, such as intentional self-inflicted poisoning, injury, or self-harm, which may or may not have a fatal intent or outcome. This definition implies that non-fatal self-harm without suicidal intent is included under this term, which is problematic due to the possible variations in related interventions. However, the WHO chooses this definition because suicide intent can be difficult to determine as it may be surrounded by ambivalence or even concealment. Some countries record hospital-treated suicide attempts, but underreporting is common and suicide attempts outside hospital settings are not included in statistics. Other terms, such as deliberate self-harm, are also used for suicide attempt.

Suicidal ideations or thoughts may vary in terms of intensity, from being sporadic and transient to being frequent and persistent. Suicidal thoughts can be active, such as considering killing oneself, or passive such as wishing to catch an incurable disease or not waking up tomorrow. Some people might express their suicidal thoughts overtly without being prompted; others present them only

after questioning or conceal them. Suicidal thoughts include suicidal plans where a distinction can be made between plans for not being alive anymore (writing a testimony, preparing economy, and writing suicidal notes) and plans for carrying out a suicidal act (selecting the method, time, and place).

Epidemiological trends and registration of suicides

The WHO estimates that the number of suicides worldwide was 803,900 in 2012 [9].

The absolute number, that is, the actual number of people dying by suicide, in a country is dependent on the number of people living in the country. Thus, when comparing suicide figures across borders, a yearly suicide rate per 100,000 inhabitants is usually used. National suicide rates based on those countries that report data on causes of death are presented in Fig. 125.1. Specific regions are noted for high suicide rates: Eastern Europe (Russia, Ukraine, Lithuania, Latvia, Poland, Hungary, Belarus, and Kazakhstan) and Eastern sub-Saharan countries (Sudan, Uganda, Kenya, Tanzania, Zambia, Malawi, and Zimbabwe). In addition, particularly countries such as India and Japan, as well as Guyana and Suriname in South America, list high rates of suicide.

The quality of death and population statistics varies substantially across the world, and one has to bear this in mind when comparing rates. For instance, low- and middle-income countries with low infrastructure might have limited resources to dedicate to recording suicide statistics. The fact that more than 75% of all suicide takes place in low- and middle-income countries (Fig. 125.2) complicates the process of estimation. Suicide has, throughout the ages, been subjected to taboo and stigmatization. Religious and cultural norms

might imply that a suicide death is unacceptable or shameful, and social or legal sanctions are possible consequences. Several religions, such as Catholicism and Islam, consider suicide a sin and the burial of a deceased by suicide might not be granted the same rituals as other deceased, and relatives might experience sanctions [10]. For such reasons, it is plausible that suicide deaths in some countries might, to a larger extent, be recorded as accidents or other causes of death, partially out of concern for the relative.

The administrative procedure of recording causes of death varies substantially across the world. In the UK, for instance, a jurisdictional coroner system determines whether a death is a suicide, an accident, or undetermined, that is, an 'open verdict' [11]. In this setting, supportive evidence, such as a 'suicide note', documenting intent of suicide, might be required before a cause of death is determined to be a suicide. In other high-income countries, the presence of suicidal intent is generally determined by medical or forensic staff. For the reasons listed previously, caution has to be applied when comparing suicide rates of different countries.

Risk factors

In the following sections, societal and individual risk factors for suicide are presented. There is no clear distinction between societal and individual risk factors; yet both groups of factors have an interdependent impact on the risk of suicide. For example, an economic crisis affects the entire society, while specific individuals will be distressed by unemployment or bankruptcy. Likewise, free-of-charge access to high-quality health care can be considered as a societal factor, while the influence by treated or untreated mental disorders on the risk of suicide is an individual factor. Still, there are clear links between the two dimensions. The relative risk associated with individual risk factors are listed in [Table 125.1](#).

Societal factors

On the societal level, there are factors which can be associated with high or low risk of suicide. Rather than focusing on individual risk factors, the French sociologist Durkheim attributed variations in suicidal behaviour between different countries to societal factors such as sense of connectedness and social cohesion. Durkheim used the term 'anomic' to describe suicides in societies with poor connectedness between people and where the individual behaviour was not regulated by a strong social cohesion [12]. He hypothesized that anomic suicides were likely to increase in periods when social norms and roles underwent rapid changes. As such, the steep increase in suicide rates seen in indigenous societies, for example among New Zealand's Maori population, Australia's aborigines, the United States' native Indians, and Canadian and Greenland's indigenous peoples, could be seen as examples of increasing numbers of anomic suicides [13, 14].

Societal factors influence the number of suicides occurring in a country. In the 1980s, the 'Perestroika' policy introduced by the Soviet leader Mikhail Gorbachev included restrictions on alcohol sales. Alcohol misuse is linked to suicide in some populations, and the implementation of the policy consequently resulted in a marked drop in the suicide rate [15]. After the dissolved Soviet Republic, structural changes and increasing unemployment, as well as rising alcohol sales, contributed to an increase in suicide rates in many post-Soviet countries. The global financial crisis of 2007–2008 was linked to an increase in the numbers of suicide, particularly in European countries and the United States [16]. While the financial crisis had an impact on a societal level, for instance, through cutbacks in state budgets, rising unemployment rates might act as an individual stressor, as suggested previously. Significant increases in suicide rates of age groups belonging to the working forces were noted in the years following. Interestingly, countries with social

Table 125.1 Relative risks denoting the risk of suicide with respect to select risk factors of suicide in relation to the general population

Risk factor	Men	Women
Schizophrenia [57]	9	19
Bipolar depression disorder [57]	11	18

⁵ Based on somatic illness requiring inpatient hospitalization (adjusted analysis).

⁶ Measured as persons living in a same-sex marriage, when compared to persons living in an opposite-sex marriage. Figures are adjusted for persons never married.

⁷ Persons who have received hormone therapy or transgender surgery or diagnosed with transgender orientation.

welfare systems, such as Finland and Sweden, seemingly were less affected by the crisis [17].

Durkheim predicted that when a country is in war, this would increase the social cohesion and strengthen the societal influence of individual's behaviour. Some support for this hypothesis has been found, for instance among the countries participating in the First World War where a decline in suicide rate was noted over the same period [18]. Decreasing suicide rates were, among others, noted in Norway and Sweden during the Second World War [19]. Newer findings indicated that civil wars might not have this effect on suicide rate, potentially explained through the lack of social cohesion when national, oppositional groups are in conflict [20].

Role models and media portrayal

Goethe's book *The Sorrows of Young Werther* depicts a tragic love story from the Romantic period where the main character ends up taking his own life. Legends from contemporary Germany report how young men would identify with the story and copy the behaviour of Werther—sometimes even dressed in similar ropes and found with the book next to their body [21]. The main character gave name to the phenomenon 'the Werther effect', which denotes famous suicide deaths (by fictive or actual persons) that are being copied. A more recent case of this was observed in Germany in 2009 where a former national soccer player R. Enke died by suicide. In subsequent years, a 31% increase in suicides by the same method was observed among men [22]. Fictive portrayals, as a suicide of a main character in a soap opera, have been linked to an increase in self-poisonings

admitted to hospital by women [23]. Media guidelines installing that reports of suicide should not list details regarding the method and avoid depicting the event as a heroic act have subsequently been developed [24]. Interestingly, the media might also have a preventive impact on suicides when reports are made according to media guidelines [25]. In order to emphasize that media may also have a positive impact, this effect is now called 'the Papageno effect'.

Individual risk factors

On an individual level, various circumstances are linked to elevated vulnerability to suicide. Coping strategies and support from network are important moderators of these risk factors. Some of the most relevant individual risk factors for suicide are listed in the following sections.

Gender and age

In most countries, suicides by men outnumber those by women at a ratio of 1:2 to 1:4. However, as can be seen in Fig. 125.3, there is great variation in the sex ratio between countries. One explanation for this is gender-specific preferences for methods; men tend to use more lethal means of suicide, while women outnumber men when it comes to suicide attempts as a result of predominantly using poisoning [26]. China is an exception to this, as Chinese women have a 25% higher suicide rate than men [27]. This is largely attributed to suicides in rural areas where young women have a very high rate of suicide and might be explained through their low social status and the availability of highly lethal means (pesticides), as well as limited options for social support.

As shown in Fig. 125.4, suicide rates increase with increasing age in those countries that report their data to the WHO. While older adults aged 75 years and older have the highest rate, more detailed studies of the suicide rates among the oldest age groups reveal even higher rates for men until age 90 years, while the rate for women peaks at age 85–94 [28, 29]. In terms of absolute numbers, most suicides in high-income countries occur among persons in mid life at around age 50. In low- and middle-income countries, most suicides take place among the very young aged 15–24 (Fig. 125.2). In all countries, suicides among children below age 15 years are very rare.

Family and close relations

Familial conditions, such as separation, divorce, and widowhood, are linked to a higher risk of suicide, while marriage is often found to be protective against suicide [30]. Having a child, particularly a young child, protects parents against suicide [31].

Stressful life events, such as the death of a child or loss of a relative to suicide, are linked to increased risks of suicide [31, 32]. Studies showed that the recent loss of a partner constitutes a stressor that is associated with higher risks of suicide, for instance in older adults [33]. Moreover, it is plausible that humiliation, bullying, financial ruin, fear of not passing exams, or losing one's job are all factors that might be associated with an increased risk of suicide.

Minority groups

An increased suicide mortality is found among homeless people; this is particularly dominant in younger age groups [34]. Imprisonment, but also being charged with a criminal offence, although not found

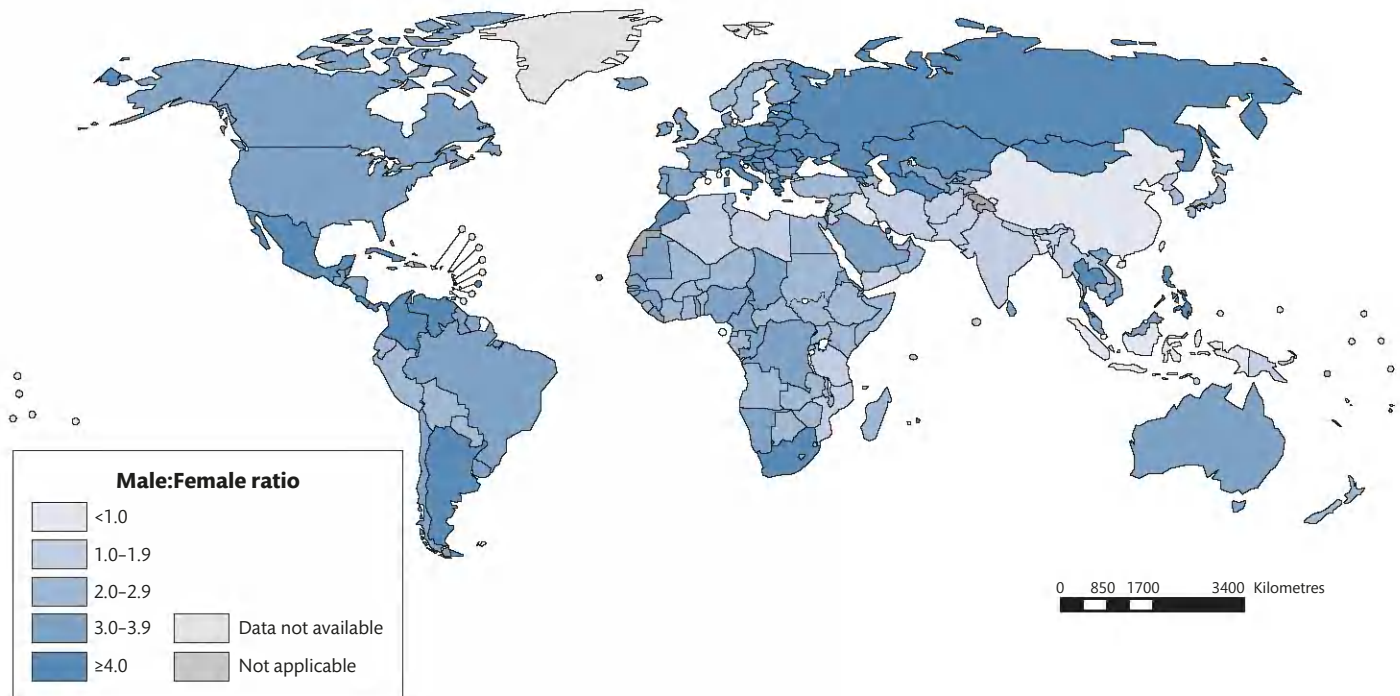

Fig. 125.3 (see Colour Plate section) Sex ratio of age-standardized suicide rates by country (2012).

guilty, are linked to increased risks of suicide [35]. The period immediately after imprisonment is associated with the highest risk of suicide [35]. For marginalized groups, such as the homeless or people with a criminal history, the elevated risk of suicide might be mediated through untreated mental disorders.

Sexual minority groups are generally thought to have a higher suicide rate, although limited evidence has been produced [36]. Based on Danish register data, persons living in same-sex partnership had higher suicide rates than those living in opposite-sex partnerships [37]. A study on transgendered persons in treatment found that these have a higher suicide rate than the general population [38].

Until recently, the rate of suicide in the military has been lower than the rate among civilians [39]. However, large cohort studies based on active US army soldiers (deployed or not) and veteran populations (that is, those who are no longer employed in the army) have shown a rise in the suicide risk in the period spanning from 2004 to 2009—even higher than in the general background population [40, 41]. In the UK, a similar trend was found in a large cohort study; however, an excess risk, when compared with a background population, applied only to veterans younger than 24 years [42]. Regarding leaving the armed forces, both US and UK studies found that the suicide risk was highest in the first years after leaving the military [42, 43].

Fig. 125.4 Suicide rate age group for 62 countries reporting to WHO Mortality Data Bank (2004-2009).

Suicide rates in different occupational groups have been examined in several studies. In a large Danish study, the highest suicide rates were found among doctors and nurses, as well as occupational groups with unstable working conditions and low salaries, mainly unskilled manual workers, for example domestic and related helpers, cleaners, and launderers. Much, but not all, of the excess risk for doctors and nurses was due to their increased use of self-poisoning, a feasible method, considering their knowledge on toxicity and relatively easy access to medical drugs [44]. Police officers constitute a professional group exposed to a high level of job stress and moreover with access to firearms. Some studies reported increased suicide rates of this group and have examined the effectiveness of prevention programmes [45, 46]. People who are unemployed have higher suicide risks than those in work. The same goes for people who are retired or on disability pensions [47].

Mental disorders

The strongest individual risk factors are mental disorders and previous suicidal behaviour. In fact, the increased risk of suicide is one of the main explanations for why people with mental disorders have a 15–20 years shorter life expectancy, compared with the general population [48]. Psychological autopsy studies where available post-mortem information on the suicide victim is collected from, for instance, family members and general practitioner found that up to 90% of people who died by suicide met the criteria for a mental disorder [49, 50]. While acknowledging that not all people with mental disorders receive treatment, a recent study found that the risk of suicide varies according to the level of mental health care received; people admitted to inpatient care had a 44-fold higher risk of suicide than the general population, whereas those receiving outpatient care or psychiatric medication had an 8- or 6-fold higher risk, respectively [51].

While suicide among psychiatric inpatients is a rare event, this population still has a high rate of suicide—147 per 100,000 patient-years [52], which is almost 13 times higher than the annual global age-standardized suicide rate of 11.4 per 100,000 provided by the WHO [9]. Two phases are linked to particularly high risks: patients who are currently admitted and those who are recently discharged from psychiatric hospital [53]. Most inpatient suicides take place within the first week of admission [54, 55]. The first days and months after discharge comprise a suicidal high-risk period, especially in the first week where the risk has been reported to be up to 102-fold (for men) and 246-fold (for women) higher, when compared to a background population with no admission history. The following clinical factors have been associated with an increased risk: history of suicide attempt, depressed mood, feelings of hopelessness or worthlessness and suicidal ideations expressed at admission, family history of suicide, diagnosis of schizophrenia, and having been prescribed antidepressant medication [56].

Virtually all mental disorders are linked to an elevated risk of suicide. A register-based long-term follow-up study investigated the cumulative incidence of suicide by time since the first psychiatric inpatient or outpatient contact for each disorder in men and women, respectively [57]. The incidences were based on a 36-year observational follow-up study of the Danish population and showed that the suicide risk is highest in the first years after first contact and that all psychiatric diagnoses had an elevated suicide risk throughout the study period. The overall cumulative risk of dying by suicide

in people who had inpatient or outpatient clinical contact with specialized mental health services was 4% in men and 2% in women and varied across diagnoses, with a particularly higher risk of suicide in those diagnosed with schizophrenia or affective disorders, compared with other diagnoses such as substance abuse. Women diagnosed with bipolar/unipolar affective disorder or schizophrenia had a 4–5% long-term risk of dying by suicide, whereas this risk in men was 6–7%.

The increased risk of suicide in people with bipolar disorder has been estimated to be 200–400 per 100,000 person-years. The International Society for Bipolar Disorders published a meta-analysis of predictors of suicide death in relation to bipolar disorder [58]. Based on 12 studies, the variables being a man and having a first-degree family history of suicide were identified as significant risk factors of suicide.

Unipolar depressions occur with a prevalence of 2–3% among men and 3–5% among women in the general population [59, 60], and the general practitioner is often the first treatment contact for people with depression. It is difficult to identify who are at eminent risk of suicide, but addressing suicidal issues is important among patients who experience depressive episodes. Many studies have examined risk factors of suicide in people diagnosed with depression, and a meta-analysis based on 19 studies found that male gender, family history of psychiatric disorder, previous attempted suicide, severe depression, hopelessness, and comorbid disorders, such as anxiety and substance misuse, were significant predictors [61]. Treatment of depression is very important to reduce suicide risk. Antidepressants are commonly used in the treatment of people with depression. New generations of antidepressants, such as selective serotonin reuptake inhibitors (SSRIs) and serotonin/noradrenaline reuptake inhibitors (SNRIs), have been linked to suicidal ideation and preparative acts and behaviour in children and young people [62, 63], but protective for those older than 64 years [62]. When prescribing antidepressants, it is important to carefully monitor patients, especially when young people are treated.

In a meta-analysis, the lifetime suicide risk in schizophrenia was estimated to be 5.6% [57, 64]. In a long-term follow-up study from the UK of a large cohort of individuals, the absolute risk of suicide was 3.23% for patients 20 years after the initial diagnosis of a psychotic disorder [65]. Based on the standardized mortality ratio, this study also reported that the risk of suicide was 12-fold higher in patients with psychosis, when compared with the general population. A meta-analysis of risk factors for suicide in schizophrenia based on 29 eligible studies found robust evidence of increased risk being conferred by depressive disorders, previous suicide attempts, drug misuse, agitation and motor restlessness, fear of mental disintegration, poor adherence to treatment, and recent loss [66].

Suicide is also increased in those suffering from substance abuse [67–69] and personality disorders, especially borderline personality disorders [70]. Further, these disorders often exist as comorbidity to depression or schizophrenia. Thus, in addition to adding to the suicide risk, it also complicates the treatment and recovery of these patients [71, 72].

History of suicide attempt

Having a history of suicide attempt is possibly the most significant risk factor of completed suicide. A meta-analysis showed that as many as 1.6% persons died of suicide within 1 year after re-presenting

to hospital with a non-fatal suicide attempt and that one in 25 had died after 5 years [73]. In these studies, the suicide risk associated with the different mental disorders almost doubled if a patient had also been admitted to hospital with a suicide attempt [57].

A Swedish register-based study examined the association between the method of attempted suicide and the risk of subsequent suicide and found that individuals who had attempted suicide by hanging, strangulation, or suffocation had higher risks of dying by suicide [74]. In particular, this study highlighted that among patients who were admitted to hospital due to suicide attempt by method of hanging, strangulation, or suffocation and who had a coexisting diagnosis of a non-organic psychosis, 68.8% of women and 69.6% of men had completed suicide within a year.

Physical disorders

Severe somatic disorders have been associated with an increased risk of suicidal behaviour. Studies of specific disorders identified that peptic ulcers [75], renal disease [75], arthritis [76], acquired immune deficiency syndrome (AIDS) [77], cancer [78, 79], cerebral stroke [80–82], myocardial infarction [83], diabetes [84], multiple sclerosis [85, 86], and epilepsy [84, 87] were linked to an elevated suicide risk. Also relatively rare diseases, such as fibromyalgia and Crohn's disease [88, 89], have been linked to increased risks of suicidal behaviour. Danish findings showed that the time immediately after discharge from treatment of somatic diseases is linked to an excess risk [90].

Population-attributable risk

Population-attributable risk (PAR) is a useful measure when thinking in terms of suicide prevention. It estimates the potential for prevention if addressing effectively specific individual risk factors, although it does not include a measure for estimating the potential for prevention of societal risk factors. The PAR denotes the proportion of all suicides prevented if one were to avoid all suicides associated with a specific risk factor. For example, if the excess risk of suicide among single men would be reduced to the level of the general population, then the total number of suicides would be reduced with 26.2% (Table 125.2). The usefulness is apparent when comparing the PAR of different risk factors, as this provides information on which risk factors are linked to larger potentials of prevention. An important consideration is the population size affected by a risk factor. As the epidemiologist Rose noted, an intervention aimed at a large population at a low risk might result in prevention of more suicides than an intervention aimed at a small, but high-risk, group [91]. The size of the exposed population for each risk factor is also included in the PAR. As seen in Table 125.2, an intervention aimed at preventing suicides in a large population, such as single men, that has a relatively small excess suicide risk has the potential to prevent one in four of all male suicides. An intervention aimed at a proportionally smaller group, such as women who have been diagnosed with schizophrenia who have a 19-fold higher risk of suicide than the general population, would prevent 3.4% of all female suicides. The factors with the highest PAR are mental disorders, recent suicide attempt, and single marital status.

Table 125.2 Population-attributable risk (%) associated with specific risk factors [100–101]

Risk factor	Men	Women
Co-habiting marital status	1.9	1.0
Single	26.2	20.6
Unemployed	3.0	2.1
Age pensioner	7.0	18.8
Disability pensioner	1.7	6.7
Imprisoned	1.0	–
Lowest-income quartile	9.3	7.2
Sickness-related absence from work	6.6	6.2
Recent suicide attempt*	11.8	24.4
All psychiatric diagnoses	32.5	53.9
Any affective disorder	8.6	19.2
– Bipolar disorders	1.0	2.2
– Recurrent depression	3.9	9.8
– Other affective disorders	3.7	7.2
Schizophrenia	3.2	3.4
Other schizophrenic disorders	2.3	3.7
Borderline personality disorders	0.1	1.7
Other personality disorders	3.5	7.7
Reaction to stress/adjustment disorders	4.0	5.3
Other anxiety disorders	0.4	1.3
Substance use disorders	7.6	6.0
– Alcohol use disorders	6.0	3.7
– Drug use disorders	1.6	2.3
Dementia	0.5	0.7
Other psychiatric disorders	2.3	4.9

* Estimated on Danish citizens in year 2010, based on numbers from the Centre for Suicide Research in DK (prevalence of suicide attempt), Statistics Denmark (population size), and Carroll *et al*, 2014 (73) (percentage of fatal repetition within a year).

Self-harm

Epidemiology and risk factors

Nav Kapur, Sarah Steeg, and Adam Moreton

Introduction

Self-harm is a behaviour, not a diagnosis, so why should it appear in a textbook of psychiatry? People commonly present to emergency departments or mental health services having poisoned or injured themselves and in a state of distress. Self-harm is probably the strongest risk factor for suicide, and yet services to help people are patchy or non-existent. Although the evidence base to inform management is growing, it remains thin. In this chapter, we will discuss what we know about the epidemiology and risk factors for self-harm.

Terminology

Characterizing non-fatal suicidal behaviour is challenging, and the terminology in this area has developed over time. ‘Attempted suicide’ is problematic because many patients who self-harm do not wish to die or are too distressed to have formed a clear intent at the time of the episode. ‘Parasuicide’ describes an act of deliberate self-injury or poisoning which mimics the act of suicide but does not result in a fatal outcome [1]. However, this still contains a reference to suicide. ‘Deliberate self-harm’ became the preferred term in the UK, but in recent years, the prefix ‘deliberate’ has been dropped in response to concerns that it was judgemental and in recognition of the heterogeneous nature of the phenomenon [2]. Self-harm refers to an intentional act of self-poisoning or self-injury, irrespective of motivation [3]. This is the term that will generally be used throughout this chapter, except when we describe individual studies. People can hurt themselves in a variety of ways—by poisoning, self-cutting, burning, and scratching, as well as by other forms of potentially more lethal self-injury such as hanging, stabbing, and jumping.

Categorizing self-harm

Should people who self-harm be categorized into those who have clear suicidal intent and those who do not? Proponents have argued that a diagnosis of ‘non-suicidal self-injury disorder’ (NSSID) would increase precision and lead to improved communication between

health professionals, as well as stimulate research into causes and prevention and the development of specific treatments. Others have argued that the term is not useful because suicidal and non-suicidal motivations often coexist, methods of self-harm change, there is no clear dichotomy of intent in self-harm populations (it is continuously distributed), and even people with low-intent episodes are at increased risk of subsequent suicide [4]. It has been suggested that there are potential problems with creating a new diagnosis of NSSID for which there are few proven treatments and which could stigmatize large numbers of young people unnecessarily. Given the uncertainty, we will use the broad and inclusive definition of self-harm, as highlighted in UK national guidance [5]. However, it should be noted that NSSID and attempted suicide disorder are included in DSM-5 as conditions requiring further study.

Understanding the epidemiology of self-harm: the iceberg model of suicidal behaviour

It has been suggested that the epidemiology of suicidal behaviour might be best conceptualized as an iceberg (Fig. 126.1). Behaviours become more common, but less severe and less visible as one descends the iceberg. The most serious episodes are at the top—deaths by suicide. Self-harm which comes to medical attention is the next level of the iceberg. Even when people present to hospitals, some episodes may go unrecognized and are hence ‘under the surface’. Self-harm in the community may be hidden and never come to the attention of health or helping services. Below this, there may be an even larger group of people who experience thoughts of self-injury without acting on them. The important point to note is that the vast majority of epidemiological research in self-harm has been carried out in hospital settings.

We know far less about self-harm in the community. It is difficult to put definitive numbers to the various levels of the iceberg, but McMahon and colleagues attempted to do just this in a recent Irish study of suicidal behaviour in young people where they estimated just 6% of self-harm episodes resulted in hospital presentation. This proportion might be higher in adults—data from a UK household survey suggested that around half of people who attempted suicide or self-harm received some form of help from clinical services [6].

Fig. 126.1 The iceberg of suicidal behaviour.

In the following sections, we will examine data on the community prevalence of self-harm from international and school surveys before moving on to the hospital-based epidemiology of self-harm.

International surveys of suicidal behaviour

One of the challenges of international survey data is ensuring consistent methodology across settings. Findings need to be interpreted cautiously, as survey data tend to be self-reported. Response rates may also vary between centres.

Nock and colleagues [7] assessed the prevalence of suicidal ideation, plans, and attempts using the Composite International Diagnostic Interview, as part of the World Health Organization (WHO) World Mental Health Survey initiative. Across 17 high-, middle-, and low-income countries, the lifetime prevalence of suicide attempts was 2.7%, with a lifetime prevalence of 9.2% for ideation and 3.1% for suicide planning. There was substantial cross-national variability, with the lifetime prevalence of suicide attempts ranging from 0.7% in Nigeria to 5% in the United States.

More recently, the WHO has estimated that the global annual rate of suicide attempts is around 4 per 1000 adults on the basis of the same survey methodology [8]. Interestingly, the 12-month prevalence rates for suicidal behaviour were found to be similar for males and females in high- and low-income countries (0.3–0.4%), but higher for females (0.6%) than males (0.3%) in middle-income countries [8].

In a UK household survey, 5.6% of adults reported a lifetime history of suicide attempts and 4.9% a history of self-harm (without suicidal intent), with a 50% overlap between the groups. The prevalence of suicide attempts during the previous year was 0.7% (these previous-year data were not available for self-harm) [6].

School surveys of self-harm

School-based surveys are a useful source of information. In an international study of self-harm in adolescents (Child and Adolescent Self-harm in Europe study), Madge and colleagues [9] reported rates for self-harm in the previous year of 8.9% for females and 2.6% for

males, and lifetime rates of 13.5% and 4.3%, respectively. In terms of methods of self-harm, over half of episodes involved self-cutting and around a fifth poisoning. Many countries have shown similar rates of self-harm in their adolescent populations, (for example, [10, 11]), although some recent research reported considerable variation. A study, using self-report data on over 45,000 15- to 16-year olds from 17 countries participating in the European School Survey Project on Alcohol and Other Drugs, found the proportion reporting a lifetime suicide attempt varied from 4% in Armenia to 24% in Hungary, with a median of around 11% [12]. Female rates were consistently almost twice as high as male rates. Regardless of the precise incidence, it is clear that self-harm is a commonly reported issue in adolescence and often a major concern for young people themselves, their parents, and their teachers.

The hospital-based epidemiology of self-harm

Register-based studies of self-harm are another valuable source of information but generally only identify people presenting to hospital. However, this is an important and relatively severe subgroup of those who self-harm.

As part of the WHO/EURO multi-centre study of suicidal behaviour, Schmidtke and colleagues [13] investigated treated episodes and found that self-harm was more common among females than males and higher rates were found among younger adults. In particular, young women aged 15–24 years and young men aged 25–29 years had the highest rates of self-harm. There was also substantial variation, with a 6- to 9-fold difference in self-harm rates, even among countries in Europe.

Ireland has a national registry of self-harm, which has been running since 2002 and collects data from hospital emergency departments [14]. In 2014, the annual rate of self-harm was 185 per 100,000 for men and 216 per 100,000 for women. The peak ages were 15–19 years for females and 20–24 years for males. In contrast to community settings, the majority of episodes (70%) involved overdoses of medication or other substances and 26% involved cutting. In interpreting these data, it should be noted that emergency department visits incur a personal cost to the patient in Ireland.

In England, self-harm data are available from 2000 for the three sites that make up the Multicentre Study of Self-harm in England (Oxford, Manchester, and Derby) [15]. In 2013, the rates of self-harm were 322 per 100,000 per year for men and 468 per 100,000 per year for women. The peak age of presentation during the study period (2000–2012) was 15–24 years for women (41% of female episodes). Men had a more even age distribution, with approximately one-third of men who self-harmed aged 15–24 years and one-third aged 35–54 years. Self-poisoning featured in 75% of episodes, and self-injury (mostly cutting) in 21% of episodes. In terms of medication ingested in overdose, despite legislation to reduce pack sizes, paracetamol was the most common substance (ingested in 35% of episodes). This was followed by selective serotonin reuptake inhibitor (SSRI) or serotonin/nor-adrenaline reuptake inhibitor (SNRI) antidepressants (17%), benzodiazepines (14%), and paracetamol-containing compounds (11%).

Trends in self-harm

There was a substantial increase in the rates of self-harm during the 1960s and 1970s in the UK [16], but accurate long-term data are

sparse. Data from the Oxford Monitoring system suggests hospital presentations for self-harm have increased by 60% since the 1970s, but annual rates based on individuals are not dissimilar to earlier years. It seems likely that rates of hospital-based repetition have increased, but the reasons for this are unclear.

International data suggest that the prevalence of suicidal behaviour may have remained relatively stable between 1997 and 2007 [7]. With respect to adolescent self-injury, a systematic review concluded that although rates were high, relative to other age groups, they did not seem to have increased internationally between 2007 and 2011 [17].

It seems likely that rates of self-harm in adults increased in response to the 2008 recession, especially in centres which experienced increased joblessness in the UK [18]. Research from Ireland suggests a greater impact on men [19]. There has been much recent concern about a possible epidemic of self-harm among adolescents. This has not been substantiated in the research literature but is a focus of much ongoing work.

Risk and protective factors for self-harm

The causes of self-harm are multiple and complex. Some researchers conceptualize self-harm as part of a 'suicidal process' that ranges from thoughts through to self-injurious behaviour and ultimately suicide for a minority of people [20]. Self-harm may share many risk factors with suicide, but some are also distinct. One striking difference is the gender ratio—self-harm tends to be more common in women, and suicide much more common in men. It has been suggested that the reasons for this disparity may include methods (men may choose more lethal methods when they hurt themselves) or help-seeking behaviour (men may be less likely to seek help if they become physically or psychologically unwell). **Table 126.1** summarizes some of the most important risk and protective factors for self-harm, and these will be discussed in more detail in the next section. Protective factors have been subject to much less research than risk factors.

Table 126.1 Risk and protective factors for self-harm

Sociodemographic factors	Gender Age Ethnicity Sexual orientation Deprivation Social support (p) Religious affiliation (p)
Biological factors	Genes Neurochemistry
Clinical factors	Psychiatric disorder Physical disorder Alcohol misuse
Psychological factors	Impulsivity Poor problem-solving skills Hopelessness
Environmental factors	Early adversity Later life events Education (p) Media

(p) indicates a possible protective factor.

Sociodemographic factors

Self-harm is more common in young people, particularly girls in mid to late adolescence. The increase in the incidence of self-harm in the early teenage years is striking and may be linked to the pubertal stage. Underlying mechanisms could be biological or social (for example, sensitivity to social cues or propensity to imitative self-harm). Self-harm in older adults tends to be associated with a greater suicidal intent [21] than in younger age groups, and its incidence may be increasing [21].

Socio-economic disadvantage is associated with self-harm in both high- [22] and low- and middle-income countries [23]. There is evidence that rates of self-harm may increase at times of economic adversity [18]. Social isolation is also an important factor [22], but good communication and family functioning may be protective [24]. A 2013 review by Beghi *et al.* reported a weak association between unmarried marital status and repetition of self-harm [25]. Although previous studies suggested that young South Asian females were at increased risk of self-harm, this has not been borne out by more recent studies and reviews [26, 27], which suggested the highest risks are in young black females. In older age groups, self-harm is most common among the white population. People from all minority ethnic groups were less likely to repeat self-harm in a large English study [26]. A review of adolescent suicidal behaviour in the United States found the highest rates among white youths [28]. Religious affiliation is likely to be protective [29], although this may be context-dependent—religious minorities may feel socially isolated and so may be at greater risk. Sexual orientation is also a risk factor for suicide attempt, with the highest risks possibly in gay and bisexual men [30].

Genetic and biological factors

A family history of suicide increases the individual's risk of suicide, a finding that may be explained by observational learning or genetic predisposition. A genetic explanation is supported by twin studies and adoption studies which suggested a heritability of between 30% and 50% (or 17% once other psychiatric disorders have been taken into account). What is inherited is unknown. No specific genes coding for suicidal behaviour have been identified. Instead much of the research interest has shifted to the link between early life experience and epigenetic mechanisms that could explain some of the link between childhood exposures, suicide risk, brain circuitry, and neurochemistry. Studies suggested that changes in the polyamine and serotonergic systems and the hypothalamic–pituitary–adrenal axis might be implicated. These could make certain individuals more vulnerable to suicidal behaviour (for a comprehensive recent review, see [31]).

Clinical and psychological factors

The prevalence of psychiatric disorders in people who self-harm varies according to the setting and method of assessment. Using diagnostic interviews and research criteria, as many as 90% of those who present to hospital may have an Axis I psychiatric disorder, with the most common single diagnosis being affective disorder (70%) [32]. However, it is possible that psychiatric symptoms at the time of an episode are relatively transient and may remit spontaneously in a substantial proportion of cases. A history of psychiatric disorder is also important. In a cross-national community study, a

prior mental disorder was associated with significantly increased risk of developing suicidal behaviours, even after adjusting for sociodemographic factors and country of residence. Mood disorders had the strongest association [33].

Alcohol consumption is also an important contributory factor to self-harm—both acute ingestion (which may increase the risk of impulsive behaviour) and longer-term misuse [34]. Physical illness is a risk factor for self-harm, perhaps more so for women than men [35]. At least for some illnesses (asthma, back pain, diabetes, epilepsy, hypertension), the association persists after adjustment for depression [35].

A number of psychological characteristics are more common among those who self-harm; these include impulsivity, poor problem-solving, perfectionism, and hopelessness [36]. It is possible to apply diagnostic labels to some of these characteristics (for example, personality disorder), but this may have the unfortunate consequence of causing stigma, diverting attention from enabling the person to overcome their problems or even leading to them being denied help [2].

Environmental factors

Childhood adversity, including early abusive experiences, can predispose to self-harm. A recent review suggested that sexual abuse was the most important of these antecedents, but that physical abuse and domestic violence were also associated with self-harm [37]. A classic review found strong cross-sectional associations between childhood sexual abuse and self-harm, but the lack of longitudinal prospective studies led the authors to conclude that these exposures could not be classified as true risk factors [38]. A meta-analysis, which only considered non-suicidal self-injury as an outcome, found a weak association with sexual abuse, which largely disappeared after adjustment for psychiatric factors [39]. On balance, it seems likely that adverse childhood experiences can lead to later self-harm, but this effect may be mediated through an association with clinical factors.

As well as individual exposures, there may also be an association between self-harm and the number and type of adverse events that an individual reports having experienced during their lifetime [22]. Early studies established that life events, particularly interpersonal ones, were important immediate precipitants of self-harm [40], and this has been confirmed more recently [41].

The role of the media in propagating suicidal behaviour, possibly by increasing the cognitive availability of self-harm methods or normalizing it as a coping strategy, is an additional environmental factor and the subject of much published work [42]. Social media is a further development, of course, and the subject of considerable ongoing research.

Outcomes

Repetition, suicide, and death from all causes are outcomes of particular interest following self-harm. Each will be explored in more detail in the rest of this chapter.

Non-fatal repetition

A recent meta-analysis of 170 cohort studies and randomized trials in people who had presented to health care services with self-harm suggested that the pooled incidence of repeat self-harm was 16.3%

at 1 year and 22.4% at 5 years [43]. Repetition rates based on patient self-report, as opposed to hospital databases, were around 5% higher at 1 year. There was also some evidence that repetition rates were lower in Asian vs non-Asian countries, perhaps due to differences in ascertainment or the method of self-harm. Poisoning in South Asia has a higher case fatality during the index episode than in the West due to the lethality of the substances ingested—for example, pesticides.

The timing of repetition is striking and has important clinical implications. Most people who repeat self-harm do so soon after they present to hospital. Data from the Manchester Self-harm Project (Fig. 126.2) suggest that 30% of people who repeat within a year will do so within 1 month of presentation and one in ten will repeat within 5 days. This means that any aftercare needs to be provided without delay.

Suicide

The Carroll *et al.* systematic review [43] found that 1.6% of people died by suicide in year after presentation with self-harm, with a pooled suicide incidence of 3.9% at 5 years and a persistent risk of suicide in the longer term. The risk of suicide was twice as high in men than in women, and higher in studies which focused on older age groups. Self-poisoning was associated with a lower risk of subsequent suicide than other methods. Gender and age together explained nearly 70% of the between-study variation. In a UK single-centre study, suicide rates were highest within the first 6 months after the index self-harm episode [44].

All causes of death

In an English study of over 30,000 individuals presenting with self-harm to three centres and followed up for an average of 6 years, approximately 6% of the cohort died—about four times the number of deaths that would be expected according to general population mortality rates [45]. The risk of death increased with levels of socioeconomic deprivation. Diseases of the circulatory and digestive systems made a major contribution to natural mortality. This study also expressed the risk of death as mean years of life lost—25–26 years for natural-cause deaths, and 40 years for external-cause deaths (for example, accidents, suicide, and undetermined deaths).

Outcome of self-harm in young and older people

The prognosis of self-harm is of great concern to young people and their parents. A cohort study of 1800 adolescents in Victoria, Australia provided a valuable insight into the natural history of self-harm in young people [46]. The researchers found that 4% of the sample reported self-harm within the previous 12 months at the start of the adolescent phase of data collection (mean age of cohort 15.9 years). This fell steadily through subsequent waves of data collection, so that by the end of the study (mean age of cohort at this stage 29.0 years), just 0.8% reported self-harm. Of the young people who self-harmed in adolescence, only one in ten continued to do so as young adults.

Some authors have argued that fatal and non-fatal self-harm are more closely related in the elderly than in younger age groups [47]. In a large English study of older adults (>60 years), the suicide rate was 1.5% within 12 months of self-harm, 67 times higher than in the general population of similar age and three times higher than in younger self-harm patients in the same cohort. Suicide was most common in those aged 75 years and over [48].

Fig. 126.2 Timing of repeat self-harm for people repeating within a year ($N = 3078$).

Source: data from the Manchester Self-harm project.

Risk factors for repetition

Many studies have examined the factors which might make repeat self-harm more likely. In a recent systematic review of 129 prospective studies, a number of factors were identified as consistent predictors of self-harm repetition [49]. Many of these were similar to the risk factors for incident self-harm. They included previous self-harm, personality difficulties, hopelessness, a history of psychiatric treatment, schizophrenia, and alcohol and drug misuse. However, the sensitivity of individual variables (ability to correctly identify those who went on to repeat) varied greatly between studies. Other factors were less consistently reported, but it was suggested they too were linked to increased repetition, for example impulsivity, comorbidity, poor problem-solving ability, sexual abuse, staff attitudes to self-harm, and stressful life events. Self-cutting was associated with a higher risk of repetition than self-poisoning. Area-based variables, such as deprivation, may also be important determinants of suicidal behaviour, but an English study suggested an individual's own characteristics were much more powerful predictors of repetition than the characteristics of the area in which they lived [50].

In a separate review of risk factors for suicide following self-harm, updating work carried out as part of the National Institute for Health and Care Excellence (NICE) guidelines [51], four risk factors emerged from a meta-analysis with robust effect sizes that showed little change, even after adjustment for potential confounders. These included: previous episodes of self-harm, suicidal intent, physical health problems, and male gender. However, the authors suggested that the factors might be of limited practical use because these were common in clinical populations. In a large, Manchester (UK)-based study [52], independent risk factors for suicide after hospital presentation for self-harm were: avoiding discovery at the time of self-harm, not living with a close relative, previous psychiatric treatment, self-cutting (vs self-poisoning), alcohol misuse, and physical health problems. The overall adjusted population-attributable fraction for the statistical model in the study (a measure of the overall proportion of self-harm repetition in a population that might be accounted for by the variables) was 65%.

Drawing risk factors together—models of self-harm

Although risk factors may provide some clues to the aetiology, they are unable to explain why self-harm occurs. Explanatory models may help us to understand the phenomena better, help to formulate testable hypotheses, and ultimately facilitate the development of appropriate treatments. One of the most influential models of suicidal behaviour is a clinical model—the stress–diathesis or stress–vulnerability model [53]. This suggests that certain individuals carry with them a predisposition to suicidal behaviour (which may be related to sex, religion, familial and genetic factors, childhood experiences, psychosocial support systems, access to lethal methods, or biological factors). The vulnerability only leads to suicidal behaviour when the individual encounters a stressor (which could be a mental disorder, alcohol or drug misuse, a medical illness, or a psychosocial crisis). Other influential models of suicidal behaviour include the ‘cry of pain’ model (which emphasizes the role of defeat and entrapment—the sense there is nowhere else to go, following the experience of a major stressor), the interpersonal–psychological model (which suggests perceived burdensomeness and thwarted belongingness are central to suicidal ideation), and the integrated motivational–volitional model, a stress–diathesis model which highlights the pre-motivational, motivational (ideation and intent formation), and volitional (behavioural, enactment) phases of suicidality. A full review is provided in [36].

Risk scales

Combinations of risk factors considered together in ‘risk assessment scales’ are in widespread use. A study from 32 hospitals in England found that the vast majority of services used risk assessment tools, and in 22 of 32 hospitals, the tools were locally developed and unvalidated [54]. A number of recent reviews [51, 55, 56] have suggested that scales are of limited usefulness in terms of predicting future outcomes such as repetition and suicide. Positive predictive values for suicide ranged from 1% to 17%, with the most relevant UK study suggesting a value of 4%. This means that of 100 people identified as being at high risk, four will die by suicide. However, a greater

number of suicide deaths occur in the large low- and middle-risk groups—the so-called population paradox. These may be missed if services are organized according to high-risk paradigms. This has important implications for management, with some authorities going as far as to suggest that viewing risk assessment as risk prediction is a fallacy. Management decisions should be based on more generic models of assessment which emphasize the need to engage with patients, rather than tick-box assessments [51].

The development of novel risk measures is the subject of ongoing research. One approach is to use data-driven methods to derive the most important combination of risk factors in a development data set and then test the instrument in a separate validation data set [56]. Examples of these empirically derived tools include the Manchester Self-Harm and ReACT rules and the Repeated Episodes of Self-Harm (RESH) score. Although robustly developed, there is no good evidence that these tools are any more useful than older scales [55]. A different approach is to use neurocognitive or psychological functioning as a marker of risk. The advantage of some of these measures is that they can be used when people are unaware of their intent or not articulating it. Traits that may be predictive include deficits in attentional shifting, deficits in verbal fluency, and poor decision-making [56]. Another novel method—the Implicit Association Test—measures the reaction time for people to respond to images (related to suicidal behaviour or neutral images) [57]. Shorter reaction times are thought to be associated with a greater propensity to suicidal behaviour. The predictive ability of the test may be improved when used in conjunction with other traditional risk factors [56].

Which risk factors are the most important clinically?

Although some risk factors are common in clinical populations and the predictive value of risk scales is dubious, clinicians clearly need to assess and treat patients. Which risk factors are the most clinically important? One practice-based review suggested that mental illness, alcohol and drug use, current thoughts and plans, gender, and previous self-harm, along with possible protective characteristics (such as dependent children, supportive family, religious beliefs) were the most important factors to take into account in a real-world clinical assessment [58].

Biological aspects of suicidal behaviour

J. John Mann and Dianne Currier

Modelling suicidal behaviours

To understand the biological underpinnings of multi-determined behaviours such as suicide and attempted suicide, it is best to conceptualize them within an explanatory model that describes the potential causal pathways and interrelations between biological, clinical, genetic, and environmental factors that all play a role in suicidal behaviour. Where possible, such a model should be clinically explanatory, incorporate biological correlates, be testable in both clinical and biological studies, and have some utility in identifying high-risk individuals.

One such model is the stress–diathesis model of suicidal behaviour wherein exposure to a stressor precipitates a suicidal act in those with the diathesis, or a propensity for suicidal behaviour [1]. Stressors are generally state-dependent factors such as an episode of major depression or the occurrence of an adverse life event. The diathesis comprises trait characteristics of reactive aggression, deficits in executive function, negative or rigid cognitive processes, impaired problem-solving, social distortions, and recurrent mood disorders [2]. Uncovering the biological mechanisms relevant to the stress and the diathesis dimensions of suicidal behaviour will facilitate the identification of both enduring and proximal markers of risk, and thus potential targets for prevention interventions.

This chapter gives an overview of the major neurobiological findings in suicide and attempted suicide, as well as emerging findings from studies of genes related to those neurobiological and stress response systems.

Serotonergic system

A key biological correlate of the diathesis for suicidal behaviour appears to be low serotonergic activity. Abnormal serotonergic function may be the result of numerous factors, including genetics, early life experience, chronic medical illness, alcohol use disorders, or substance use disorder, many of which have been correlated with an increased risk for suicidal behaviour. Moreover, serotonergic dysfunction may underlie recurrent mood disorders, as well as behavioural traits that characterize the diathesis such as aggression, pessimism and dysfunctional attitudes, hopelessness, and deficits in decision-making.

Serotonin is involved in brain development, behavioural regulation, sleep, mood, anxiety, cognition, and memory and is shown

to be disturbed in various psychiatric disorders. Serotonergic function is under genetic control, and moreover deficits in functioning have been shown to be enduring, marking it as a biological trait. The serotonergic system became a target for investigation in relation to suicide when, more than 40 years ago, Asberg and colleagues observed that depressed individuals who had either attempted suicide by violent means or subsequently died by suicide in the study follow-up period were more likely to have lower 5-hydroxyindoleacetic acid (5-HIAA) levels in the cerebrospinal fluid (CSF) [3]. Since that time, the function of the serotonergic system in suicide and attempted suicide has been examined in many paradigms, and while not all studies agree, there is substantial consensus that individuals who die by suicide, or make serious non-fatal suicide attempts, exhibit a deficiency in CNS serotonin neurotransmission.

Evidence of hypofunction comes from CSF and post-mortem studies. 5-HIAA is the major metabolite of serotonin, and the level of CSF 5-HIAA is a guide to serotonin activity in parts of the brain, including the prefrontal cortex. There have been over 20 studies of CSF 5-HIAA and suicidal behaviour in mood disorders, and a meta-analysis of prospective studies of 5-HIAA found that in mood disorders, lower CSF 5-HIAA levels increased the chance of death by suicide by over 4-fold over follow-up periods of 1–14 years [4].

Several post-mortem studies of suicide have reported lower brainstem levels of 5-HIAA and/or serotonin [5-hydroxytryptamine (5-HT)] (for a review, see [5]). These deficits in 5-HT or 5-HIAA are observable across diagnostic groups [6] and, despite early reports to the contrary, appear to be independent of the suicide method. A limitation of these studies is that they did not use toxicological sensitive assays of brain tissue or psychological autopsy interviews to rule out recent antemortem antidepressant exposure which would potentially lower 5-HIAA levels. A more recent study that carefully ruled out such medication exposure found higher levels of 5-HT and 5-HIAA in the brainstem of depressed suicides [7]. This observation appears to be largely specific to the brainstem, because no differences are generally found between suicides and controls in 5-HT level in other brain regions, including the hippocampus, occipital cortex, frontal cortex, temporal cortex, caudate, striatum, or hypothalamus [5]. Serotonin neuron cell bodies are in the brainstem raphe nuclei, while their axons innervate most of the brain, including the ventral prefrontal cortex. Morphological analysis of stained serotonin neurons in the brainstem of depressed suicides and non-suicides

observed greater cell density in the dorsal raphe nucleus in suicides [8] and greater expression of the rate-limiting biosynthetic enzyme for serotonin—tryptophan hydroxylase—per neuron [9], suggesting that reduction in serotonin activity is associated with dysfunctional cells, and not with fewer neurons. That observation is consistent with the report of more 5-HT in the brainstem of suicides [7].

Neuroendocrine challenge studies using fenfluramine provide further evidence of anomalous serotonergic function associated with suicidal behaviour. Fenfluramine is a serotonin-releasing agent and a reuptake inhibitor that may also directly stimulate post-synaptic 5-HT receptors. The release of serotonin by fenfluramine causes an increase in serum prolactin levels that is an indirect index of central serotonergic responsiveness. In depressed patients, those with a history of suicide attempts have a more blunted prolactin response to fenfluramine challenge than non-attempters, with evidence that the effect is more related to lethality of past suicide attempts [10].

Lower serotonergic transmission in the central nervous system (CNS) may be accompanied by a compensatory upregulation of some serotonergic post-synaptic receptors, such as 5-HT_{1A} and 5-HT_{2A} receptors, and a decrease in the number of serotonin transporters [5]. There is a reported increase in the concentration of post-synaptic 5-HT_{2A} receptors in the prefrontal cortex of suicides, compared with non-suicides [11]. This increased binding is reflected in more protein and may be due to elevated gene expression in young suicides [12]. Elevated 5-HT_{2A} binding has also been reported in the amygdala in depressed suicides [13]. In depressed and non-depressed suicides, there is evidence that 5-HT_{2A} receptors are upregulated in the dorsal prefrontal cortex, but not the rostral prefrontal cortex [11].

Platelet studies examine 5-HT_{2A} in living subjects with respect to non-fatal suicide attempt. 5-HT_{2A} receptors, serotonin reuptake sites, and serotonin second messenger systems are present in blood platelets, and changes in these platelet measurements may reflect similar changes in the CNS. Multiple studies have reported higher platelet 5-HT_{2A} receptor numbers in suicide attempters, compared with non-attempters and healthy controls [14].

Studies of second messengers indicated impaired 5-HT_{2A} receptor-mediated signal transduction in the prefrontal cortex of suicides [15], and in platelets, 5-HT_{2A} receptor responsivity is significantly blunted in patients with major depression who have made high-lethality suicide attempts, compared to depressed patients who have made low-lethality suicide attempts [16]. The implications of such a defect in signal transduction, if present in the brain, would be that although there may be greater density of 5-HT_{2A} receptors, the signal transduced by 5-HT_{2A} receptor activation may be blunted.

Some post-mortem studies of the post-synaptic 5-HT_{1A} receptor have reported higher binding in the prefrontal cortex and more rostral segments of the raphe nuclei, and lower binding in the more caudal raphe nuclei, hippocampus, prefrontal cortex, and temporal cortex [17]. Less 5-HT_{1A} auto-receptor gene expression has also been reported in the dorsal raphe [18] and would favour higher serotonin neuron firing rates.

Post-mortem studies of depressed suicides reported fewer 5-HT transporters in the prefrontal cortex, hypothalamus, occipital cortex, and brainstem [19]. Moreover, in suicides, this deficit appears localized to the ventromedial prefrontal cortex and anterior cingulate, whereas depressed individuals who died of other causes had lower binding throughout the prefrontal cortex [20].

The emerging picture from post-mortem studies of greater 5-HT_{2A} receptor binding in the frontal cortex of depressed individuals who die by suicide, fewer brainstem 5-HT_{1A} auto-receptors, and fewer serotonin transporters in the cortex, as well as findings of greater tryptophan hydroxylase (the rate-limiting step in serotonin synthesis) immunoreactivity in serotonin nuclei in the brainstem [9], all point to homeostatic changes designed to increase deficient serotonergic transmission, evidenced by low 5-HIAA in the CSF and brain, and blunted prolactin response to fenfluramine challenge.

Serotonergic dysfunction and suicide endophenotypes

Reactive aggressive traits are potentially part of the diathesis for suicidal behaviour [1]. Increased aggression has been associated with suicide and more highly lethal suicide attempts, and impulsivity has shown a stronger relationship to non-fatal suicide attempts [21]. Reduced activity of the serotonergic system has been implicated in impulsive violence and aggression in studies in a variety of paradigms, including: low CSF 5-HIAA levels in individuals with a lifetime history of aggressive behaviour with personality and other psychiatric disorders [22, 23]; a blunted prolactin response to the serotonin-releasing agent fenfluramine in personality disorder patients [24, 25]; and greater platelet 5-HT_{2A} binding correlated with aggressive behaviour in personality and other psychiatric disorder patients [26, 27]. In a post-mortem study of aggression, suicidal behaviour, and serotonergic function, a positive relationship was found between lifetime history of aggression scores and 5-HT_{2A} binding in several regions of the prefrontal cortex of individuals who had died by suicide [28].

Positron emission tomography (PET) studies have shown a deficient response to serotonergic challenge in the orbitofrontal cortex and medial frontal and cingulate regions in individuals with impulsive aggression, compared to controls [29, 30], and lower serotonin transporter binding in the anterior cingulate cortex in impulsive and aggressive individuals, compared to healthy controls [31]. The prefrontal cortex is important in the inhibitory control of behaviour, including impulsive and aggressive behaviour [32]. Thus, aggressive/impulsive traits, related to serotonergic dysfunction, are potentially an aspect of the diathesis for suicidal behaviour, whereby aggressive/suicidal behaviour is manifested in response to stressful circumstances or powerful emotions. This tendency might be conceived of as a diminution in brain inhibitory circuits or as a volatile cognitive decision-making trait.

Noradrenergic system

According to the stress–diathesis model of suicidal behaviour, it is the confluence of stressful events with the diathesis that is thought to precipitate a suicidal act. Thus, investigating the functioning of stress response systems in suicidal individuals is important for elucidating neurobiological concomitants of suicidal behaviour and identifying targets for preventative intervention. The noradrenergic system and the hypothalamus–pituitary–adrenal (HPA) axis are two key stress response systems.

The majority of noradrenaline neurons in the brain are located in the brainstem's locus caeruleus. Post-mortem studies of suicides have documented fewer noradrenergic neurons in the rostral locus caeruleus, the part that projects to the brain [33]. There are also

indications of cortical noradrenergic overactivity, including lower α - and high-affinity β_1 -adrenergic receptor binding [34], and lower β -adrenoceptor density and α_2 -adrenergic binding in the prefrontal cortex in individuals who died by suicide [35]. There is some, but not unanimous, evidence from prospective studies of lower CSF levels of 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite of noradrenaline, in future suicides [36], although not in those making non-fatal suicide attempts [37]. Low CSF MHPG levels predict both the probability of a suicide attempt and the lethality of the attempt.

Fewer noradrenergic neurons observed in depressed suicides may indicate a lower functional reserve of the noradrenergic system, which, if accompanied by an exaggerated stress response with a greater release of noradrenaline, may result in noradrenaline depletion, leading to depression and hopelessness, both of which are contributory factors to suicidal behaviour.

Noradrenergic response to stress in adulthood appears to be greater in those reporting an abusive experience in childhood [38]. Such individuals are potentially at greater risk in adulthood for major depression and suicidal behaviour. Childhood abuse may be associated with an increased risk for depression and suicidal behaviour because of a dysfunctional stress response both via the noradrenergic system and via the HPA axis, and secondary effects of noradrenaline depletion and elevated cortisol levels. There is interaction between the noradrenergic system and the stress response activity of the HPA axis, with reciprocal neural connections between corticotropin-releasing hormone (CRH) neurons in the hypothalamic paraventricular nucleus and noradrenergic neurons in the human brainstem and locus caeruleus [39].

The hypothalamic-pituitary-adrenal axis

The HPA axis is a major stress response system. Major depression is associated with hyperactivity of the HPA axis [40], and suicidal patients in diagnostically heterogeneous populations exhibit HPA axis abnormalities, most commonly failure to suppress cortisol normally after dexamethasone [36]. We found most future suicides were dexamethasone suppression test (DST) non-suppressors [4]. In mood disorders, DST non-suppressors had a 4.5-fold greater risk of dying by suicide, compared with suppressors [4]. Moreover, non-suppression may be characteristic of more serious attempts that result in greater medical damage [41, 42] or the use of violent methods in the suicide attempt [43]. In other indices of HPA axis function, suicide attempters had attenuated plasma cortisol responses to fenfluramine, although that may indicate less serotonin release, and not an HPA abnormality [44, 45], and lower CSF CRH levels, compared to non-attempters [46], though not all studies agree.

Larger pituitary and adrenal gland volumes have been reported in depressed suicides [47, 48] and fewer CRH binding sites in the prefrontal cortex of depressed suicide victims, which may mean receptor downregulation due to elevated corticotropin-releasing factor (CRF) release [49].

As with the noradrenergic system, early life adversity appears to have lasting effects on stress response in the HPA axis in adulthood. Abnormalities in HPA axis function have been implicated in poor response to drug treatment and a greater likelihood of relapse in major depression, both of which increase the risk for suicidal acts [36]. Increased anxiety and agitation reflect another potential pathway

whereby an abnormal stress response, in both the noradrenergic and the HPA axis, contributes to risk for suicidal behaviour.

Other biologic systems

Abnormality in the dopaminergic system has been reported in depressive disorders [50]. However, studies of dopaminergic function and suicidal behaviour are relatively few and inconclusive [5]. Low dihydroxyphenylacetic acid levels, indicative of reduced dopamine turnover, in the caudate, putamen, and nucleus accumbens have been reported in depressed suicides [51], although the same group of investigators found no difference in number or affinity of the dopamine transporters [52]. Accordingly, it is unlikely that the reduced dopamine turnover initially observed in depressed suicides is a result of decreased dopaminergic innervation of those regions. Prospective studies disagree as to whether CSF homovanillic acid (HVA) levels predict suicidal behaviour [53–55]. Low CSF HVA levels may be related to higher lethality suicide attempts in males.

There is a well-documented relationship between thyroid dysfunction and depression [56], and some studies have linked thyroid function and suicide. Abnormal thyroid-stimulating hormone (TSH) response to thyrotropin-releasing hormone (TRH) has been observed in individuals who died by suicide in a follow-up study [57]. Abnormal TSH response to challenge tests has also been associated with poor response to antidepressant treatment and a higher relapse rate which may increase the risk for suicidal behaviour [58].

Neurotrophins are involved in brain development and growth, neuronal functioning, and synaptic plasticity. Lower protein levels and gene expression of brain-derived neurotrophic factor (BDNF) in the prefrontal cortex and hippocampus [59, 60] and less mRNA of nerve growth factor, neurotrophin 3, and neurotrophin 4/5 in the hippocampus [61] have been reported post-mortem in suicides. Lower plasma BDNF levels have been reported in major depressive disorder (MDD) suicide attempters, compared to MDD non-attempters and healthy controls [62].

Suicide is more common in groups with very low cholesterol levels or after cholesterol lowering by diet (for a review, see [63]). This relationship between cholesterol levels and suicide may be mediated by serotonergic function, as studies of non-human primates on a low-fat diet found lower serotonergic activity and increased aggressive behaviours [64]. Long-chain polyunsaturated fatty acids, particularly omega-3 [docosahexaenoic acid (DHA)], may also be a mediating factor in the relationship between low cholesterol levels and increased risk for depression and suicide [65]. A decrease in DHA concentration was associated with a 14% increased risk for suicide death for every standard deviation decrease in DHA level in a large study of military suicides in the United States [66]. However, other post-mortem studies did not find any association [5]. Lower DHA percentage of total plasma polyunsaturated fatty acids and a higher omega-6:omega-3 ratio predicted depressed individuals who made a suicide attempt during a 2-year follow-up [67], and lower eicosapentaenoic acid is found in red blood cells of suicide attempters, compared to controls [68].

Other potential candidate neurobiological systems for investigation with respect to suicidal behaviour come from genetic studies. One novel approach examined the correlations between candidate genes and gene expression in the prefrontal cortex of suicides, with

the aim to identify correlations that were independent of mood disorder diagnosis [69]. That study identified genes related to suicidal behaviour which had not been previously identified in candidate gene studies of suicide, but which did overlap with the broad biologic domains identified in earlier expression studies in suicide, including CNS development, homophilic cell adhesion, regulation of cell proliferation, and transmission of nerve impulse [69–71]. Other recent work points to potential involvement of the immune system, for example *CD44*, a gene connected with the immune system that has been identified in three studies of suicides, and Galfalvy *et al.* additionally found its expression in both BA9 and BA24 was significantly low [69]. Immune system dysregulation has been reported in major depression [72, 73], but there has been little investigation of its role in suicide. The inflammatory and neurodegenerative hypothesis of depression hypothesizes that neurodegeneration and reduced neurogenesis are caused by inflammation, cell-mediated immune activation, and their long-term sequelae [74]. Disordered neuroimmune function may be present in suicide, and its pathogenesis related to genes identified in these studies. Finally, another area of emerging interest is a possible link between suicide and allergic reactions that may alter the function of the orbital prefrontal cortex [75, 76].

Neurobiology, genetics, and suicidal behaviour

Family, twin, and adoption studies support a genetic contribution to suicidal behaviour, independent of psychiatric disorder (for a review, see [77]), and genetic studies have sought to determine the responsible genes for suicide and suicide attempt through linkage and single-nucleotide polymorphism (SNP) association studies. Candidate genes for most studies were selected based on evidence from neurobiological studies in suicide, as a result of which the serotonergic system has been the most extensively investigated. A tri-allelic polymorphism in the serotonin transporter promoter has two alleles with lower transcriptional activity and fewer transporters. In varied psychiatric populations, despite some negative findings, the S, or the more common lower-expressing allele, has been associated with suicide and suicide attempts, particularly violent or high-lethality attempts [78]. Functional MRI studies have found greater amygdala activation in individuals with the SS genotype when they were exposed to negative stimuli such as angry or fearful faces, negative words, or aversive pictures (for a review, see [79]). The amygdala is densely innervated by serotonergic neurons and 5-HT receptors are abundant, and the amygdala plays a central role in emotional regulation and memory. Excessive responses to emotionally negative events, such as abuse, may be over-encoded and contribute to stress sensitivity in adulthood, and thereby to major depression after stress and even suicidal behaviour.

Other genetic studies of the serotonergic system, including 5-HT_{1A}, 5-HT_{2A}, 5-HT_{1B}, and other serotonin receptors, have largely reported negative results, although there have been some positive findings for the 5-HT_{2A} 102C allele and attempted suicide or suicidal ideation [78]. For tryptophan hydroxylase (TPH1 and TPH2 are the two forms of tryptophan hydroxylase, with TPH1 only expressed in the brain during development), associations have

been reported with suicide and suicide attempt and TPH1 SNPs; however, multiple negative findings have also been reported. Haplotype and SNP studies have suggested the involvement of the *TPH2* gene in suicide and suicide attempt; however, again not all studies agree [78]. Monoamine oxidase A (MAO-A) plays a key role in the metabolism of amines. Low MAO activity results in elevated levels of serotonin, noradrenaline, and dopamine in the brain. The *MAO-A* gene has functional variable number of tandem repeats; however, no association has been found between this upstream variable number of tandem repeats (uVNTR) and suicidal behaviour, although there is some indication that it may be related to aggression [78], and it is linked to the impact of adversity in childhood on adult antisocial behaviour and trait impulsiveness [80, 81].

Genetic studies on the dopaminergic system, noradrenergic system, and BDNF are few and generally negative [78], although there are reports of a positive association of the catechol-O-methyltransferase (*COMT*), a major catecholamine-catabolic enzyme, gene in Finnish and Caucasian suicide attempters [82] and Japanese suicides [83]. A recent study implicates gamma aminobutyric acid (GABA)- and glutamate-related genes and suicidal behaviour [84]. Inconsistent findings in genetic studies of suicidal behaviour may be due to the complexity of the suicide phenotype, gene–gene interactions, the presence of multiple psychiatric disorders, population racial differences, possible epigenetic effects, and the influence of gene/environment interactions. Nonetheless, new microarray technologies that test the expression of thousands of genes simultaneously, allowing better gene coverage, and haplotype mapping approaches offer promise for future investigation. Other options include examining more basic endophenotypes such as mood regulation and decision-making.

Genes and environment

Early life stress, in conjunction with genetic vulnerability, can have enduring effects into adulthood and affect psychopathology and the functioning of biologic systems, including the serotonergic and stress response systems [85]. For example, monkeys exposed to maternal deprivation in infancy and having the 5-HTTLPR lower-expressing S allele in the serotonin transporter gene manifested a lowering of CSF 5-HIAA levels that persisted into adulthood [86]. In 6-month-old macaque monkeys exposed to social stress, those with the S allele had a higher adrenocorticotrophic hormone (ACTH) response, an HPA axis hormone related to stress response, compared with those without that allele and S allele animals who were maternally reared [87]. Thus, the low-expressing S allele not only increased vulnerability to stress in development, but early life stress may also further interact with the genotype to lower the serotonergic function and increase the sensitivity to stressful events later in life, both of which are risk factors for suicidal behaviour.

In human studies, among individuals who had experienced childhood maltreatment, those with the low-expressing S allele were at risk for suicidal ideation and suicide attempt [88], and those with a lower-expressing variant of the *MAO-A* gene were more likely to manifest antisocial behaviour and more impulsivity as adults [80, 81].

Future directions

There is much still to be learnt about the biologic aetiology of suicidal behaviour and the pathways and mechanisms through which biologic dysfunction is involved in suicidal acts. New techniques for imaging the brain, identification of basic intermediate phenotypes, and denser gene markers will contribute to elucidating the biologic factors and mechanisms involved in suicide and attempted suicide and identifying potential targets for prevention.

Prevention of suicide and treatment following self-harm

Keith Hawton, Kate E. A. Saunders, and Alexandra Pitman

Introduction

The World Health Organization (WHO) estimates that approximately 800,000 people die by suicide worldwide every year and regards suicide prevention as a major public health priority [1]. However, unlike other major causes of death such as cancer or heart disease, suicide is a behaviour, not a diagnosis, with a myriad of contributory factors. Although 87–91% of people who die by suicide are thought to have had a diagnosable mental disorder [2, 3], an understanding of the suicidal mind requires consideration of other key factors underlying a person's decision to take their life. Access to methods of suicide, cognitive style, social problems, and social modelling, for example, are all targets for interventions that interrupt the pathway from suicidal ideation to suicide attempt [4]. Therefore, a number of population and high-risk approaches have been employed, with varying degrees of success, and these are summarized in this chapter.

The design of interventions to prevent suicide and respond to those who self-harm is founded on an understanding of recent international trends in suicide and self-harm. These have been described in Chapters 125–127 in this section. The changing nature of the epidemiology of suicide, both at a national and an international level, means that interventions can become outdated and may fail to target groups that have become at risk. This requires ongoing surveillance of patterns of suicide, translated into appropriate and effective new intervention approaches. Most notably, emerging methods of suicide require a rapid response in terms of restricting access to means.

It is important to note that conventions regarding suicide and self-harm nomenclature differ both temporally and internationally. For simplicity, in this chapter, the term 'self-harm' is used to include any act of intentional non-fatal self-poisoning or self-injury, irrespective of the motive or degree of suicidal intent [5]. The term 'suicide' is used in the place of completed suicide or fatal suicide attempt. Given the relationship of suicide to self-harm, this chapter should be read in conjunction with Chapter 126 describing the epidemiology and management of self-harm.

Prevention of suicidal behaviour

The WHO recommends that for national responses to suicide to be effective, a comprehensive multi-sectoral suicide prevention strategy is needed [1]. Their emphasis is on: restricting access to means of suicide, including pesticides, firearms, and certain medications; early identification and effective management of psychiatric disorders and harmful alcohol use; and social support for vulnerable individuals in communities. High-income countries have developed suicide prevention strategies that combine broad population or universal approaches with complementary high-risk or targeted prevention interventions, discussed further later in this chapter, with evidence favouring population strategies [6]. Relatively rapid changes in the epidemiology of suicide require suicide prevention strategies to be able to respond to emergent high-risk groups [6]. They must also be able to meet the needs of the diverse groups at risk of suicidal behaviour, ranging from those with experiences of early trauma in childhood, people in specific occupational groups, those facing acute life events, to those with debilitating mental illness, including those with prior self-harm. Interventions intended to reduce the risk of suicide in these groups are likely to have their effects mediated via improvements in wider mental health and social functioning. Because the risk of suicide varies by ethnic group [7], the effectiveness and cultural acceptability of specific suicide prevention interventions are likely to vary in different cultural settings. It is therefore important that tailored suicide prevention programmes are developed both nationally and for specific cultures sub-nationally. For example, among younger age groups, the male excess of suicides observed internationally is reversed in India and China [8], identifying young women in rural areas as requiring tailored suicide prevention interventions.

While ethical issues in relation to suicide prevention are not covered in detail in this chapter, it is important that they are recognized. The concept of rational suicide and whether suicide should always be prevented is particularly contentious. For example, in the Netherlands, where euthanasia or assisted suicide (EAS) is legal, EAS of psychiatric patients tends to occur in patients with complex and chronic psychiatric, medical, and psychosocial histories,

predominantly women, and usually after discussion with multiple physicians, however often with disagreement between them [9].

Principles of prevention

Broadly there are two approaches to suicide prevention (**Box 128.1**). One can distinguish between population approaches, which aim to decrease risk in the population as a whole, and high-risk group strategies, in which specific groups that are at increased risk are targeted. High-risk group strategies often appear more attractive and realistic. However, risk factors for many disorders are widely spread in the population and so the high-risk strategy tends to exclude a large number of people at moderate risk and is often ineffective in reducing the burden of a disease at the population level. Conversely, population strategies may appear more difficult to achieve but are more likely to be effective in reducing population levels of disease (see also Chapter 125).

It is unclear to what extent national suicide prevention programmes are effective, although evidence of effectiveness for specific components of such strategies is emerging [11]. An impressive programme, developed in Finland, was based on information from a detailed national study of all suicides in 1 year and included a wide range of elements [12]. The programme was evaluated as relatively successful [13]. In England, a national suicide prevention strategy with a suicide target was introduced in 2002 [14], followed by a revised strategy in 2012, although this time without a target [15]. Strategies have now been introduced in a large number of countries [1]. While prevention strategies are difficult to evaluate [16], there are indications that programmes for prevention of suicide on a national scale may be effective.

It is also important to note that suicide prevention is age-specific, and preventive interventions in different age groups are likely to differ.

Box 128.1 Examples of strategies for prevention of suicide and attempted suicide

Population strategies

- Reducing the availability of means for suicide*
- Educating primary care physicians*
- Influencing media portrayal of suicide
- Educating the public about mental illness and its treatment
- Educational approaches in schools*
- Befriending agencies and telephone helplines

High-risk strategies

Prevention of suicide in:

- Patients with psychiatric disorders*
- Specific age groups
- Suicide attempters
- High-risk occupational groups
- Prisoners
- People bereaved by suicide

* Denotes those with established evidence supporting effectiveness [9, 10]

Population strategies

Reducing availability of means for suicide

This is the most widely discussed population strategy [17]. It is based on evidence that if the availability and/or danger of a popular method for suicide changes, then this tends to have an impact on suicide rates. The general principles of prevention through reducing the availability of means are firstly that if a dangerous means is available, then acts of self-harm are more likely to result in death, especially when they occur impulsively, and secondly that the eventual suicide rate in survivors of serious attempts is remarkably low. Also the common adage that if people are intent on dying by suicide they will find a means is not borne out by the evidence on the effectiveness of means restriction. The success of policies to restrict access to specific means will depend on what other means are available, their relative lethality, and the extent to which substitution of a method occurs. The following are some examples of impacts of means restriction policies.

Gas

Perhaps the clearest example of the potential effectiveness of restricting access to a common method of suicide was the reduction in suicides in the UK which occurred in the 1960s and early 1970s when toxic coal gas supplies were gradually replaced with non-toxic North Sea gas [18]. Prior to this time, coal gas poisoning through people placing their head in a gas oven was the most common method of suicide in the UK. As North Sea gas was gradually introduced, the suicide rate dropped steadily, eventually being reduced by approximately a third [18]. It is estimated that as many as 6000 deaths may have been prevented by this change [18]. The effect also illustrates the point that when one method of suicide is no longer available, people do not automatically turn to another, or if they do, it may be to one that is less likely to cause death. Thus, it was some years before the suicide rate rose again, this being related to an increase in deaths from poisoning with carbon monoxide from car exhausts. Another factor that may have been relevant to the decline in suicides was the reduction in prescribing of barbiturates, these being replaced by far less toxic benzodiazepines.

Suicide by carbon monoxide poisoning from car exhausts used to be a common method. However, this became less common as cars were fitted with catalytic converters, which detoxify the exhaust gas. This resulted in a decline in suicide rates in countries where this method of suicide had become more common, particularly in young males [19].

Firearms

The widespread availability of guns in certain countries, particularly the United States, has been proposed as an important reason for their relatively high suicide rates. Guns are used in more than half of all suicides in the United States, and their use for suicide correlates with the holding of gun licences in households [20]. Some controversy surrounds the question of whether restricting the availability of firearms through, for example, making gun purchase more difficult and improving firearm storage in households leads to a reduction in suicide rates, but the weight of evidence seems to indicate that it does [11].

Analgesics

In the UK and some other countries, there has been particular concern about deaths from self-poisoning with paracetamol (acetaminophen). Due to evidence that countries which have fewer tablets per pack seem to have a lower rate of mortality from paracetamol self-poisoning and because overdoses of paracetamol are often taken impulsively and involve household supplies, legislation was introduced in the UK in 1998 to reduce the number of tablets of paracetamol (and aspirin) available per pack. This resulted in fewer overdoses, decreased cases of hepatotoxicity due to paracetamol toxicity, and a reduced number of deaths from both paracetamol and aspirin [21, 22].

Also in the UK, withdrawal of the analgesic co-proxamol (paracetamol combined with the highly toxic opiate dextropropoxyphene) in 2005–2007 resulted in virtual elimination of deaths due to self-poisoning with this drug and no evidence of an increase in deaths involving other analgesics, at least until the end of 2010 [23].

Popular sites for suicide

Much attention has been paid to improving safety at popular sites for suicide. This includes, for example, erecting suicide barriers on bridges, multi-storey car parks, and other sites. For example, erection of barriers on the Clifton Suspension Bridge in Bristol in the UK, a popular site for suicide, has resulted in far fewer deaths by jumping [24]. It has been estimated that safety measures at such sites may reduce suicide considerably [25].

Pesticides

Ingestion of pesticides is common in several low- and middle-income countries in which there are large numbers of small rural farming communities. It is thought to be responsible for a large proportion of suicides globally [1]. Banning sales of more toxic pesticides is one approach that has been shown to have a profound effect on national suicide rates. Safer storage of pesticides in domestic settings and improved emergency access to medical treatment are other approaches.

Hanging

Hanging is an extremely common method of suicide in many countries. This may reflect the decreased availability of other methods, together with the frequency with which it is portrayed in the media. Prevention in terms of restricting access to means is difficult, except in institutional settings. Making psychiatric hospital wards safer through removing ligature points and introducing collapsible curtain rails may reduce hanging deaths in this setting [26]. Similar safety measures in prisons may also be helpful.

Clinicians involved in the development of suicide prevention strategies should look very carefully at local patterns of suicide which might provide clues about potentially effective measures for reducing access to methods. This includes prescribing less toxic medication where feasible, especially to patients at risk of self-harm.

Attempts to limit contagion effects

Exposure to suicidal behaviour of other people can increase the risk of suicide and self-harm. This can result in suicide clusters where a greater than expected number of suicides occur in a locality or setting in a particular time period (so-called 'point clusters'). Clusters may be temporal where, for example, there is a spike in the number

of suicides that are geographically unrelated, but similar in terms of methods and characteristics of individuals involved. Clusters of suicides and of self-harm are not infrequent in young people and in institutional settings such as psychiatric hospitals, schools, and prisons [27]. In planning local suicide prevention strategies, it is important to prepare policies to address such clusters, with, for example, identification of the agency that will co-ordinate the local response, a plan for addressing media responses to the cluster, and a policy for identifying people at risk and providing help [28].

Influencing media portrayal of suicidal behaviour

A growing, if mixed, evidence base demonstrates that irresponsible reporting and portrayal of suicide in fictional or non-fictional contexts can give rise to imitative suicidal behaviour [29, 30], through a process of social modelling [31]. Practices such as featuring a suicide on the front page of a newspaper, repeated coverage, speculation about the triggers, and publishing details of the method, location, or suicide note are thought to increase the risk of suicidal behaviour in vulnerable people.

This effect appears to be particularly powerful in relation to the death by suicide of entertainment and political celebrities [32] and in young people [29]. Conversely, reporting that highlights the ability of suicidal individuals to cope positively in adverse circumstances may be negatively associated with suicide rates [33] and is to be encouraged.

In view of these concerns, prevention agencies in several countries have attempted to work with the media to reduce sensationalism and inappropriate language when reporting or portraying suicide or self-harm to minimize possible negative influences. There is mixed evidence for the effectiveness of such media activity and of guidelines [34], and little in the way of sanctions for those who do not adhere to them [35]. Experiences of working with media agencies in Europe, Australia, and New Zealand suggest that reactive and punitive approaches, such as enforcing regulatory agencies' relatively weak penalties for breaching guidelines, are unlikely to be as effective as collaborative approaches [35]. Mental health professionals are encouraged to work with the media, where opportunities arise, to promote responsible reporting of suicide and mental ill-health and to challenge stigma.

With the growth of new media, the sheer volume of online and print content overwhelms most systems of surveillance, and it often falls on the general public to take a 'name and shame' approach to promote journalistic change. The Internet also offers multiple fora for people to describe or encourage specific suicide methods. If not moderated appropriately, there is a risk of unchecked encouragement of suicide in vulnerable individuals. Attempts to build alert systems into sites such as Facebook and Twitter have not always been successful. However, use of search engine optimization and advert targeting has the potential to promote supportive organizations such as the Samaritans.

Education of the public about mental illness, its treatment, stigma, and help-seeking

Given estimates that 87–91% of people who die by suicide have a diagnosable mental disorder [2, 3] and that the distress caused by mental illness is a key mediator of suicidality, optimizing treatment of underlying mental health problems may contribute to decreasing suicide mortality rates. The same might be said for self-harm, given

that up to 84% of patients who present to hospital having self-harmed are thought to have an underlying psychiatric diagnosis [36]. Optimal treatment for mental disorder starts with detection and referral by general practitioners (GPs)—described later in this chapter—but also the willingness of patients in distress to consult a health professional. The stigma of mental illness is a major barrier to help-seeking, as is ignorance about mental illness and the potential to treat it. The contribution of this to the reluctance of men and young people to seek formal help is a particular concern in the UK, given high rates of suicide in young and middle-aged men [8]. It has also been suggested that the stigma of mental illness contributes to suicidality, although this may be mediated by correlates of stigma such as social isolation, unemployment, hopelessness, or stress [37].

Public education about the recognition and treatment of mental illness is one approach intended to reduce stigma and increase self-presentation to health services among people suffering from mental distress. The intended effects of such programmes are to reduce stigma stress, increase detection and treatment of mental disorder, and reduce suicidal behaviour. Again, such programmes are hard to evaluate, given that mortality outcomes are so distal and subject to intercurrent socio-economic influences. Any effect on suicide rates is likely to be mediated by more proximal outcomes such as rates of depression, anxiety, and social functioning. A review of international evidence describing the impact of anti-stigma campaigns found modest evidence for their effectiveness in increasing knowledge and reducing stigmatizing attitudes, limited to short-term effects [38]. Harnessing the Internet to extend the reach of anti-stigma messages has the potential to penetrate specific groups and to reset social norms that have tended to stigmatize those who struggle with mental ill-health.

Education of primary care physicians

Primary care physician education in the recognition and treatment of depression had previously been regarded as one of the suicide prevention interventions for which there was relatively strong evidence for effectiveness [10]. This was based on the experiences of the Swedish island of Gotland [39–41]. However, despite short-term benefits in terms of proactive treatment of depression and a reduction in suicides [39], these effects are now understood to be short-lived [40] and more marked in women [41]. An updated systematic review noted the lack of trial data published since the Gotland initiative, with weak evidence from ecological studies that primary care physician education might reduce suicide rates in Hungary, Slovenia, and Sweden [11].

Primary care is regarded as the setting in which there is great potential to identify mental illness and prevent suicide, given that in up to 75% of suicide cases in the United States [42] and up to 63% of cases in the UK [43], a primary care presentation occurred in the year before death. However, this relies on primary care practitioners making a diagnosis of depression (or other mental disorder) and initiating acceptable evidence-based treatment. Additionally, psychological autopsy studies indicate that the population attributable fraction for a mental disorder in suicide ranges from 47% to 74% [2]. Predicting which patients are most likely to attempt suicide goes beyond what can be expected from any clinician, given our current understanding of the poor predictive value of risk prediction tools [44, 45].

Given the wider benefits demonstrated in the Gotland study, GP educational interventions might be regarded as beneficial to public mental health, even if the impact on suicide rates is less marked.

Educational approaches in schools

School or college interventions are usually universal in nature, as opposed to targeting those most at risk of youth suicide.

There have been three broad approaches in trying to prevent suicide through school-based programmes. The first of these has tended to focus on increasing pupils' knowledge and awareness of suicide. Some evidence from the United States showed that such a programme appeared to lead to a small increase in pupils' ratings of the acceptability of suicide, although it is not known if this was associated with any change in the rates of self-harm or suicide.

Suicidal behaviour in young people often appears to be related to depression, anxiety, low self-esteem, difficulties during upbringing (for example, abuse, deprivation), life events (especially break-up of relationships, family problems, and bullying), and poor problem-solving skills [46]. Troubled and suicidal young people often seek help from their peers. A second school-based strategy has been the development of educational programmes in schools about recognition of psychological distress in individuals and their peers, problem-solving, and peer support. A trial of a Youth Aware of Mental Health Programme intervention significantly reduced (by more than 50%) the incidence of suicide attempts and suicidal ideation at 12 months' follow-up, compared with the control group. Similar reductions were not associated with a manualized gatekeeper programme or screening for high-risk individuals by professionals [47]. This suggests that changes in suicidal behaviour are more likely to occur when pupils are personally engaged in the intervention.

A third approach is to screen adolescents with questionnaires to detect children and adolescents at risk of psychiatric disorder and possible suicidal behaviour. Pupils that are so detected will then need referral to an appropriate agency for further assessment and possible treatment. While this approach was not found to be associated with any reduction in suicidal behaviour, when compared to no intervention, it is likely to be important in the early detection and treatment of pupils with emerging psychopathology. (Suicide in children and adolescents is considered further in Chapter 125.)

For psychiatrists and others involved in developing local prevention strategies, it is important to recognize that school-based approaches to prevention constitute a highly sensitive area and one where the most effective (and least risky) approach is at present unclear. Another important aspect of suicidal behaviour in school pupils is management of the aftermath of suicides and its impact on other pupils (see postvention in *People bereaved by suicide*, p. 1309) and how to tackle outbreaks of self-harm [46].

Telephone helplines and Internet-based support

Some individuals who attempt suicide will find the anonymity of a telephone helpline or an Internet forum more acceptable than consulting health professionals about their problems. Others prefer to use leaflets or the Internet to access information on self-management of suicidal thoughts. The voluntary sector plays a key role in the provision of Internet-based information and non-judgemental support for those who feel suicidal. This might be in the context of social isolation, mental health problems, relationship problems, or other social issues. The model used by Samaritans is one of the best known and, over the years, has evolved from a drop-in service to include a service accessible via telephone, letter, or email. Other telephone helplines offering support to suicidal people are now widely available

in Australia, Canada, the United States, and northern Europe. Freephones may be installed at sites frequently used as a location for suicide [48], and helplines may be advertised on websites in a targeted fashion where suicidal language is detected on web posts.

Survey methods have demonstrated a high level of satisfaction with suicide helplines, with users tending to discuss suicidal thoughts and mental health problems and to use the service as part of a range of support sources [49]. However, methodological problems make it difficult to trial the effect of telephone helplines and other Internet resources on suicide rates. Until randomized controlled studies are conducted of callers to suicide helplines, with sufficient follow-up, it remains uncertain whether suicide helplines are effective. Their effects on the mediators of suicide risk, such as social isolation, severity of depression, and impaired problem-solving, may be easier to evaluate.

Gatekeepers

The term gatekeepers refers to ‘individuals in a community who have face-to-face contact with large numbers of community members as part of their usual routine’ [50]. They are usually trained in the identification of those at risk of suicide and then in referring them for support and treatment. This approach has been used in schools and the military, as well as in primary care and emergency department settings. The use of gatekeeper programmes is popular in many countries. Observational data suggest there is only limited evidence that such approaches serve to reduce suicides or suicide attempts [11], and there have been no randomized controlled trials.

Strategies for high-risk groups

A wide range of prevention strategies can be targeted at high-risk groups.

Patients with psychiatric disorders

Risk identification and reduction

All psychiatric disorders carry an increased risk for suicidal behaviour. Those with the highest suicide risk are those with borderline personality disorder, anorexia nervosa, depression, and bipolar disorder [51]. Risk of suicide appears to be highest in the first few months following a diagnosis across all mental disorders. Other risk factors for suicide include previous attempts, family history of suicidal behaviour, and living alone. Comorbidity of alcohol abuse, personality disorder, and other psychiatric disorders also increases the risk. There is a robust association between mood instability and suicidal ideation, irrespective of the diagnosis, and this association persists even when accounting for mood, anxiety, and substance abuse [52].

One difficulty in using a risk identification approach is that the risk factors identified from studies of groups of people who have died from suicide are often misleading when applied to individual patients. Many of the identified risk factors apply to a relatively large number of individuals (for example, those living alone), the majority of whom will not be at risk. In clinical practice, it is important to be aware of patients who, due to their individual characteristics, are at long-term high risk, as well as the dynamic factors which may serve to increase risk (for example, drugs and alcohol).

Risk scales

There is increasing evidence that scales for predicting the risk of suicide and non-fatal suicidal behaviour are ineffective at the

individual patient level [44] and that they should not be relied on to guide patient management [53]. The most pragmatic approach is to ensure that proven effective treatments for patients with psychiatric conditions are available, to focus on risk reduction in all patients, and to be particularly cautious at times of apparent high risk. The first few weeks after psychiatric hospital discharge are a key risk period [54]. In a UK study, a third of suicides among psychiatric patients occurred within 3 months of discharge from hospital, almost half of whom died within the first month [55]. Other risk periods follow a relationship break-up or other significant loss, shortly after discharge from hospital, and following recent suicidal behaviour by another patient or someone else close to the individual.

Preventative strategies

Prevention of suicide in patients with psychiatric disorders should be a major element of suicide prevention strategies [56]. Important strategies in preventing suicide in patients with psychiatric disorders include active treatment of individual episodes of illness, psychological therapy to improve compliance with treatment, review of access to means, and encouraging self-management.

Pharmacological treatments

Antidepressants

The role of drugs licensed for depression in the treatment of suicidal behaviour is debated. In a non-systematic review, reductions in suicide attempts of between 40% and 80% have been reported in depressed patients treated with antidepressants [57]. The antidepressant response may also relate to clinical presentation. A trial in the Netherlands in which paroxetine was compared with placebo in patients who had all repeated self-harm but who did not suffer from current depressive disorder showed apparent benefits for a subgroup of patients who received paroxetine, namely those who had a history of 1–4 episodes of self-harm. Patients with a history of five or more episodes did not seem to benefit [58]. A meta-analysis of all data submitted to the US Food and Drug Administration (FDA) revealed a reduction in suicidal thoughts and behaviour in those aged 25 years and over, but an increase on those measures for participants below the age of 25 [59]. The risk of attempting suicide is 2.5 times higher in the month preceding antidepressant treatment than in the month following treatment [60].

These findings have highlighted the need to be cautious in the use of antidepressants, to provide early follow-up after initiating therapy, and to consider combining antidepressant treatment with other therapies, especially for adolescents (in whom only fluoxetine is currently recommended for the treatment of depression).

Lithium

The protective effect of lithium in people with affective disorders is well established. A systematic review of trials of lithium therapy vs a range of other drugs and placebo in patients with affective disorders has shown convincing evidence that lithium may prevent suicide [61]. Lithium reduced the risk of death and suicide by 60%, compared to placebo. The anti-suicidal effect was found to be greater than the effect on mood episodes, suggesting that it may be a specific effect perhaps related to changes in aggression or impulsivity. It is not known if lithium has anti-suicidal properties in other groups of patients.

Neuroleptics

Suicidal acts are common in those suffering from psychotic illnesses. Clozapine has been identified in some studies as having a protective effect. In the Intersept (International Suicide Prevention Trial) trial, clozapine was compared to olanzapine in a multi-centre randomized, open-label study in individuals with schizophrenia or schizoaffective disorder who were deemed to be at high risk of suicide [62]. Clozapine was associated with a significant reduction in suicidal ideation and suicide attempts and fewer interventions to prevent suicide. There were also fewer deaths from suicide, but this was not a statistically significant finding. Data from the Clozaril National Register also suggest that current users of clozapine have a lower mortality rate than recent or past users [63]. However, this analysis used no control group and discontinuation of clozapine was associated with a worse clinical outcome.

Ketamine

Ketamine can have rapid antidepressant effects and may be a useful treatment option for acute suicidality. A case series involving 14 subjects who presented to an emergency department showed rapid and significant decreases in suicidality, which were sustained over 10 days [64]. In one randomized controlled trial, total absence of suicidal ideation was observed in over half of patients treated with ketamine, compared with 24% of those given midazolam [65]. Two systematic reviews of the effectiveness of ketamine in unipolar depression have shown that it may reduce suicidality in patients being treated for depression [66]. Ketamine is also reported to be effective in reducing suicidal ideation in people with bipolar disorder [67]. These findings are promising, but little is known about the effects of ketamine on self-harm or how long the anti-suicidal effects might persist.

Service provision and continuity of care

Aspects of the provision of mental health services can affect the rates of suicide in clinical populations. In the UK, lower suicide rates were observed in areas which implemented the recommendations of the National Confidential Inquiry into suicide and homicide by people with mental illness [68]. Recommendations included removal of ligature points, provision of 24-hour crisis teams, 7-day follow-up following discharge, and training for frontline staff. Continuity of care is likely to be a particularly important factor in preventing suicide in patients at risk, involving care being continued during periods of remission. Unlike affective disorders where risk is greatest during depressive episodes, the risk in schizophrenia tends to be highest between episodes of acute psychotic illness when patients may have insight and feel hopeless about their circumstances and prospects. Risk is related more to affective symptoms than to core features of the disorders [69]. In the UK, specific concerns have been raised about the use of out-of-area inpatient beds, given a significant increase in suicides after discharge from a non-local unit [55]. This is likely to relate to social isolation and disruption in communication and care planning associated with out-of-area admissions. Frequent reorganizations of psychiatric services have also been linked to increased suicidal behaviour [70].

Specific at-risk groups

Those who misuse drug and alcohol

Programmes for suicide prevention must reinforce healthy behaviours with respect to alcohol and substance misuse, irrespective of whether an individual has a formal diagnosis. Treatment of those who abuse substances is likely to be the best approach to prevention for patients, in parallel with social measures such as restricting access to alcohol or minimum pricing. The introduction of policies to restrict access to alcohol has been associated with a reduction in suicide in Slovenia and Russia, although the effect was limited to men [71–73]. The elevated risk in the weeks following the break-up of a relationship for patients with severe alcohol abuse [74] again points to the need for continuity of support in the community.

Prevention of suicide in patients with comorbid disorders, especially the combination of depression with alcohol abuse and/or personality disorder, is challenging, as compliance with treatment is often less than in patients with single disorders. Effective prevention is likely to depend on close integration of care between different statutory care agencies.

Chronic physical illness and pain

Chronic illnesses, particularly cancer and respiratory diseases, are associated with an increased risk of suicide [75, 76]. The relationship between pain and suicidal behaviour is also highly significant [77, 78]. Risk is particularly associated with severe and recurrent headache, psychogenic pain, chronic abdominal pain, and medicolegal issues related to pain. Suicide prevention in this group is complicated by the bi-directional relationship between pain and psychopathology. All patients with chronic illness should be screened for depressive disorder and asked about suicidal ideation if screening positive. Proactive treatment should be instigated if a mood disorder is identified.

People who self-harm

In view of the clear association between non-fatal self-harm and suicide, establishment of adequate services for people who self-harm, including the provision of careful assessments of patients in the general hospital, and offering treatments for which at least some indicators of benefit are available, are important elements in any national suicide prevention strategy. There is good evidence that well-trained non-medical psychiatric staff can effectively carry out assessments and arrange aftercare. Furthermore, psychosocial assessment following self-harm may be associated with a reduction in repeat episodes [79]. Models for ideal services exist such as those published by the National Institute for Health and Care Excellence [53, 80] in the UK.

High-risk occupational groups

Certain occupational groups are known to be at relatively high risk of suicide. In England, recent evidence indicated that these include men in the construction industry and in media and cultural occupations and women in primary school teaching, nursing, and cultural and media occupations, together with people of both genders in caring occupations.

Prisoners

There are relatively high suicide rates in prisoners [81], especially young males held on remand. While one aspect of prevention is through ensuring that prisons and police cells are safe in terms of absence of ligature points, there are a range of other potentially useful and humane strategies [82]. These include careful assessments of new inmates using risk assessment procedures, training of staff with regard to both assessment skills and attitudes towards mental health problems and suicide prevention, in-reach programmes by befriending organizations such as Samaritans, court diversion of individuals with major mental health treatment needs, and prompt access to psychiatric and psychological services.

People bereaved by suicide

People bereaved by suicide have an increased risk of depression, psychiatric admission, suicide attempt, and suicide, when compared with those bereaved by other types of death [83, 84]. Risk of suicide attempt after a close contact's death is elevated, regardless of whether they were related to the deceased or not [85], suggesting that wider social networks are vulnerable to adverse mental health outcomes. The term postvention is used to describe support offered to someone after the suicide of a close contact. Such post-bereavement interventions are intended to prevent the emergence of mental health problems and include national helplines, online support, individual counselling, group work, school and college in-reach after suicide, and support from professionals. Countries such as the United States and Australia lead the way in terms of the range of services and public health resources devoted to postvention. In most countries, the majority of provision lies within the voluntary sector. Much of the momentum for this has been provided by people bereaved by suicide who, in the United States, are also known as suicide survivors.

There is weak evidence supporting the effectiveness of postvention offered in school-based, family-focused, and community-based settings to reduce the risk of suicide-related outcomes [86]. Trials of interventions to reduce other adverse outcomes of suicide bereavement have found little evidence for effectiveness [87]. Evaluations of any such interventions will need to be conducted on a country-by-country basis, given cultural dimensions of grief, bereavement, and suicide and of stigmatizing attitudes to those bereaved by suicide.

Treatment of people who self-harm

Self-harm occurs for a wide range of reasons. In many cases, the primary aim is not death, but some other outcome such as processing distress, temporary escape, or communicating distress to other people. The needs of individual patients vary widely, meaning that a broad range of potential treatments are required. Treatments include both psychosocial and pharmacological approaches, which might be combined, for example, if a patient suffers from moderate or severe depression in the setting of employment and financial difficulties, when treatment with an effective drug might be combined with problem-solving therapy.

Factors relevant to treatment needs in people who self-harm are discussed in the following sections.

Repetition of attempts and risk of suicide

Repetition of attempts is common, with 15–25% of those who present to hospital engaging in further self-harm within a year [88, 89]. Self-harm is also associated with an elevated risk of suicide, although the frequency of suicide following attempted suicide varies internationally [90], depending partly on the overall characteristics of the patient population and the general population suicide rates. Repetition of self-harm increases the risk of suicide [88]. Prevention of repetition of self-harm and suicide is understandably a major aim in treating people who intentionally harm themselves.

Psychiatric disorders and psychopathology

In a systematic review of studies worldwide, an estimated 87% of adults who presented to hospital having self-harmed had at least one psychiatric disorder, with depression, anxiety, and substance misuse being particularly common [36]. In adolescents, a pooled average of 81% had psychiatric disorders, with depression, anxiety, and attention-deficit/hyperactivity disorder (ADHD) being the most frequent. In addition, some four out of ten patients may have personality disorders [91]. While treatment directed at the underlying causes of such disorders, where possible, will be important in managing patients who self-harm, often the disorders themselves will require specific treatment.

Negative life events

Social problems are particularly common in people who self-harm [92], including difficulties in interpersonal relationships, especially with partners and other family members, employment problems, particularly in males, and financial difficulties. Physical and sexual abuse, neglect, and domestic violence are relatively common. Life events, especially loss of a relationship, a job, or housing, frequently precede self-harm [93].

Poor problem-solving skills

Difficulties in problem-solving, particularly in relation to interpersonal relationships, are characteristic of people who self-harm [94]. This distinguishes them from patients with psychiatric disorders who have not carried out a suicidal act.

Impulsivity and aggression

There are strong links between suicidal behaviour and impulsivity and aggression. There is also accumulating evidence that hypofunction of brain serotonergic systems is linked to aggression (and possibly impulsivity) and also to suicidal behaviour [95] (see Chapter 127). It is unclear whether this represents a state phenomenon associated with psychiatric disturbance or a trait phenomenon, but current evidence favours the latter.

Hopelessness and low self-esteem

Hopelessness, or pessimism about the future, is an important predictor of repetition of suicidal behaviour and a risk factor for eventual suicide [93]. Low self-esteem is another important characteristic associated with suicidal behaviour [4]. There is likely to be a link between low self-esteem and a tendency to experience hopelessness when facing adverse circumstances.

Motivational problems and poor compliance with treatment

Some people who attempt suicide may be poorly motivated to engage in aftercare, which affects treatment adherence. Organizational factors in general hospital psychiatric services (including continuity of care) and the attitudes of clinical staff may be important factors influencing whether patients engage in aftercare. In adolescents, family group interventions appear to improve adherence with aftercare, as do brief interventions in the emergency department [96].

Psychosocial assessment

While conducting the assessment, the clinician should try to assess the imminent risk of suicide or further self-harm (Box 128.2). However, suicide risk assessment scales perform badly [44, 45] and reliance on them to determine aftercare is discouraged. Several factors associated with an increased risk of suicide following attempted suicide relate to the nature of the act (for example, violent method, leaving a suicide note, high suicidal intent), but even these have low predictive power, especially in the longer term. The best predictor of repeat self-harm is a previous episode. Rather than focusing primarily on risk assessment, it is recommended that clinicians direct their attention to risk reduction in *all* patients. This includes safety and crisis plans such as restricting access to means and collaborative crisis planning with the patient. Safety planning may be enhanced by involvement of family members and other key individuals. Another key component is clear communication between agencies, with the patient and with family members and other key individuals (as appropriate).

Box 128.2 Assessment of patients who self-harm

Factors to cover in history-taking

- Life events preceding the attempt
- Motives for the act, including suicidal intent (Box 128.1)
- Problems facing the patient
- Psychiatric disorders
- Psychiatric history
- Previous suicide attempts
- Personality traits/disorders
- Alcohol and drug misuse
- Family and personal history
- Current circumstances
- Social (for example, nature of social relationships)
- Domestic (for example, living alone)
- Occupation (for example, whether employed)
- Exposure to suicide/self-harm in friends or family members
- Accessing Internet sites relevant to suicidal behaviour
- Online social networking or similar activities related to suicidal behaviour

Additional suggested assessments

- Risk of further self-harm and of suicide
- Coping resources and supports
- What treatments are appropriate to the patient's needs?
- Motivation of the patient (and significant others where appropriate) to engage in treatment

Planning aftercare

Aftercare following self-harm should be planned according to each patient's specific needs. An individual with moderate to severe depression and difficulties with employment or finances might best be helped through a combination of pharmacotherapy and psychological therapy such as problem-solving and support. Someone with relationship and substance misuse difficulties might best be helped with a combination of specific substance misuse treatment and couple or family therapy. Someone with difficulties in impulse-control and attachment problems might be offered longer-term psychotherapy such as dialectical behaviour therapy (DBT). Whichever therapy is offered, risk reduction measures and careful monitoring of mood and suicidal ideation are recommended (Box 128.3).

Psychosocial treatments

A range of psychosocial therapies for patients who self-harm have been evaluated in randomized controlled clinical trials [97, 98]. The findings from these reviews and some individual studies are summarized here.

Brief cognitive behavioural therapy-based interventions

A meta-analysis of the results of trials of cognitive behavioural therapy (CBT)-based psychotherapy, compared with treatment as usual (TAU), indicated that CBT-based psychotherapy (including either problem-solving therapy or CBT) is associated with fewer individuals repeating self-harm [97]. There is also evidence of other positive outcomes, including greater reductions in depression, hopelessness, and suicidal ideation. This approach is useful, either used alone or in the context of other treatments.

Dialectical behaviour therapy

DBT is a relatively intensive form of therapy, combining individual therapy sessions focused on addressing an individual's life problems, group therapy focused on acceptance of emotions, reducing emotional responsivity and development of interpersonal skills, and access to therapist support.

DBT is thought to be appropriate for patients with a history of multiple episodes of self-harm, especially those with features associated with borderline personality disorder. Treatment in adults

Box 128.3 Factors that suggest high suicidal intent

- Act carried out in isolation
- Act timed so that intervention unlikely
- Precautions taken to avoid discovery
- Preparations made in anticipation of death (for example, making a will, organizing insurance)
- Preparations made for the act (for example, purchasing means, saving up tablets)
- Communicating intent to others beforehand
- Extensive premeditation
- Leaving a note
- Note alerting potential responders after the act
- Subsequent admission of suicidal intent

usually lasts a year. While few trials have been conducted in patients who self-harm, a meta-analysis of trials comparing DBT to TAU indicated that individuals receiving DBT had fewer subsequent episodes of self-harm. DBT has also been developed for adolescents, but in a briefer format. Early evidence suggests that, compared with TAU, DBT may reduce repetition of self-harm and benefit mood and self-esteem in adolescents with a history of repeated self-harm.

Contact interventions

Contact interventions are those in which contact is maintained remotely with patients who have self-harmed, for example through regular mail contacts with patients, usually via postcards. Typically these include expression of concern for the patient's welfare and details of emergency contact information and are sent monthly for a few months and then bi-monthly for the remainder of the first year after a self-harm episode. A meta-analysis of trials comparing this approach combined with TAU with TAU alone suggested equivocal results in terms of self-harm repetition. However, a trial in Iran, where community psychiatric service provision (that is, TAU) is limited, suggested a significant benefit in terms of reduced repetition of self-harm [99]. There is little evidence for benefits of other contact interventions such as those via telephone.

Other psychosocial treatment innovations

As treatment adherence is often an issue in individuals who self-harm, efforts have been made to improve attendance at treatment sessions. Continuity of care, through having the assessing clinician provide aftercare, has been shown to increase the proportion of patients who attend for treatment [100]. Among patients who failed to attend an outpatient appointment, those who had a home visit from a nurse were more likely to attend subsequent follow-up than those where no such visit occurred [101]. For adolescents, 'therapeutic assessment' has been developed, in which, in addition to a routine assessment, there is a focus on understanding the meaning of their self-harm, on formulation of their problem, and linking this to benefits of aftercare, together with family involvement in the process. In trials, this was associated with more adolescents attending treatment sessions than where a routine assessment was provided [102]. However, it should be noted that none of these service-orientated innovations was associated with reduced subsequent frequency of repeated suicide attempts, although existing trials had limited power to evaluate this outcome.

A rapidly growing recent development is the provision of therapy through mobile health applications (apps) on remote electronic devices such as smartphones [103]. This is clearly a growth area with the major advantage that it might be helpful for people who do not access clinical services. However, trials are so far lacking.

Pharmacological treatments

In spite of the high prevalence of psychiatric disorder, particularly depression [36], in people who self-harm, there have been relatively few trials evaluating the effectiveness of pharmacological agents in this population [104]. This perhaps reflects the problems of treatment adherence and risk of overdose. The likely most effective pharmacological approach is treatment of any underlying psychiatric disorder.

Care should be taken to prescribe the safest appropriate treatment. Tricyclic antidepressants should be avoided in view of their high toxicity. Selective serotonin reuptake inhibitors (SSRIs) are generally deemed to be the safest, although citalopram is significantly more toxic than other SSRIs [105]. Prescriptions should be limited to small quantities of medications where necessary. Lithium has the strongest evidence for prevention of suicidal behaviour [61].

In adolescents, there are concerns about the use of SSRIs in particular, because of an association with suicidal ideation. However, reduced prescribing of SSRIs in response to warnings from regulatory bodies was actually associated with increased rates of suicide in young people [106]. There is also evidence that a combination of fluoxetine and CBT may have greater benefit in terms of suicidal ideation than either alone in the treatment of adolescents with depression [107]. Where a drug is prescribed for either adults or young people with depression, early follow-up (within a few days) is indicated because this is when agitation and possible suicidal ideation are most likely to occur.

Conclusions

In this chapter, we have focused on a wide range of specific initiatives that may help prevent suicide, especially in people with psychiatric disorders. We have emphasized the need for a comprehensive multi-sectoral approach to suicide prevention. This should be tailored to specific local patterns of suicide. For people in contact with psychiatric services, prevention may be achieved through specific aspects of service provision, as well as through indicated therapies. Evidence of effectiveness of specific initiatives is gradually emerging. We have focused in some detail on people who have self-harmed. This is justified both because of the strength of the association between self-harm and suicide and also because of the impact that self-harm has on the individuals involved and the family and friends. Again, potentially effective therapies are being identified. In considering prevention of self-harm and suicide in people with psychiatric disorders, an essential complement is a population-based strategy that ensures easy access to well-designed and supportive services, staffed by those with an awareness of the needs after self-harm and training in suicide prevention.

Deconstructing dualism

The interface between physical and mental illness

Michael Sharpe and Jane Walker

Introduction

Patients usually attend doctors because they are concerned about symptoms. When these symptoms are associated with persistent distress and/or disability, we refer to the patient as having an illness. When assessing the patient's illness, the doctor aims to make a diagnosis, on the basis of which management can be planned. The diagnoses available to doctors are conventionally categorized into either 'medical' or 'psychiatric'. This division of illnesses into two distinct types is such an accepted feature of current medical practice that we take it for granted. But is it really the best way to think about patients' illnesses and to plan their care? In order to answer this question, we examine below what is meant by 'medical' and 'psychiatric' diagnoses. The disadvantages of this dichotomous approach will then be considered, and potential solutions outlined.

Diagnosis

Medical diagnosis

A medical diagnosis is a label for a type of illness that is: (1) conventionally treated by medical (non-psychiatric) doctors; and (2) listed in classifications of medical conditions such as the *International Classification of Diseases*, tenth revision (ICD-10). Most medical diagnoses are based on identifiable bodily pathology (abnormal structure and/or function). Therefore, to make a medical diagnosis (such as cancer), doctors enquire about specific bodily symptoms, before confirming the presence of bodily pathology by seeking physical signs and doing biological investigations (such as X-rays).

Psychiatric diagnosis

A psychiatric diagnosis is a label for a condition that is: (1) conventionally treated by psychiatrists; and (2) listed in the psychiatric diagnostic classifications of ICD and the *Diagnostic and Statistical Manual of Mental Disorders* (DSM). Psychiatric diagnoses are not based on bodily pathology (with the possible exception of the

so-called 'organic disorders'). They are instead associated with the idea of 'psychopathology', that is, proposed abnormalities of the mind. Unlike bodily pathology, these abnormalities of the mind cannot be objectively identified. Rather they are inferred from the patient's reported mental symptoms and their behaviour.

What makes an illness psychiatric, rather than medical?

Why are some illnesses regarded as 'mental' or 'psychiatric', as opposed to 'medical'? Examination of the criteria for those diagnoses reveals that factors common to most 'psychiatric' illnesses are:

- An absence of identifiable bodily pathology.
- An abnormal mental state implying psychopathology.
- A presentation with abnormal behaviour.

Mind-body dualism

The fundamental assumption underpinning this dichotomous view of illness as either medical or psychiatric is that it is both conceptually valid and clinically useful. The idea that the mind is fundamentally distinct from the body (or the brain) is referred to as mind-body dualism. Mind-body dualism is commonly attributed to the writings of the philosopher Descartes. This so-called Cartesian dualism has exerted a profound influence on Western medical thought and still shapes our thinking, training, and service provision today [1].

However, it is increasingly clear that dualism is at best an oversimplification and at worst a cause of serious theoretical and clinical problems. Theoretically, it can be argued that there is no such thing as a purely 'bodily' illness or a purely 'mental' illness and that all illnesses have both mental and bodily aspects [2]. Clinically, the associated assumption that bodily symptoms always indicate bodily pathology and that mental symptoms always indicate psychopathology is not consistent with clinical experience. Two important examples are: (1) when bodily symptoms occur without bodily pathology; and (2) when mental symptoms occur with bodily pathology ([Table 129.1](#)).

Table 129.1 Diagnoses, symptoms, and bodily pathology

Symptoms	Bodily pathology	Diagnosis
Bodily symptoms	Present	Medical diagnosis
	Absent	<i>Somatization</i>
Mental symptoms	Present	<i>Comorbidity</i>
	Absent	Psychiatric diagnosis

'Medically unexplained symptoms'

When patients present with bodily symptoms, but *no* evidence of bodily pathology, it is unclear whether their illness should be best regarded as 'psychiatric' or as 'medical' because they do not clearly fulfil the criteria for either. But the imperative to classify every illness as either medical or psychiatric in order to determine the type of treatment requires that an allocation is made.

One solution is to allocate these illnesses to psychiatry. This is done by assuming that the patient's somatic symptoms are, in fact, explained by psychopathology. The relative absence of mental symptoms, from which psychopathology is usually inferred, is explained by the idea that the psychopathology has been 'somatized'. This means that an abnormal mental state is not apparent because it has been 'converted' into bodily symptoms. The process of somatization (literally making the mental physical) is poorly specified. However, the concept can be seen in a variety of diagnostic labels, including 'somatization', 'somatoform disorder', 'conversion disorder', and 'bodily distress disorder'.

Another solution is to allocate the illness to medicine. This is made possible by assuming that the patients really do have bodily pathology (even though it is as yet unidentifiable). The absence of identifiable bodily pathology may be explained on the basis that it is present but simply not detectable using currently available diagnostic technology. A medical diagnosis that implies disease, such as 'fibromyalgia' in rheumatology or 'syndrome X' in cardiology, is then made.

A third, and all too common solution, is for the patient to be rejected as 'not really ill' by both psychiatry and medicine, leaving them in a no-man's-land between these specialties.

The problems with all three of these solutions has been particularly well illustrated by the controversy and conflict surrounding the condition called chronic fatigue syndrome (CFS), or myalgic encephalomyelitis (ME), in which there has been often fraught controversy about the nature of the illness and an associated lack of care [3].

Comorbidity

When a patient has both bodily pathology *and* mental symptoms, they may be given *both* a medical diagnosis (based on the bodily pathology) and a psychiatric diagnosis (based on presumed psychopathology). The resulting mental-physical 'comorbidity' or 'multimorbidity' gives rise to both theoretical and practical problems, however.

The theoretical problem concerns the psychiatric diagnosis. To make this diagnosis, the doctor must identify symptoms which are considered to be evidence of the underlying psychopathology. However, some symptoms may be considered as resulting from either psychopathology or bodily pathology. For example, if a patient

has mental symptoms of weight loss and a lack of energy and a medical diagnosis of cancer, based on bodily pathology, should the weight loss and lack of energy be counted towards a psychiatric diagnosis of depression or be regarded as a symptom of the cancer? There is no generally agreed answer to this conundrum (although a variety of ways of addressing it have been proposed [4]), probably because it is a manifestation of the fundamentally flawed dualistic assumption.

The main practical clinical problem that results from making two diagnoses, one medical and one psychiatric, is a failure to adequately treat the patient. This is because the patient is considered to have two illnesses, each of which requires diagnosis and treatment by a different specialty, often based in different hospitals. As treatment of the medical condition usually takes precedence, the patient's psychiatric diagnosis often goes untreated [5].

Solutions to dualism

Theoretical solutions

New scientific knowledge, such as the demonstration of a bodily (neural) basis to many 'mental' symptoms, is increasingly rendering crude dualistic thinking theoretically untenable [2]. Mind and brain are increasingly regarded as two sides of the same coin—the 'mind/brain'. If this paradigm shift is adopted, it will imply that 'psychiatric' illnesses are no more distinct from 'medical conditions' than the nervous system is separate from the rest of the body. According to this new way of thinking, it would make no sense to dichotomize illnesses into 'medical' and 'psychiatric' types. Illness is just illness [6].

Practical solutions

However the theoretical arguments play out, for the present, we must accept that dualism continues to shape our everyday thinking, practice, and service organization. But we can surely agree already that there is a need for psychiatry to become less 'brain-less' and for medicine to become less 'mind-less' [7]. In this regard, the psychiatrist is especially well placed to make a major contribution to the care of all patients by ensuring that biological, psychological, and social aspects of illness are considered in every case. This so-called 'bio-psychosocial' approach, first proposed by George Engel, provides a framework for considering multiple causes of illness [8]. A further enhancement of this approach is to divide the relevant biological, psychological, and social aetiological factors into those that predisposed the patient to the illness, those that precipitated or triggered it, and those that are perpetuating it or impeding recovery. The last group of causes is a target for treatment, and the first two for prevention. A way of tabulating factors to consider in a bio-psychosocial formulation is shown in [Table 129.2](#).

Service solutions

Finally, the consequence of the long-standing professional and organizational separation of medicine and psychiatry must be addressed. One service solution has been the establishment of so-called liaison (linking) psychiatry services to general hospital inpatient units. Another recent and welcome development has been the increasing integration of psychological management into general medical care [9].

Table 129.2 A bio-psychosocial formulation

Main factors	Sub-factors	Predisposing	Precipitating	Perpetuating
Biological	Disease			
	Physiology			
Psychological	Cognition			
	Mood			
	Behaviour			
Social	Interpersonal			
	Social and occupational			
	Health care system			

Such developments are likely to be important for psychiatry's future status as a medical discipline [10].

Conclusions

Hitherto we have taken it for granted that it is both appropriate and desirable to dichotomize illnesses into medical and psychiatric types, based on identifiable bodily pathology and inferred psychopathology, respectively. Such an approach has, however, created obstacles to integrated and effective patient care. A better understanding of neuroscience is challenging the theory of dualism and may lead to a more unified conceptualization of illness. The growing need to address the epidemic of patients with multi-morbidity is already making dualistic management redundant and favouring more integrated models of care. The influence of dualism is finally on the wane. The question is, 'will it be missed?'

Neural mechanisms in chronic pain relevant for psychiatric interventions

Chantal Berna and Irene Tracey

Introduction

Pain is defined as ‘an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage’ [1]. Acute pain is a warning system alerting the subject of possible harm and leading to corrective or preventive action, both immediate (flight or fight) and delayed (learning, avoidance). However, inherent to this definition, it is clear that pain can exist as an emotional experience also without actual ‘tissue damage’ or physical harm. This broad definition is important as it encapsulates what can occur in chronic pain, that is, persistent pain outliving the usual time for tissue healing (>3–6 months). Chronic pain is one of the largest medical health problems in the developed world, affecting 19% of adults in Europe, with a considerable impact on quality of life, productivity, and costs for the society [2]. A recent report by the American Institute of Medicine assessing the significance and impact of chronic pain in America presented similar figures, with an estimated cost to society of about 600 billion dollars per annum, due to both medical care and lost productivity [3].

Pain as the transduction, transmission, and perception of a nociceptive signal

Nociception, that is, the neural and molecular processes involved in acute pain perception, has been progressively elucidated. This includes the *transduction* of the nociceptive input through different peripheral sensory neurons (nociceptors) into a neural signal, followed by the multisynaptic *transmission* to the central relays and *perception* in the sensory cortices (Fig. 130.1).

Most nociceptors are myelinated A fibres or unmyelinated small-diameter axons (C fibres). They project to the superficial laminae I and V (A δ) and I and II (C fibre) of the dorsal horn of the spinal cord [4]. Local spinal circuits—excitatory and inhibitory—allow for bi-directional changes in spinal outputs. Excitatory transmitters, such as glutamate and substance P, can facilitate and ‘wind up’ neuronal responses, whereas inhibitory interneurons releasing endogenous opioids and gamma aminobutyric acid (GABA) can

modulate spinal activity. From the dorsal horn, three major projection pathways lead the signal to the brain: the spinomesencephalic [to the periaqueductal grey (PAG)], the spinothalamic (to the thalamus as a relay to the cortex), and the spinoreticular pathway (to the reticular formation of the medulla and pons as a relay to the thalamus and cortex) [5]. Molecular biology and the study of patients suffering from congenital insensitivity to pain have contributed significantly over the past decades to form a more complete understanding of these mechanisms of transduction and transmission, providing new opportunities for possible pharmacological targets such as the sodium channel Nav1.7, the transient receptor potential (TRP) family, and acid-sensing ion channels (ASICs) [6]. In parallel, improved knowledge of the molecular and cellular changes that occur post-injury and in the chronic pain state is providing novel options for therapeutic interventions such as nerve growth factor (NGF) antagonism [7]. These advances, among others, have contributed to chronic pain being classified as a disease in its own right [8, 9], with specific underlying mechanisms distinct from the ones involved in acute pain.

Neural networks of sensory perception

Neuroimaging has helped to develop knowledge about the neural networks of sensory perception. The current concept for the central aspects of pain perception is mostly based on acute induced pain studies and considers a large bilateral network available for variable activation, including the thalamus, the posterior and anterior insulae, the secondary somatosensory cortex, the anterior cingulate cortex, and the PAG matter, among other regions (Fig. 130.2) [10, 11].

The principle is that different brain regions and networks can be recruited variably and dynamically for activation (or not), depending on the nociceptive drive, context, attention, emotions, and cognitions, allowing for rapidly adaptive behavioural responses to each individual specific situation [5]. It should be obvious that most of the brain regions active in this dynamic network are not pain-specific (that is, the ‘hurt’ of pain) but subserve many features

Fig. 130.1 (see Colour Plate section) Acute nociception as a three-neuron order system. The peripheral nociceptor is responsible for the transduction into a neural signal (1). This is followed by transmission through neurons (2), with possible descending and local modulation (3), leading to the final perception at the cortical level (4).

relevant to this multifactorial experience in matters of anticipation, anxiety, attention, sensory discrimination, motor preparation, etc. (for example, [12]). Some regions of this brain network also likely encode the saliency of pain within a particular context [13]. Overlap of activity in regions like the anterior cingulate and divisions of the insula, as well as distinctions in the activated networks when comparing physical pain, empathy (that is, feeling for others in pain), and moral suffering (such as studied through social rejection), highlight that while *many cortical areas* are recruited by multiple processes, *specific networks and patterns of activation* can be characteristic of a certain perception or function. Such distinctions are being increasingly disambiguated with more advanced imaging analysis methods and paradigms [14–16]. We should remember that

experiencing emotional pain is what makes us human, as underlined by William James and other philosophers. Distinguishing between pain that has a peripheral maintaining drive (sometimes wrongly labelled ‘physical’) and centrally generated or maintained pain (often-times labelled ‘emotional’) has been a preoccupation for scientists, the medical profession, lawyers, and insurance brokers, with frequent misunderstandings and confusion—leading to downgrading the relevance of ‘emotional’ pain because it does not have a ‘physical’ origin. Newer research, taking into account the complexities of the neural pathways that integrate emotional and physical experiences, can allow distinctions at more subtle levels. Hence, an emotional response to social exclusion should not be confused or amalgamated with centrally amplified pain following a nerve injury with resulting

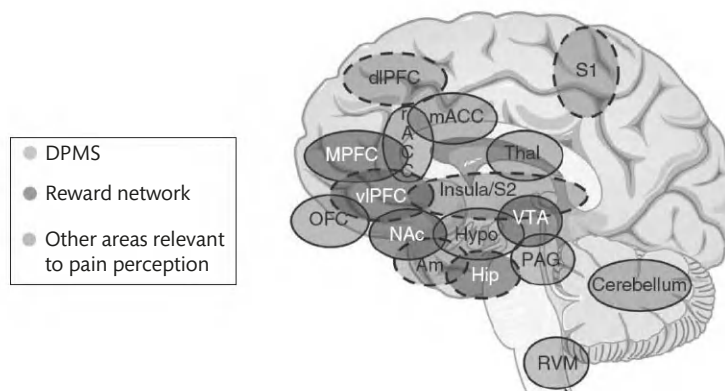

Fig. 130.2 (see Colour Plate section) Cerebral areas and networks involved in pain perception and regulation, as well as reward. The key networks consist of the descending pain modulatory system (DPMS, green) and the reward network (purple). Alterations in function, connectivity, and structure have been described in these networks in chronic pain. rACC/mACC, rostral/medial anterior cingulate cortex; vlPFC, ventrolateral prefrontal cortex; dlPFC, dorsolateral prefrontal cortex; mPFC, medial prefrontal cortex; OFC, orbitofrontal cortex; insula/S2, insular and secondary somatosensory cortex; S1, primary somatosensory cortex; Am, amygdala; Hip, hippocampus; Hypo, hypothalamus; Thal, thalamus; PAG, periaqueductal grey; VTA, ventral tegmentum.

central sensitization. We are not making judgements about which pain (or suffering) is more important—for the patient, the experience is paramount, whatever the cause. However, better discrimination and identification of what constitutes an individual's pain (that is, balance of peripheral and central components) are important if we are to target treatments more effectively.

Modulation of pain perception

Nociception and pain can have a highly non-linear relationship; there is frequently a mismatch between the nociceptive input and the resultant pain perception. In fact, the bottom-up input can be modulated by a number of mechanisms along the pain neuraxis, leading to different final experiences. For instance, the processing of the signal can be modified through either dampening of the signal or the recruitment of supplementary cortical areas. This is important as it allows for a person's pain experience and subsequent behavioural response to adapt to the situation in which they are—enabling an improved decision and outcome. A major regulatory pathway is the descending pain modulatory system (DPMS), which has central relays in the dorsolateral prefrontal cortex (DLPFC), rostral anterior cingulate cortex (rACC), amygdala, hypothalamus, rostral ventromedial medulla (RVM), and PAG matter and releases endogenous opioids in the dorsal horn of the spinal cord, as well as noradrenaline and serotonin [10, 17] (Fig. 130.2). In the RVM, serotonin (5-HT) can inhibit (via 5-HT₁ receptors) or facilitate (via 5-HT₂ or 5-HT₃ receptors) spinal neuronal activity; endorphins also have bi-directional effects, while noradrenaline has inhibitory activity through the α_2 adrenoceptor. The DPMS is a powerful system that is recruited for its inhibitory (pain-inhibiting) features when subjects are distracted from pain or during placebo analgesia. The opposite facilitatory arm is recruited in response to injury. It is now known from animal and human studies that an imbalance in this system (too much facilitation and not enough inhibition) is a major factor explaining the chronic pain phenotype.

Many studies in healthy participants have demonstrated the potential for modulation of acute pain through cognitive processes such as distraction, expectations, or context [18–20]. The involvement of the central relays of the DPMS was demonstrated in experimental placebo analgesia, with naloxone (opioid antagonist) blocking this effect and inhibiting the functional connectivity between the rACC and the PAG [21]. Opposite effects can take place with negative expectations. For example, the effect of an infusion of remifentanyl, a powerful opioid, can be annulled when participants are deceptively led to believe the medication was not delivered anymore [22].

Furthermore, anxiety and negative mood can heighten the pain experience to the same nociceptive input either through direct modulation of core pain-processing areas or via indirect means. These affective modulations in the experimental context seem to rely on recruiting other pathways, involving the prefrontal cortex (PFC), hippocampus, and amygdala, among other structures [23–27].

These concepts become more complex in the clinical situation, as the three levels (transduction, transmission, perception) can all be modified in chronic pain—as further discussed in the section on acute and chronic pain [28, 29]. For instance, the bi-directional control means that the DPMS has also been involved in facilitating nociceptive processing. Indeed, it has now been shown that an imbalance

between facilitation and inhibition (too much facilitation and too little inhibition) contributes to the development, maintenance, and exacerbation of chronic pain states in both animal (for example, [30, 31]) and human studies [32–35]. Therefore, an intervention in chronic pain only targeting the periphery (trying to dampen the volume of the transduction) is most often bound to fail, as it omits central processes, such as anxiety, depression, or central sensitization, which can upregulate the experience.

Transition from acute to chronic pain—a process with possible predisposing factors

Not all patients with acute pain go on to develop a chronic condition, and there seems to be different levels of risk. While there are not yet any readily useable detection methods for individuals at higher risk, there is a growing understanding of the vulnerability and protective factors that might lead to implement early preventive interventions or to develop better-targeted treatments. Vulnerability factors for developing chronic pain can be present at birth, such as female gender or genetic make-up; brought on by the environment such as adverse life events; or, in many circumstances, be the result of a combination of both (Fig. 130.3) [36]. On the other hand, inherent features of resilience are progressively being investigated and demonstrated to be different from vulnerability factors (or the absence thereof) [37]. For example, a novel line of research is focusing on the value of positive affect [38]—an important area for further research and development.

Genetic factors involved in pain perception

The genetic make-up of certain enzymes and receptors is of importance for pain perception. Catechol-O-methyltransferase (COMT) is an enzyme degrading catecholamine neurotransmitters (that is, adrenaline, dopamine, and noradrenaline) in the synaptic cleft, thereby regulating different neurophysiological functions. Certain frequent polymorphisms of *COMT* seem to affect experimental pain processing, endogenous opioid transmission, and perhaps the response to opioids [39]. While *COMT* variants do not appear to be predisposing factors for developing chronic pain, they have been shown to impact a number of affective and cognitive tasks in which the PFC plays a key role [40]. For example, *COMT* variations can affect the response to placebo modulations in patients [41] and could also be involved in the response to psychological approaches to pain management [40].

Preclinical models have shown that serotonin is involved in chronic pain, although it is a complex system with serotonergic receptors demonstrating pro- or anti-nociceptive function, depending on a number of factors (type of animal model, anatomical site, subtype of receptor). Polymorphisms in serotonin receptors could be involved in the regulation of pain affect and perhaps response to opioids [40].

Priming processes

Animal studies of early-life exposures to pain are striking examples of how life events can mark future pain perception; it can result in heightened pain sensitivity in fully developed individuals [42]. In addition to prior pain, early-life stress, such as maternal separation, can also be sufficient to induce hypersensitivity in later life [43]. Increased axonal

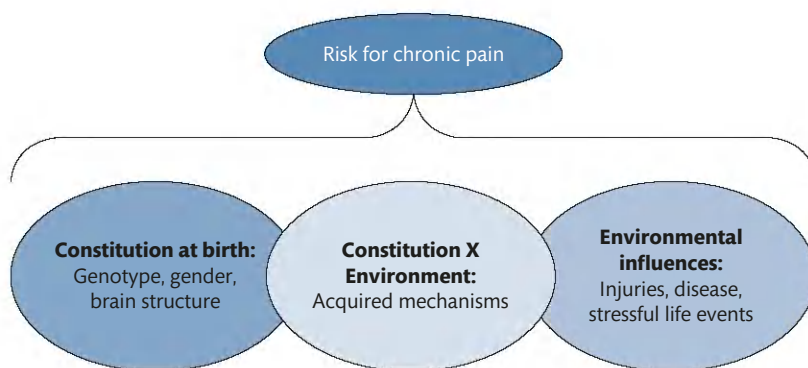

Fig. 130.3 Factors of vulnerability for a chronic pain state. These factors emerge at different levels, whether endogenous (genetic predispositions and cerebral structures) or environmental or through a combination of the two.

sprouting, NGF-induced neuronal plasticity, changes to the opioid system, or alterations in the hypothalamic–pituitary–adrenal axis and in the spinal microglia could possibly explain these processes [42, 44]. Parallel human work was done through neuroimaging in school-age children who were born preterm; central functional alterations have been demonstrated, with an impact on cognitive outcomes and pain processing [45, 46]. A similar mechanism, known as priming, has been demonstrated in adult animals; for example, repeated nerve injury or stress before an experimental nerve lesion can result in prolonged hypersensitivity, when compared to a single lesion [47]. The main pathways examined to explain this phenomenon are the peripheral afferents and the spinal microglia [36].

Hypothetically, early-life stressors that are known to relate to neuroticism and anxiety could have developmental influences on the DPMS via alterations in the coupling of the amygdala–PFC network to the brainstem nuclei, leading to an unfavourable imbalance in inhibitory and facilitatory drive, which could predispose individuals towards developing chronic pain. Based on this hypothesis, personal specificities such as variants in personality, psychological traits, response to opioids, or reactivity to standard pain testing could rely on changes in central networks and represent risk factors for increased pain perception [32, 48–51]. While differences were found at the central level between these groups and controls, it is unclear if the central correlates of these behavioural and psychological variants in healthy people translate to any clinically meaningful impact regarding the risk for chronic pain. Nevertheless, testing the DPMS function in patients could classify them for the risk in response to surgery; two pain modulatory processes thought to be mediated through the DPMS—temporal summation (that is, an individual's level of pain in response to a rapid succession of similar noxious inputs) and diffuse noxious inhibitory control (DNIC) (that is, the level of pain reduction when the stimulus of interest is associated to a second noxious stimulus)—were shown to be predictive of post-surgical pain levels [52, 53].

Importance of the reward–motivation–learning system

While studies in patients have shown clear functional and structural differences, compared to healthy controls, this does not provide

evidence of a causal link. It also leaves open the question of whether these changes in central networks are causal or consequential to chronic pain. Yet, recent longitudinal studies have underlined the particular wiring of the central reward–motivation–learning network as a potential key factor of vulnerability (Fig. 130.2). This is especially interesting, when one considers relief as an integrated reward process in pain [54]. An impressive and large prospective observational neuroimaging study followed 159 patients with subacute low back pain over the course of a year ($N = 69$ completed follow-up) as they recovered ($N = 30$) or developed chronic pain ($N = 39$, prolonged follow-up to 3 years) [55–59], providing important data and insight into the evolution of chronic pain. Results from the first neuroimaging session during the subacute pain phase demonstrated that greater functional connectivity or ‘coupling’ of the nucleus accumbens (NAC) with the PFC was strongly predictive of pain persistence. Hence, cortico-striatal circuitry could be causally involved in the transition from acute to chronic pain. Interestingly, this stronger coupling remained present throughout the transition to chronic pain, despite grey matter density decreases in the NAC. Furthermore, in the group that went on to develop chronic pain, white matter fractional anisotropy differences in the PFC were identified at an early time point, possibly representing structural vulnerabilities. These results suggest a role for the brain's reward–motivation–learning circuitry during the transition from acute to chronic pain. Finally, stronger white matter and functional connections within the dorsal medial PFC–amygdala–accumbens circuit, as well as smaller amygdala volume, represented independent risk factors, accounting together for 60% of the variance of pain persistence at 3 years' follow-up [59].

Separate work has underlined differences in NAC activity in response to relief from acute experimental pain between controls and patients with chronic low back pain [60], as well as patients with fibromyalgia [61].

Healthy volunteer studies have also shown that baseline activity in the ventral tegmental area and the NAC was predictive of subsequent opioid-induced analgesia and central activity in the DPMS [51]. Animal studies supported also the need for a functioning reward system to experience analgesia [62].

Provided the appropriate relative context, the hedonic value of pain can be ‘flipped’ from threat to reward, with increased activity in reward

regions, working in concert with the DPMS [18]. Such work provides further evidence for the importance of these networks in pain appraisal, which is a key feature of ongoing chronic pain states. Furthermore, dispositional optimism and pessimism influence the central processing of unexpected relief outcomes, with diametrically opposite NAC activity [63]. Finally, the dopaminergic system has also been involved in placebo effects, with a correlation between placebo analgesia and levels of dopamine release [64]. While these findings raised the question of possible direct effects of dopamine on placebo analgesia, an interesting separate study suggested rather that this dopaminergic activity is related to the relief of pain because when fully blocked through a dopamine antagonist, the placebo effect still took place [65].

It seems likely that the transition to chronic pain is dependent on the state of the mesolimbic–prefrontal connectivity and function, that is, of the motivation–learning and reward circuitry. Yet it remains ambiguous what this means. While it has been interpreted as a predictor for a *transition* from acute to chronic pain, an alternative explanation could be that these patients suffer from *an inability to experience relief and hence analgesia from treatment*, that is, they have a ‘broken analgesic system’ and so, by definition, remain in pain as they get no relief [66].

Other cognitive factors of risk

Other cognitive factors have been investigated as predisposing to chronic pain. Most notably, catastrophizing, a cognitive–emotional process involving magnification, helplessness, and rumination when facing pain, has been shown to be tied to negative outcomes [67] and to be an independent predictor of ill adaptation to pain and pain-related affective dysregulation [38].

Another proposed vulnerability factor could consist of the chosen attentional focus when confronted with concomitant nociceptive stimuli and cognitive tasks. In fact, two different profiles were identified, with participants demonstrating either a ‘pain focus’ or being able to remain focused on a parallel cognitive task, with resulting faster reaction times [68]. Participants focusing on pain demonstrated more grey matter in regions implicated in pain and salience, greater functional connectivity in sensorimotor and salience resting-state networks, less white matter integrity in the internal and external capsules, and anterior thalamic radiation and corticospinal tract, while well matched for sex, neuroticism, pain sensitivity, and catastrophizing. Interesting parallels can be drawn with the literature on anxiety where cognitive biases towards threat, as well as inefficient attentional regulation of emotionally and non-emotionally salient stimuli, have been demonstrated [69, 70].

Chronic pain as a brain disease: maladaptive plasticity and psychological maintaining processes

Once pain is chronic, the central circuitry involved in processing further nociceptive stimuli might be quite different from what is studied in acute pain, both at a structural and at a functional level. In fact, meta-analytic studies have shown decreases in grey matter volumes in different cortical and brainstem areas, as well as increases in the thalamus, and this has been found across different chronic pain conditions [71]. Whether these differences are causal or

consequential to chronic pain is still up for debate, although human and animal studies are suggestive of pain causing the changes, as when pain is relieved, the structural changes normalize [72–75]. Such reversal is important, as it calls into question the early interpretations of what these volume changes represent (that is, incompatible with neurodegeneration) [76].

A cerebral region of specific interest is the hippocampus, given its role in pain amplification in the context of anxiety and stress; reduced hippocampal volumes were found in patients with chronic pain, compared to controls, suggesting a sustained endocrine stress response. This came with associated increased activity in the hippocampal complex in response to acute pain [77]. These elements together could, in turn, contribute to the persistent pain state.

At a functional level, pain perception in patients with chronic low back pain involves less somatosensory and more limbic networks, compared to acute pain models [56]. As mentioned, there is also an imbalance in the DPMS, with too little descending inhibition and too much descending facilitation. In fact, central sensitization is a normal adaptive response post-injury; yet failure to resolve this beyond the acute stage is a maintaining factor of chronic pain states. The signs of central sensitization have been demonstrated by increased PAG activity in certain patients with osteoarthritis [32], replicating experimental human models of brainstem amplification mechanisms [34, 35, 78]. This factor could also be involved in functional pain syndromes or fibromyalgia [79, 80]. Importantly, central aberrant mechanisms are the target of duloxetine, a serotonin and noradrenaline reuptake inhibitor that supposedly ‘rebalances’ the inhibitory/facilitatory drive, as well as of tricyclic antidepressants [81]. In fact, a study in painful diabetic neuropathy found that poor DNIC efficiency predicts the efficacy of duloxetine and that this treatment allowed to re-establish normal DNIC [82].

Of course, the poster-child for maladaptive plasticity is phantom limb pain where original theories suggested that altered brain representation of body parts into the ‘vacated’ deprived cortex (from the missing limb) causally produced pain in patients [83]. However, recent work now suggests different interpretations might better explain the pain of phantom limb, with lively debate and discussion ensuing [84–87]. This is not only an academic question; the maladaptive model has also been used to support treatments, which might be misdirected in this newer light [88, 89].

Psychiatric comorbidity is extremely frequent, with most patients suffering from chronic pain declaring symptoms of anxiety or depression [90–92]. Post-traumatic stress disorder is also a frequent co-occurrence with possible reciprocal maintenance [93, 94]. As in the experimental context described, depressed mood can have a negative impact on pain control and perception [95]. Furthermore, catastrophic thinking has been shown to affect pain perception through altered PFC activity [96]. Anxiety, fear of pain, avoidance, and related cognitive behavioural mechanisms have been extensively described as relevant to pain suffering and loss of function [97, 98]. These factors need to be addressed through psychological or mind–body approaches in chronic pain [99–101].

Therapeutic implications

Clarifying the maintaining factor, whether peripheral or central, and diagnosing emotional, cognitive, and neurogenic (autonomous

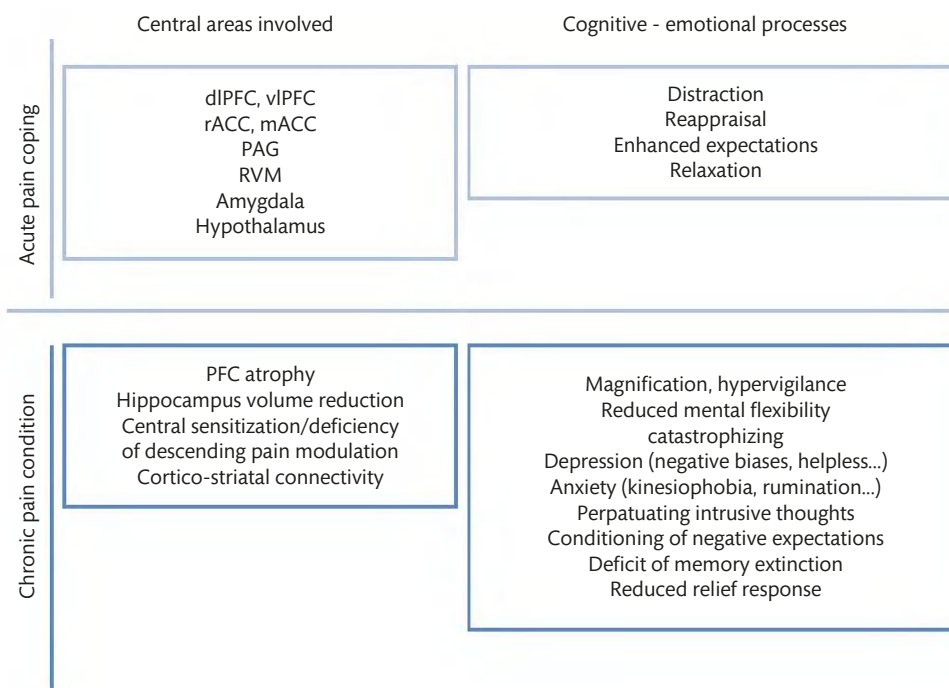

Fig. 130.4 Contrasting acute pain coping to the chronic pain condition. This non-exhaustive graphical representation highlights some of the commonalities and differences in neural processing areas and cognitive–emotional processes between acute pain in the healthy state and chronic pain pathology. The alterations in chronic pain shown here cannot be addressed by acute pain medication and require psychiatric or rehabilitative approaches to achieve improved function.

nervous system, DPMS, etc.) processes allow for appropriate treatment targeting. When there is evidence for central maintaining factors, it appears illusory to expect that medications, which act peripherally, such as non-steroidal anti-inflammatory drugs, could address the full depth of the problem. Molecules acting centrally and psychotherapy, as well as rehabilitation, may be needed (Fig. 130.4). Hence, there is an indication for medications such as duloxetine, tricyclic antidepressants, gabapentin, and pregabalin [81]. Opioidergic agents present somewhat a special case worth discussing. Opioids act centrally, at the very core of the DPMS, and there is even evidence for acute relief of emotional suffering [102]. Yet the clinical literature suggests long-term opioid therapy has a rather poor outcome in chronic pain [103], and there is a concerning association between opioid dose and the risk of activity interference, depression, and suicide [104, 105]. Mechanisms underlying the adverse outcomes of long-term opioid therapy for chronic pain are not yet well understood, but tolerance and induced hyperalgesia (a form of central sensitization due to opioids) could be involved.

Psychological and mind–body approaches, such as cognitive behavioural therapy, meditation, hypnosis, or yoga, are supported by clinical research [101, 106–108]. Increasingly, there is also brain imaging evidence for such therapies, with hints at the mechanisms involved in their benefits, mostly from healthy volunteers [109–112]. In patients, it has been demonstrated that a course of cognitive behavioural therapy can increase PFC activation of patients with fibromyalgia in response to pain or change resting-state connectivity that seems tied to catastrophizing [113, 114].

In sum, treating the psychiatric comorbidity and adverse psychological adaptation mechanisms needs to be taken as seriously as addressing the physical injury [115, 116]. This understanding is key

to the involvement of psychiatrists in the treatment of chronic pain [117], a field where multi-disciplinary care has shown to be very important [118] and in which exclusive opioid pharmacological treatment has been recently strongly warned against [103, 119].

Considerations on somatic symptom disorder

In certain circumstances, chronic pain is associated with somatic symptom disorders, which can be diagnosed in the presence of at least one of three psychological criteria: health anxiety, disproportionate and persistent concerns about the medical seriousness of the symptoms, and excessive time and energy devoted to the symptoms or health concerns. However, this new DSM-5 diagnostic category is under debate [120]. Beyond the syndromes including pain, the neural mechanisms involved in somatic symptom disorders are not yet well qualified [121]. Our understanding of certain functional pain syndromes, as well as somatic symptom disorders, might benefit from new theories and research regarding the nature of perception [122]. This line of research has also offered explanatory models for placebo effects [123]. Bayesian models of perception suggest that prior information can alter the *interpretation* of new stimuli, with prior beliefs and sensory information biasing new perceptions by overriding the current input [124].

Conclusions

Finally, whatever the cause, the underlying risk factors, or the specific pathophysiological path of a chronic pain sufferer, ‘terminal’

chronic pain can be seen as failure of an individual's coping abilities and of their adaptation resources. If the condition has been ongoing for long enough, patients are likely to present with depression or anxiety, social isolation, functional impairment, and possibly opioid reliance. They are at a dead-end, which requires a fundamental change of course to get back to a life worth living and to experience well-being and happiness. When medications, surgeries, and procedures are not helpful, psychological techniques fostering change are required. In any case, the comorbid psychiatric or psychological conditions, which can act as maintaining factors, must be addressed.

Treatment of fibromyalgia (chronic widespread pain) and chronic fatigue syndrome

Jonathan Price

Fibromyalgia (chronic widespread pain)

Clinical presentation and epidemiology

Fibromyalgia (FM) is the second most common musculoskeletal presentation, after osteoarthritis. It is a complex presentation (**Box 131.1**) [1], combining the core symptom (chronic widespread pain) with other very commonly associated symptoms (for example, fatigue, sleep disturbance, cognitive difficulties, non-pain somatic symptoms, low mood, anxiety). In addition, coexisting somatic syndromes [for example, irritable bowel syndrome (IBS), chronic headache, temporomandibular disorder, chronic fatigue] are common. Its complex nature, spanning traditional medical specialty boundaries, presents considerable challenges to health care professionals. FM is best conceptualized as a *centralized* disease state, in which symptoms and sensations from any part of the body are centrally amplified, rather than as a peripheral disorder of fibrous tissue and muscle.

The point prevalence of FM is estimated at 2.7% globally [2]. It is higher among women, with a female:male ratio of perhaps 2:1, a ratio which has shifted to much closer to parity since the requirement for multiple tender points was dropped from the diagnostic criteria. Prevalence is higher in middle-aged and older adults and in lower socio-economic status groups, especially the unemployed.

Diagnostic issues

FM was known by other terms until 1990 when diagnostic criteria were published that included both symptoms and, on examination, 'tender points' [3]. Recently, updated criteria have emphasized the importance of *chronic* (>3 months) pain that is *widespread* across the body [4]. Importantly, an FM diagnosis does not now exclude the diagnosis of any other disorder, and additional diagnoses are likely in order to fully describe the clinical condition of a typical patient. It is likely that the diagnosis and classification will start to consider FM and similar, often overlapping, disorders in a more integrated

way, emphasizing their considerable similarities, rather than their differences [5, 6].

FM has some unique features but shares some symptoms, epidemiological features, and underlying mechanisms with other 'chronic overlapping pain conditions' (COPCs) (for example, tension-type headache, temporomandibular disorder) [5] and chronic non-pain conditions [for example, chronic fatigue syndrome CFS]. Indeed, FM is commonly comorbid with COPCs with non-pain somatic symptom syndromes (for example, CFS and IBS) and with mental disorders (especially anxiety disorder and depressive disorder). Furthermore, the population of patients with rigorously diagnosed FM is not discrete—there is a population penumbra, with patients on either side of the cutpoints of diagnosis being similar, rather than different. In other words, we are not 'carving nature at the joints.' Finally, clinical diagnoses of FM are not confirmed by objective diagnostic tests, because such tests do not exist. These issues present major challenges for clinicians, and especially for researchers, and may also contribute to diagnostic delay; in a typical FM patient, there has often been more than 2 years of symptoms, and several medical consultations, before diagnostic confirmation [7]. A positive early diagnosis is likely to improve outcome, and FM should be suspected in any patient with chronic widespread pain not straightforwardly explained by injury or inflammation.

Aetiology

This chapter focuses on the role of three key factors which form the focus of successful treatment: central sensitization, fear avoidance, and physical deconditioning. Interested readers are referred elsewhere [8] for a broader review of psychosocial factors in chronic pain. A broader range of relevant factors are listed in **Table 131.1**.

Central sensitization

In the last two decades, the focus for understanding FM has shifted from peripheral nerves and muscles towards the role of the central nervous system (CNS). This shift is reflected in the range of recommended treatments, all of which act directly (for example,

Box 131.1 The 'FFIBRO' mnemonic for the core symptoms of fibromyalgia

Fatigue	Fatigue and tiredness
Fog	Cognitive dysfunction, memory and concentration impairment
Insomnia	Poor sleep initiation, sleep maintenance, poor sleep refreshment
Blues	Depression, anxiety
Rigidity	Stiff muscles, stiff joints
Ow!	Pain, which is widespread across the body and long-standing

Source: data from *Nat Rev Rheumatol.*, 5(4), Boomershine C, Crofford L, A symptom-based approach to pharmacologic management of fibromyalgia, pp. 191–199, Copyright (2009), Springer Nature.

antidepressants) or indirectly (for example, physical exercise) on the CNS. CNS sensitization appears to play a central role, such that the brain amplifies signals arriving from the peripheries by facilitating spinal transmission and by modifying cortical processing [9]. The person therefore feels more pain than is expected from the nociceptive stimulus (hyperalgesia) or feels pain from a stimulus that does not usually cause pain (allodynia). Central sensitization therefore contributes to the development of FM, other centralized pain states, and non-pain somatic symptom syndromes and allows us to attribute and manage a single cause in complex patients presenting with multiple symptoms spanning body systems.

Fear-avoidance (or 'kinesiophobia')

The person's fear of pain leads to avoidance of activities believed to cause or worsen the pain, that is, avoidance of movement and physical exertion. This leads to physical deconditioning and adverse psychological consequences, and thereby to exacerbation of the pain experience [10]. Importantly, the fear-avoidance model incorporates

both cognitive elements (beliefs about the consequences of movement and about the meaning of pain) and behavioural elements (avoidance of movement and exercise). Fear-avoidance is common in FM patients and correlates well with symptom severity and physical disability [11]. It provides a target model for treatment development with wide applicability in chronic musculoskeletal pain, and emerging evidence suggests that reduced fear-avoidance mediates the physical benefits of structured exercise interventions in FM.

Physical deconditioning

This plays a key role in the development and maintenance of central sensitivity. A vicious cycle is set up (Fig. 131.1).

These three factors—central sensitization, fear-avoidance, and physical deconditioning—usually enable a coherent explanation of causation to be provided to patients and carers. They also provide a firm basis for a management plan that is fundamentally patient-centred, incorporating: a *phenotype* that it predisposed to be pain-prone; *fears* about the impact of physical activity and *beliefs* about the need to rest and protect the body from the adverse effects of disease; and consequent and inherently reasonable *behavioural responses*, including symptom monitoring and excessive rest. These maladaptive beliefs and behaviours can be reinforced by the responses of relatives and other carers, and also by the responses of health care practitioners; both groups may encourage rest, in the hope that this may enable the body to recover from an as yet undiscovered disease process.

Assessment

In primary care, the assessment of FM will necessarily be pragmatic. In secondary care, clinicians should aim for a thorough understanding [12]. In both settings, assessment is a key part of treatment, not only by guiding it, but also by providing the trust and reassurance that chronic pain patients need to be able to move forward with potentially counter-intuitive approaches such as exercising despite increased pain. The interested reader is referred to Lotze and Moseley [13], who eloquently integrate compassion and modern pain science in the clinical assessment.

Assessment should include:

- *Pain behaviours*, for example, complaints of pain to others, including health care professionals, requests for medicines, avoidance of feared activities, reduced mobility, use of aids, protective postures.
- *Pain cognitions*, including dysfunctional beliefs, such that pain signals an underlying disease or that pain should respond to avoidance of usual activities; a tendency to catastrophize, that is, to assume the worst possible outcome; and low self-efficacy, that is, a lack of confidence in the person's own ability to influence their pain, now and in the future.
- *Pain impacts*, including on mood (low or anxious), on sleep, and on physical, social, and occupational functioning,
- *History from corroborants*, to confirm the patient's beliefs and behaviours, and allow the assessment of carers' beliefs and behaviours.

An appropriate physical examination should be carried out to: (1) rule out the presence of the inflammatory arthritides or, if one is present, to assess its contribution to overall morbidity; (2) assess the

Table 131.1 Aetiological factors in FM (key treatment targets in italics)

extent of physical deconditioning; and (3) provide appropriate reassurance to the patient that important physical diagnoses have been appropriately considered and excluded. A small number of appropriately targeted investigations are likely to be appropriate, but each should be clearly justified [14]. Clinicians should carefully balance the need for physical investigation with the prudent avoidance of over-investigation and over-medicalization of FM.

Management

FM can be challenging to manage, but clinicians should be encouraged that a reasonable evidence base exists and that this has helpfully been summarized and interpreted in recent clinical guidelines and reviews [14–18]. The guidelines differ in their details, partly due to recent changes in regulatory approvals for specific pharmacological approaches. However, there is broad agreement on principles (**Box 131.2**). In addition to these clinical guidelines, a recent review has documented the important academic and leadership challenges [19]. Finally, there is scope for a note of caution; for most of the evidence-based treatments described in this chapter, there remains a dearth of randomized controlled trials (RCTs) of high quality. An inevitable side effect is that robust evidence for comparative effectiveness of individual treatments is very limited. The interested reader is referred to a recent network meta-analysis [20].

Overall approach

RCTs have demonstrated the effectiveness of several treatments, both non-pharmacological and pharmacological, in FM. Initially, non-pharmacological approaches should be pursued [18]. They may be used in combination in an integrated, multi-disciplinary

way (for example, patient education plus exercise programme supervised by a physiotherapist). Failure of this approach should lead to the considered introduction of a pharmacological agent, alongside continued non-pharmacological management and with ongoing monitoring of key symptoms and function. The approach throughout is individualized for the particular needs and preferences of a particular FM patient.

Self-management plays a fundamental role in the management of FM throughout the spectrum of severity. Patients must understand the nature of the illness, its likely causes, the role of health care practitioners, and, importantly, their own role in active day-to-day management. This statement applies equally to key carers. **Table 131.2** outlines the characteristics of an optimal management approach to be promoted by the health care professional to the FM patient.

The European League Against Rheumatism (EULAR) guideline [18] provides a flowchart incorporating a stepped-care approach (**Table 131.3**), which facilitates prompt treatment. It is important to intervene promptly when patients present with FM, because longer pain duration is associated with the development and embedding of maladaptive illness behaviours, kindling of maladaptive pain pathways, more challenging management, and poorer prognosis. Referral to secondary care is appropriate when the illness does not respond to initial treatments, when there is uncertainty over the diagnosis, perhaps in the presence of significant comorbidity, and when there is significant psychiatric comorbidity that does not respond to initial treatments.

Empirically supported treatments

The specific treatments for FM for which there is reasonable or good evidence are now addressed in turn. Each treatment will be outlined, key clinical issues described, and the available evidence summarized.

Patient education

Effective patient education is pivotal to the effective care of FM. Multi-faceted, patient-focused education is likely to provide much needed coherence and reassurance that there is hope. Whenever possible, close family members/key carers should also be involved in discussion (see **Table 131.4** for the key messages for patients).

Box 131.2 Key aspects of management of fibromyalgia, derived from current clinical guidelines

- 1 Deliver initial care for FM in primary care;
- 2 Incorporate both pharmacological and non-pharmacological approaches, but with an initial focus on the non-pharmacological; and
- 3 Encourage active patient participation in treatment, facilitated by
- 4 High-quality patient education.

Table 131.2 Characteristics of an optimal management plan in FM

<i>Internally consistent</i>	That is, with a clear conceptualization of treatment that is based on an explanation of causes, especially maintaining factors
<i>Externally consistent</i>	That is, deliberately target and reduce or eliminate ambiguity between involved health care professionals concerning the causes of the illness, and the methods and goals of treatment
<i>Incorporating the reduction or stopping of inappropriate medication</i>	That is, those that are inconsistent with the aetiological understanding being promoted, and that are not required for the management of comorbidities
<i>Multimodal</i>	That is, involving both physical and educational/psychological components, in every case
<i>Promoting a graded increase in physical activity</i>	Aiming to reduce disability and improve morale and well-being, rather than to reduce pain
<i>Promoting an increase in patient responsibility and independence</i>	Rather than maintaining dependence on health services
<i>Individualized</i>	To the needs and preferences of the specific patient, and to their response or non-response to specific treatments
<i>Structured</i>	With a beginning (assessment, education, first step), a middle (empirical, stepwise approach to selecting successful treatment(s)), and an end (relapse prevention)
<i>Addressing the information needs of carers</i>	Who need to share a common understanding of causes and cures, and the chosen approach
<i>Adopting the principles of stepped care</i>	So that the maximum number of patients can benefit from appropriate management, in a resource-constrained health care system

The first, and fundamental, part of patient education is giving the diagnosis. Most FM patients will have tolerated incoherent and inconsistent explanations, without a clear way forward, for months or years. There is reassuring evidence that an FM diagnosis does

Table 131.3 Stepped care according to the revised EULAR guidelines

<i>Step one</i>	Patient education and information sheet; leading to, if insufficient response ...
<i>Step two</i>	Physical therapy, with individualized graded physical exercise, which may be combined with other recommended non-pharmacological therapies such as hydrotherapy/acupuncture, if necessary; leading to, if insufficient response ...
<i>Step three</i>	Reassess the patient to target individualized treatment, focused as follows: <ul style="list-style-type: none"> • If pain-related depression, anxiety, catastrophizing, overly passive—psychological therapies—mainly CBT—for more severe depression or anxiety, consider psychopharmacological treatment • If severe pain or sleep disturbance, then pharmacotherapy: for severe pain—duloxetine, pregabalin, tramadol; for severe sleep problems—low-dose amitriptyline, cyclobenzaprine (tricyclic-related), or pregabalin at night • If severe disability or sick leave, multimodal rehabilitation programmes

Source: data from *Ann Rheum Dis*, 76(2), Macfarlane G, Kronisch C, Dean L, *et al.*, EULAR revised recommendations for the management of fibromyalgia, pp. 318–328, Copyright (2017), BMJ Publishing Group Ltd and the European League Against Rheumatism.

not reinforce the sick role, and most patients should respond positively to a clear diagnosis, supported by a coherent and rational explanation.

Crucially, however, a diagnosis is not simply about delivering a name for the disorder. It is about explaining the nature of the illness, explaining that it is common and affects many people, and providing a coherent explanation of the cause which maps onto the proposed management plan. A high degree of fit between patient understanding of the cause (and especially maintaining factors) and the management plan is likely to predict treatment engagement and clinical response. ‘Explaining pain’ (EP) treatments or ‘pain biology education’ are of increasing interest [13, 21]. In these, the focus is on helping the pain patient understand that pain is a creation of the brain, designed to indicate the possibility of harm, rather than an accurate measure of tissue damage. The focus is on using education about pain biology to change the *meaning* of pain which then alters the experience of pain. Clearly, there is significant overlap here with more explicitly cognitive interventions.

The core of patient education should be about effective management, as patient behaviours are pivotal. The patient needs to understand what is needed to improve outcomes, and needs to feel enabled to start to act (self-efficacy). A *graded increase in physical activity* is the critical intervention, and patients must understand the rationale for this somewhat counter-intuitive approach in order to make a material and persistent change in their lifestyle. Some brief cognitive work may be needed to tackle unhelpful beliefs impeding engagement with a graded exercise programme. This emphasizes that education should be individualized to the needs of the specific patient. For example, patients who fear the adverse consequences of physical activity (fear-avoidance) need a targeted cognitive intervention, perhaps assisted by behavioural experiments. Such an intervention need not take place within the feasibility constraints of a formal psychological treatment but rather should usually be delivered by non-specialist staff in the clinic setting.

Evidence for the effectiveness of patient education in FM is extensive but is skewed towards highly time- and resource-intensive educational interventions. There are clearly important questions about the feasibility of such interventions in primary care. However, the fundamental importance of effective patient education is not doubted. The clinical challenge is to maximize its effect within the usual significant resource constraints. Undoubtedly, *good-quality written information* can help to leverage benefit, with minimal additional cost. *Careful selection of the recommendations for a particular patient and active endorsement of the treatment approach by a trusted clinician* are also critical.

Graded exercise

A graded, but persistent, increase in physical activity is the critical recommendation for patients with FM. EULAR guidance [18] concludes that there is ‘strong evidence for’ exercise and that exercise may benefit pain, function, sleep, and morale.

The relevant evidence comprises many RCTs, which have been summarized in three key Cochrane Collaboration reviews [22–24]. The best evidence is for supervised aerobic exercise training, which improves aerobic fitness, pain, physical function, and well-being. Strength (resistance) training also has a range of benefits and appears to be more effective than flexibility training, but possibly less effective than aerobic exercise. Aquatic (that is, water-based)

Table 131.4 Key messages for patient education

<i>You have a real illness</i>	We see many patients with problems like yours. We know that you are not imagining it or making it up. We want to help.
<i>The illness is called FM</i>	It is common—about one in 40 people have this illness.
<i>FM is problematic, but benign</i>	It is an illness that causes symptoms and disability. But it is not an illness which causes a long-term decline.
<i>FM is an illness of the nervous system, not an illness of the muscles and joints</i>	In FM, the body is especially good at generating pain signals, even when there is no cause for the pain. This is why medicines usually used for other illnesses, such as epilepsy and depression, can help; they change the way that the nerves in the brain and spine transmit pain signals from the muscles.
<i>FM is not caused by persistent infection</i>	An illness, such as a flu infection, may be a trigger for the illness, but ongoing infection is very unlikely. (Note: many patients, especially those who also satisfy the criteria for CFS, believe that they are harbouring an occult infection which explains their symptoms.)
<i>Exercise is the most effective treatment that we have for FM</i>	Exercise helps to build up the body and make it more resistant to challenges. Exercise improves blood flow to the muscles by causing blood vessels to grow more thickly through the muscle. Exercise may help to 'reset' the nervous system, so that it deals better with pain signals.
<i>Exercise causes temporary muscle discomfort, which is a sign of the muscle reorganizing to become stronger</i>	Exercise breaks the body down before it builds it back up, and so muscle pain and muscle tenderness are entirely normal after exercise, and not a sign of illness or abnormality. Competitive and recreational athletes know this very well. (Use a simple model to explain this, describing, for example, how muscle fibres disaggregate after acute exercise and then reorganize over a period of 24–72 hours.)
<i>FM symptoms are worsened by stress and low mood</i>	Learning self-help approaches to anxiety (relaxation, cognitive approaches, behavioural approaches) and depression is important. Antidepressants and other formal treatments, including CBT, also have a role to play.
<i>FM is helped by active involvement of the patient</i>	I can't cure this illness for you. I need you to work hard with the treatment plan, and I will do my best to support you.
<i>With treatment, FM can have a much smaller impact on your lifestyle</i>	Together, we can work at enabling you to manage and control your illness, so that it has much less of an impact on your life. I want to work with you on your rehabilitation, focused on what you can do, and on what you would like to do in the future.

exercise training appears to be as effective as land exercise training. The choice of exercise modality (aerobic vs strength/resistance; land vs water) therefore depends on patient preference and on feasibility, determined by both the availability and the impact of medical comorbidities. Fast walking, cycling, and swimming are good initial recommendations, as they have lower musculoskeletal impact than running.

FM patients have often been through a lengthy period of reduction in physical activity, frequency, duration, and intensity, due to their pain and related symptoms, and the majority would be classified as sedentary (<5000 steps per day). A sudden and significant step change in activity level is unlikely to be successful. Graded increments in activity, clearly prescribed or described by a health care professional or sports professional, are needed. Although small increases in activity (2000–3000 steps per day) may help, the greater the increase in activity, the greater the improvement in function, mood, and physical health-related quality of life, but not pain intensity [25]. Increased physical activity is, of course, also likely to have associated benefits for physical health (for example, body mass index, blood pressure, and glucose tolerance) and mental health.

Early worsening of pain and fatigue is common, and patients need encouragement to persist and to attribute such symptoms to the body's rebuilding in response to increased activity, rather than attributing them to worsening of a disease process. Many patients are concerned about pain, soreness, and tenderness arising in muscles in the hours and days following exercise, especially in the early stages of exercise training. This phenomenon is well known to athletes and others who undertake physical exercise for training purposes and is known as 'delayed onset of muscular soreness' (DOMS). This is an inevitable consequence of physical activity beyond the person's norm, in which muscular breakdown following exercise is accompanied by soreness and muscular fatigue, before the muscles rebuild

more strongly over a period of 2–3 days. In other words, increased muscle pain in this context is a sign of *adaptation* and improving physical fitness, rather than of disease. This is an important message for FM patients—physical sensations of pain and fatigue during and after exercise do not mean that the body is being damaged, but rather they are signs that the body is responding normally to the challenge and becoming stronger. It may therefore be better to use the word 'training', rather than exercise, with FM patients.

Understandably, motivation to exercise, and to exercise in a planned and strategic way over a period of weeks and months, is crucial to success. A minority of patients will find this straightforward, but a majority will struggle and need assistance at the outset and in an ongoing way. Tips for success are listed in [Box 131.3](#).

So-called 'activity cycling' is common and unhelpful. In this situation, patients are overactive on 'good days' and then underactive on the inevitable painful and tired subsequent 'bad days'. The aim should be that the patient gradually, but steadily, increases their physical activity level, independent of how they feel on the day—in other words, on good days, they may do less than what they feel capable of, but on bad days, they aim to do more than what they feel capable of.

Cognitive behavioural therapy

It makes intuitive good sense to incorporate *cognitive* elements into a purely *behavioural* intervention (exercise) for FM. Many patients will be reluctant to engage in a graded exercise programme, due to concerns about feasibility (for example, access to means or time), effectiveness (why should this help?), and toxicity (won't this make me worse?). Personalized assistance with overcoming practical concerns, and with the identification and challenge of maladaptive beliefs about the effectiveness and adverse effects of exercise, is highly appropriate. There are several key cognitions in FM that deserve targeting. These include that pain or other symptoms indicate actual bodily harm, that exercise will

Box 131.3 Tips for success with exercise for FM

- Involve key carers/relatives when explaining the rationale and the detail.
- Explain the muscular deconditioning cycle, and check understanding (Fig. 131.1).
- Be specific about what graded exercise is, and personalize the discussion.
- Help the patient to set clear treatment goals.
- Interpret 'exercise' very broadly and sensibly, especially when there are problems starting.
- Emphasize the importance of persistent engagement with the exercise programme—stopping and starting is unlikely to be helpful.
- Consider using a mechanical pedometer or a smartphone app to provide a daily record of activity levels.
- Be aware of the potency of fear-avoidance of physical activity.
- Be aware of 'activity cycling'.

cause pain or other symptoms, and that the increased symptoms following exercise are a sign of increased activity in the disease process, which then leads logically to resumed avoidance of exercise.

EULAR guidance [18] concludes that there is 'weak evidence for' cognitive behavioural therapy (CBT), based upon a Cochrane review [26] of 23 RCTs, in which there was a statistically significant difference in pain and mood at end of CBT and in which improvement was sustained at 6 months. Unfortunately, the RCTs have substantial heterogeneity. It is therefore difficult to extrapolate directly to clinical practice in FM. Furthermore, there are several difficulties associated with the practical use of CBT, including highly varied cognitive behavioural interventions, the availability of therapists and their varied skill level, and varied treatment fidelity. Limited availability may, in part, be addressed by innovative delivery via groups or the Internet [27].

Multicomponent treatments

EULAR guidance [18] concludes that there is 'weak evidence for' the combination of treatments, and especially psychological or educational therapies combined with graded exercise. A systematic review [28] defined multicomponent therapy as 'at least 1 educational or other psychological therapy, and at least 1 exercise therapy' and concluded that it was effective in reducing pain post-treatment, compared to control interventions. However, there is considerable complexity in the nature of 'multicomponent' interventions, especially regarding their level of integration [29]. 'Multi-disciplinary' and 'interdisciplinary' interventions lie along a continuum where the latter implies that the various disciplines have a common, coherent approach, rather than continuing to work within their own silo.

Antidepressants and anticonvulsants (as 'neuromodulators')

Most guidance, including EULAR [18], recommends pharmacological approaches, including antidepressants, as second line, that is, following failed intervention with education and exercise. An optimal therapeutic approach may be described as 'cautious pharmacological input' [30]. A recent summary of medicines for which there is evidence of effectiveness in FM, including specific contraindications and cautions, is helpful [31].

Importantly, in treating the core syndrome of FM, antidepressants and anticonvulsants are not functioning via their impact on mood

but are functioning as *neuromodulators* influencing central sensitivity; the analgesic effect of antidepressants occurs in FM patients who are not depressed and is independent of any antidepressant effect. It is important to emphasize this to FM patients for whom these medicines are being prescribed, to avoid their objection that either their illness is 'real', and not 'mental', or that they are not depressed. Most patients will accept the explanation that antidepressants change the functioning of 'nerves in the brain', to improve the outcome of depression, and that they can also therefore change the functioning of nerves in the spine and muscles, and so can alter the experience of pain in FM.

Hauser suggested three main reasons for why antidepressants should be used second line: (1) modest evidence of effectiveness; (2) high individual variability in response; and (3) problematic adverse effects [32]. While she concludes, somewhat implausibly, that amitriptyline, duloxetine, and milnacipran 'are first-line options for the treatment of FM', she goes on, thoughtfully, to state:

'Physicians and patients should be realistic about the potential benefits of antidepressants in FM ... A small number of patients experience a substantial symptom relief with no or minor adverse effects ... However, a remarkable number of patients drop out of therapy because of intolerable adverse effects or experience only a small relief of symptoms, which does not outweigh the adverse effects.'

The usual recommendation is to start with a low or very low dose of amitriptyline (25 or 10 mg, or even 5 mg, at night) and to titrate up, according to tolerance, to 75 mg. However, many patients will not be able to tolerate this modest dose and, even if they do, many will take the medicine for less than a year [33]. The usual cautions apply in older patients, and especially those with cardiac disease.

If amitriptyline is ineffective or poorly tolerated, then the serotonin/noradrenaline reuptake inhibitors (SNRIs) duloxetine or milnacipran should be considered [34]. The use of the tricyclic amitriptyline and these SNRIs is firmly rooted in the relevant biology—both serotonin and noradrenaline influence the descending modulatory pain pathways. There is little randomized evidence to support the use of the SNRI venlafaxine in FM. Cyclobenzaprine, a tricyclic-like muscle relaxant, is another alternative to amitriptyline ('weak evidence for') [18]. Finally, other alternatives include the anticonvulsants pregabalin ('weak evidence for') and gabapentin ('research only') [18]. Both of these medicines affect voltage-gated calcium channels, which are modulators of afferent pain signals.

The choice of an appropriate medicine should consider the symptom profile, likely side effects profile, likely patient tolerance of side effects, and patient preferences, which may be influenced by other FM patients' experiences. Clinical practice tends to favour amitriptyline or an SNRI with prominent depression, an anticonvulsant with prominent sleep disturbance, and an SNRI with prominent fatigue. Intolerance of medicines, even at low or very low doses, is a frequent problem [35], probably due to increased somatic sensitivity in FM, although other mechanisms are also likely to contribute to this nocebo effect.

¹ Reproduced from *CNS Drugs*, 26(4), Hauser W, Wolfe F, Tolle T, *et al.*, The role of antidepressants in the management of fibromyalgia syndrome: a systematic review and meta-analysis, pp. 297–307, Copyright (2012), with permission from Adis Data Information BV.

The prescription of strong opioid analgesics is inappropriate, as is long-standing prescription of any opioid. This reflects the lack of evidence for their effectiveness, with consequent lack of support from guidelines, alongside an increasing concern about their excessive use in some countries, with a high prevalence of use (10–60%) among FM opioid users [36]. Some evidence supports the use of tramadol, an opioid with some SNRI activity, and EULAR [18] concludes ‘weak evidence for’, but adverse effects and misuse are frequent issues.

Rather than ‘prescribe and forget’, an integrated approach to pharmacological treatment should be adopted. This should include:

- Careful patient and carer education;
- Continued exercise/activity intervention;
- Careful selection and targeting of medicines;
- An empirical approach, based on simple trials of one medicine at a time, with patient monitoring of key symptoms and function;
- Stepwise increase in dosing, to a dose likely to be therapeutic;
- Monitoring of adherence;
- Prompt discontinuation of ineffective medicines; and
- Pruning of medicines lists to reduce iatrogenic harm.

The last issue is crucial—FM patients are typically taking 8–10 medicines, for a variety of reasons [33], and such a number is unlikely to represent optimal management, even where there are multiple comorbidities. Application of simple *n* of 1 trials in this patient group may advance the rigour of decision-making and improve individual patient outcomes from pharmacotherapy [37].

Emerging randomized evidence suggests that combinations of CNS-acting medicines may increase response rates. For example, in a recent randomized crossover trial, patients received placebo, pregabalin, duloxetine, and pregabalin–duloxetine combination [38], with pain response of 18%, 39%, 42%, and 68%, respectively. Unsurprisingly, adverse effects, including drowsiness, were more common with combination treatment, and it seems prudent to reserve this approach for patients who have failed both first-line non-pharmacological treatment and second-line single-agent pharmacological treatment.

Failure to respond

Continued symptoms and disability are common, despite education, graded exercise, and a single pharmacological agent at the maximum tolerated dose. In this situation, a number of pragmatic approaches may be adopted, chosen according to the patient’s particular clinical situation and preferences. These include:

- *Combinations of drugs, rather than monotherapy.* One approach is to combine a morning SNRI with an evening anticonvulsant. Another is to combine a morning selective serotonin reuptake inhibitor (SSRI) with a low dose of amitriptyline in the evening. There is some limited evidence that SSRIs alone may provide some benefit. Adjunctive medicines, such as paracetamol, tramadol, and non-steroidal anti-inflammatory drugs (NSAIDs), may give additional benefit.
- *Supervised exercise or comprehensive rehabilitation programmes.* Patients who do not respond adequately to an exercise programme, often due to either poor motivation or poor exercise tolerance, may benefit from structured exercise in a more supervised

setting, perhaps following referral to a physiotherapist, or in an exercise group supervised by a health care professional.

- *Psychiatric referral.* This may be appropriate when a patient with depression has not responded to first- and second-stage antidepressant treatment, when suicidal ideation is significant or worsening, and when psychiatric problems may benefit from the input of the multi-disciplinary psychiatry team.
- *Pain management programme referral.* For more complex patients, perhaps with multiple comorbidities, consider referral to a pain management programme, which delivers more intensive support for self-management, with a mixed group of chronic pain patients, but using core principles of education, graded activity, and cognitive behavioural approaches [39].
- *Other approaches for which there is more limited evidence* such as complementary or alternative therapies. If the patient is enthusiastic about an empirically unsupported treatment, it should be considered in a non-judgemental way if the clinician does not view it as actively detrimental or unsafe—the placebo effect is a powerful tool in FM.

Empirically unsupported treatments

EULAR guidance [18] does not recommend a variety of treatments, including biofeedback, capsaicin gel, hypnotherapy, massage, and S-adenosyl-methionine (all ‘weak evidence against’); other complementary and alternative therapies (‘strong evidence against’); and chiropractic (‘strong against’, due to safety concerns). It also does not recommend many other treatments due to inadequate evidence, including electrothermal therapy, phytothermotherapy, music therapy, storytelling, magnet therapy, transcranial magnetic therapy, and direct current stimulation.

Many FM patients use complementary and alternative therapies. Clinicians should routinely ask patients about their attitudes to such therapies and about their use of them but should be clear that there is currently insufficient evidence to recommend them. Indeed, the use of such therapies alongside treatments with an established evidence base may be counterproductive, due to concomitant engagement with an alternative aetiological model.

Management of comorbidities

Comorbid diagnoses impact significantly on an FM patient’s clinical presentation, prognosis, and treatment. It is therefore desirable to fully diagnose comorbid disorders, in order to characterize the patient’s situation, understand their likely illness trajectory, and plan appropriate and comprehensive management. While targeting multiple problems simultaneously is unrealistic, and unlikely to be effective, if one or two symptoms are especially problematic, they may benefit from targeted treatment. A syndrome such as IBS, for example, may benefit from dietary advice, increased physical activity, and an antispasmodic.

Low mood sufficient to constitute a depressive episode deserves prioritization, as it reduces engagement with treatment, is associated with a worsened prognosis, and increases suicide risk, which is a significant concern in FM. In the presence of pain, mental disorders, such as depression, tend to be missed and, even when recognized, tend to be treated inadequately. This is despite their undoubted contribution to disability and chronicity.

Prognosis

In secondary and tertiary care, continued pain, fatigue, and sleep and mood disturbance are the norm over a period of several years [40]. This reinforces the need for early identification and energetic evidence-based treatment in primary care, based upon the rehabilitative model described in the previous section. The focus of many patients is on symptoms, including pain and fatigue; while these are unlikely to resolve, the impact on them and on health services can be significantly reduced. The aims of FM treatment should therefore be broad and include increased activity/reduced disability, improved mood and self-efficacy, increased employment, reduced sickness/benefit payments, and reduced use and cost of health care services.

The prediction of outcome in an individual patient at treatment outset is challenging. Psychosocial factors may help to predict prognosis, such as: (1) beliefs that the pain is harmful or severely disabling; (2) low mood and social isolation; (3) fear-avoidance; (4) an expectation that the patient will be a passive recipient of care, rather than an active participant in treatment; and (5) comorbid depression.

Overall, FM is not associated with increased mortality, but it has been associated with a 10-fold increased risk of suicide in a secondary care population [standardized mortality ratio (SMR) 10.5, 95% confidence interval (CI) 4.5–20.7] [41]. This emphasizes the need for:

- Therapeutic optimism, facilitated by and facilitating a pain rehabilitative approach;
- The identification and management of comorbid depression; and
- Routine or urgent referral for psychiatric assessment when needed.

Relapse prevention

Perhaps surprisingly, despite the chronicity of symptoms in most patients with FM, little attention has been paid to long-term management and prevention of relapse from treatment response. There is some evidence that the benefits of exercise may persist [42]. However, predisposing factors, such as genetic vulnerability, imply that FM responders remain vulnerable to setbacks and that continued improvement should not be taken for granted.

A common-sense approach suggests that, prior to discharge from health care, responders should be reminded that:

- They have a lifetime vulnerability to central sensitivity and FM.
- They should maintain non-sedentary levels of physical activity.
- They should identify early warning signs of a return of FM and share those signs with key relatives/carers.
- If the early warning signs emerge, they should redouble their self-care strategy.
- If their self-care fails to deliver early improvement, they should seek additional help from their health care provider.

It may be helpful to provide these key messages in written form for the patient's and carer's records.

Chronic fatigue syndrome

CFS is a complex disorder, in which severe fatigue, combined with several other symptoms, causes impairment across a wide spectrum,

from mild restriction to severe and bedbound. Clinical management and advances in understanding are impeded by entrenched and diametrically opposed positions on the roles of rest and physical activity, which are each seen variously as either cause or cure. The following text reviews in brief some of the issues and ends with a plea for a meeting of minds.

Clinical presentation and epidemiology

Fatigue is a common, almost universal, sensation and a normal bodily response to sustained effort. The challenge for clinicians and researchers has been to determine when 'normal' fatigue ends and when an important and problematic clinical disorder begins. In essence, this relates to chronicity and severity, although, as an indicator of the extent of difficulty, no less than nine sets of diagnostic criteria have been developed in the last 30 years. These have helpfully been summarized in a recent systematic review [43]. The 'Oxford criteria' [44], used in the largest and most controversial treatment trial to date [45], are summarized in [Box 131.4](#), and the most recent criteria [46] for 'systemic exertion intolerance disease' (SEID) in [Box 131.5](#). This new term is intended to convey the undoubted impact of the disorder and to reduce what the authors called the 'stigmatization and trivialization' resulting from the existing terminology.

While the diagnostic criteria for CFS/SEID are relatively straightforward, it is clear that the population of patients with CFS is a complex and heterogenous one, with multiple comorbidities. Muscle pain and joint pain are common, and there is considerable overlap between FM and CFS populations, with FM co-diagnosis indicating a more burdened CFS population. Other functional somatic syndromes are common, and diagnostic overlap has contributed to an energetic debate regarding the advantages of 'lumping' such syndromes together to emphasize commonalities in features and aetiology vs 'splitting' to emphasize differences [47]. Depression and anxiety are more common in CFS than in FM or IBS, but far from universal [48].

Epidemiology

The prevalence of CFS is uncertain, in part due to significant discrepancy between point prevalence in the community determined by self-reporting of symptoms (3.5%) and clinical assessment (0.9%) [49]. An added complication is the decline in prevalence of CFS through time. Between 1990 and 2001, combined fatigue diagnoses

Box 131.4 The Oxford criteria for chronic fatigue syndrome (CFS)

- Fatigue is the main symptom.
- Fatigue is severe and disabling, and affects physical and mental function.
- Fatigue present at least 50% of the time for a period of at least 6 months.
- Other symptoms may occur, including muscle pain, mood problems (including depressive and anxiety disorder), and sleep problems.
- Not explained by a medical condition, for example severe anaemia.
- Not in a person with schizophrenia, bipolar disorder, substance misuse, eating disorder, or organic brain disease.

Box 131.5 The US criteria for systemic exertion intolerance disease (SEID)

Requirement for all three of:

- 1 Substantial impairment of occupational, educational, social, or personal activities:
 - Present for >6 months;
 - With fatigue that is: new (that is, not lifelong); and
 - Not due to ongoing excessive exertion; and
 - Not substantially alleviated by rest
- 2 Post-exertional malaise
- 3 Unrefreshing sleep Plus at least one of:
- 4 Cognitive impairment
- 5 Orthostatic intolerance (for example, recurrent dizziness when standing from recumbent)

[CFS, post-viral fatigue syndrome (PVFS), asthenia] fell by 44% [50]. Recent findings confirmed a continued fall between 2001 and 2013 [51], with a modest decline in CFS incidence (3% annually), a more rapid decline in PVFS (8%), and a precipitate decline in asthenia (30%). Alongside this shift, there has been a rise in FM diagnosis, such that FM in the UK is now about three times more frequent than CFS [51]. This is confirmed by evidence from high-quality community surveys (0.8% CFS vs 2.7% FM) [2, 49]. The reasons for these trends are unclear; there is no good evidence for changes in diagnostic labelling. Recent data from Norway indicated two age peaks for incident CFS (10–19 and 30–39 years) and a female:male ratio of >3:1 [52].

Aetiology

There is no clearly established, widely agreed aetiological understanding for CFS. This undoubtedly reflects the clinical heterogeneity and aetiological complexity but also reflects the fundamental disagreements about the nature and causes of the illness. The aim here is to encourage the reader to engage with the relatively rapid advance in evidence relating to relevant aetiological factors and to form balanced opinions that are supported by evidence.

There is no doubt that physical disorder, such as common viral illnesses, often acts as a trigger/precipitating factor for severe fatigue and, in some individuals, the development of CFS. What are in dispute are: (1) the extent to which psychological or social factors predict the development of CFS after such illness (that is, are predisposing factors); and (2) the extent to which ongoing physical illness (such as chronic viral infection) contributes to persistent symptomatology (that is, is a maintaining factor). In a study of patients with glandular fever, chronic fatigue was not predicted by the severity of the glandular fever, as measured by symptom count [53]. Predictors included personality factors, such as perfectionism, and also cognitive factors such as ascribing symptoms to their glandular fever, believing that the illness would last a long time and impact detrimentally on their life, and not believing that they could control their illness. Emerging evidence suggests that CFS patients have specific cognitive biases which reinforce and maintain maladaptive cognitions and associated behaviours. These include an attentional bias for fatigue-related information and a tendency to

interpret ambiguous information as implying bodily dysfunction [54]. As in FM, fear of movement and avoidance of physical activity are common in CFS and related to symptom severity and physical disability [11]. Fear-avoidance lies at the core of the cognitive behavioural model of CFS, in which catastrophic interpretations of physical symptoms (and an unhelpful focus on symptoms) motivate behaviours, including activity avoidance and activity cycling.

A fundamental divide in thinking about CFS is the role of rest. On one side, rest (or relative rest) is viewed as an essential component of *treatment* of CFS, to allow the body to recover from the illness and gain in strength to fight putative infection or other ongoing physical challenge to wellness. On the other side, rest is viewed as an essential part of the *cause* of CFS [55], by leading to deconditioning. The adverse effects of excessive rest on multiple physiological systems are well established in healthy humans [56] and in patients with chronic physical illness such as renal failure [57].

There has been an ongoing search for physical causes of chronic fatigue. There is no doubt that, in some patients, a clear physical cause can be found. Prudent history-taking, physical examination, and investigation are therefore needed in possible cases of CFS to rule out significant physical pathology. Specific red flag features have been identified such as: difficulty in focusing the eyes, inflammatory arthritis or connective tissue disease, cardiorespiratory disease, weight loss, sleep apnoea, and lymphadenopathy [58]. However, little appears to be gained by an aggressive search for a physical disorder in the presence of normal physical examination and unremarkable screening investigations. In recent years, there was much early excitement when the retrovirus xenotropic murine leukaemia virus-related virus (XMRV) was found in the blood of most CFS patients, only for new evidence to dash hopes of a cure based on this finding [59]. The meaning of abnormalities in brain regional connectivity in CFS patients, the extent of which appears correlated with fatigue severity [60], is uncertain. Demonstrable effects of exercise [61] and psychological treatment [62] on neuroinflammation offer encouragement that a more integrated understanding of the causes of CFS can be developed.

Management

The UK's National Institute for Health and Care Excellence (NICE) guidance [58] recommends referral to specialist care within 3–4 months for adults with moderate symptoms, and immediately for patients with severe symptoms. Specialist care includes patient-centred rehabilitation programmes, which aim to improve physical and cognitive function and to manage symptoms. *Patient education* plays a key role and contributes to genuinely collaborative care, including shared decision-making. There is robust empirical support for two treatments: *graded exercise therapy* (GET) and *cognitive behavioural therapy* (CBT), and this is considered in the following sections. The evidence for *pacing* is disputed. There is little evidence for the effectiveness of *neuromodulators*, including antidepressants, unless a depressive illness is present. The evidence for pharmacological interventions has recently been reviewed, with no promising solutions evident [63].

Systematic reviews of RCTs support the use of GET [64] and CBT [65], but trials are small and there is a lack of comparative evidence with pacing. There is debate about the optimal specification of pacing in CFS, but in essence, it is an approach in which the patient functions within their perceived energy levels, rather than aiming to

systematically increase their level of functioning, as in GET or CBT. It is popular with patients, often advocated by patient groups, and it is unfortunate that better evidence does not exist. The PACE trial [66] was intended to provide a definitive answer to the important question about the relative merits of specialist medical care alone vs additional pacing, GET, or CBT. The main conclusions were that CBT and GET improved outcomes when added to specialist medical care, pacing did not, and adverse events seemed similar across the trial treatments. Overall, however, outcomes were modest and the proportion of recovered patients was low, perhaps reflecting clinical heterogeneity. Unfortunately, following the publication of short-term [45], adverse events [67], and long-term [68] results, fundamental and apparently bitter disagreements between the researchers and their critics have emerged, and their positions appear entrenched to a degree that is unique in medicine. The respective positions are well summarized in recent papers [69, 70]. The differences are clearly mirrored in the divergent recommendations of patient support organizations and medical organizations [71]. Those who are interested in uncertainty and the nature of scientific evidence, facts, and beliefs are strongly encouraged to read the cited documents. As the then deputy editor of the *BMJ* stated in 2011 [72]:

‘Why can’t CFS/ME be like other common chronic conditions where patients, carers, doctors, and researchers work together to pose research questions, gain understanding, and—in the absence of clear explanations and cures—at least find ways to respond to patients’ needs, help them live with and manage symptoms, and get more out of life?’²

Factitious disorder and malingering

Thomas Merten and Harald Merckelbach

Factitious disorder and malingering: two forms of feigned symptom presentation

Patients do not always present their symptoms in an honest manner. Their symptom reports may be affected by goals and motives that lie outside the realm of proper diagnosis and treatment of existing health problems. Distorted symptom presentations may occur in the forensic context where substantial incentives or secondary gain (for example, injury claims for compensation) are immanent, but also in clinical, as well as rehabilitative, settings.

Patients sometimes strive for certain benefits without their therapists being aware of this (that is, patients follow a 'hidden agenda'). Van Egmond, Kummeling, and van Balkom [1] asked psychiatric outpatients whether or not they expected to gain something from being a patient. A substantial minority (42%) said that this was indeed the case. They admitted that their patient status may help them to get a new home, sickness benefits, or a resident permit. A hidden agenda may fuel feigning and treatment stagnation [2]. The link between feigning and poor therapeutic success—including lack of cooperation, high dropout, and increased health care utilization—has now been well documented [3, 4] and should in itself be sufficient reason to consider feigning as a diagnostic option.

Exaggerated symptom reports may be motivated by a need to protect self-esteem. For example, Smith, Snyder, and Perkins [5] found that some individuals reported more symptoms in an evaluative vs non-evaluative situation, suggesting a self-protecting motive, according to the authors' interpretation. Mild symptom exaggeration or denial will not substantially hamper diagnostic decision-making. More blatant forms of distortions, however, may compromise clinical decisions. Such illness deception is commonly labelled factitious disorder or malingering. Both are commonly used categorical denominators to describe forms of significantly distorted illness behaviour, but phenomenologically they might not be distinguishable from each other at all. Indeed, some authors have argued that factitious disorder and malingering constitute one diagnostic entity [6]. We will return to this issue.

According to widely accepted definitions, malingering is the deliberate invention or gross exaggeration of health problems (symptoms), motivated by external incentives (secondary gain). The *Diagnostic and Statistical Manual of Mental Disorders*, fourth (DSM-IV) and fifth editions (DSM-5) [7, 8] described this deliberate

invention as 'intentional production' of false symptoms. However, Young [9] argued that the DSM definition should be modified by substituting *production* by *presentation*, highlighting different forms of how false or exaggerated symptoms can be demonstrated. Thus, Young defines malingering as 'the intentional *presentation with* false or grossly exaggerated symptoms [physical, mental health, or both; full or partial; mild, moderate, or severe], for purposes of obtaining an external incentive ...' (p. 180; italics in the original).

The extant literature on malingering includes different manifestations, ranging from pure fabrications of symptomatology over grossly exaggerated symptoms and perseverations (continued assertion of symptoms that have been present in the past) to false imputations (that is, intentionally attributing genuine symptoms to a false source) [10]. The wide range of distorted symptom reports that are brought under the definition of *malingering* partly explains largely different views on its prevalence. There is no consensus on where to draw the line between mild and gross exaggeration, and how to treat the intermediate zone.

In and of itself, malingering is not a mental disorder, but rather a behavioural strategy that healthy or sick people might use in certain situations (for example, after a motor vehicle accident, in a situation of social misery). This strategy may be appropriate or not in a specific situation; it may be judged morally wrong or right (and differently so by different people or from different angles), and it may be highly adaptive or severely maladaptive.

In contrast, factitious behaviour is commonly perceived to be a mental disorder and described as such by the International Classification of Diseases (ICD) [11] and the DSM [7, 8]. Exactly like malingering, it describes the deliberate false presentation (invention, production, gross exaggeration) of health problems. Yet, the underlying motive for factitious symptom presentation is thought to be internal (that is, primary gain), rather than external, as is the case with malingering. This internal motivation is commonly assumed to be unconscious and related to the sick role (patient care, medical procedures, diagnosis and treatment of claimed health problems). The Munchausen's syndrome (named after the German Freiherr von Münchhausen, dubbed the Baron of Lies), in which patients actively try to mimic symptoms (for example, by hurting themselves), was first described by Asher [12] and continues to be considered as the most prototypical form of factitious behaviour. Factitious behaviour is closely tied to self-harm [13] (but for a discussion, see [14]). Thus,

Table 132.1 The differential diagnosis between three forms of non-authentic symptom presentation largely rests on subjective judgment about the intention and the motivation for symptom distortion

Diagnostic category	Distorted symptom presentation	Incentives for distorted symptom presentation	Examples of incentives
Malingering	Intentional, deliberate, controlled (conscious)	Cognizant, self-reflective (conscious); external incentive, secondary gain	Sick leave, financial compensation, escape from legal responsibility
Factitious disorder	Intentional, deliberate, controlled (conscious)	Non-reflective, unaware (unconscious); internal incentive, primary gain	Medical treatment, including surgery, sick role
Somatoform, dissociative, and conversion disorders	Unintentional, involuntary, uncontrolled (unconscious)	Non-reflective, unaware (unconscious); internal incentive, primary gain; secondary gain may also be present	Conflict management, stress reduction

Reproduced from Merten T, False symptom claims and symptom validity assessment. In: Otgaar H, Howe M [eds], *Finding the truth in the courtroom? Problems with deception, lies, and memories*, Copyright (2018), Oxford University Press.

unlike malingering, factitious behaviour is maladaptive, which may be the reason why it is included in subsequent versions of the DSM as a disorder.

However, motivational aspects are crucial for distinguishing between malingering and factitious disorder. The presence of external rewards per se does not exclude factitious disorder, given that the potential for some form of secondary gain is usually considerable for patients in Western welfare states (such as sick leave, sick pay). The fact that secondary gain can be identified does not automatically mean that it plays a reinforcing role in patients' symptom presentation [15]. In many cases, it will be difficult to clarify the true and complete motivational background of false or grossly distorted illness presentations. This may become completely impossible when both external and internal factors are apparently present and interact in a complex way (for case examples, see [16]). All that might be said with some confidence about such complex cases is that symptoms are *feigned*.

Feigning comprises both malingering and factitious disorder. It is defined as 'the deliberate fabrication or gross exaggeration of psychological or physical symptoms without any assumptions about its goals' ([17], p. 6). However, before an expert can ascertain feigning in a given case, he or she has to take another decision that is conceptually as complex and problematic as the clarification of the underlying motivation—whether or not false symptoms are presented intentionally, voluntarily, consciously.

Feigning and genuine mental disorder

Striking discrepancies between subjective symptom report and objective signs are not limited to feigned health problems. In fact, they constitute the key feature of what historically has been called hysteria. In 1917, Jones and Llewellyn [18] wrote: 'Nothing, it may be said, *resembles malingering more than hysteria; nothing hysteria more than malingering*. In both alike we are confronted with the same discrepancy—between fact and statement, between objective sign and subjective symptom ...' (p. 117, *italics* in the original). Phenomenologically, patient behaviour in the context of factitious disorder, malingering, and somatoform or dissociative disorders may be completely indistinguishable. To address this problem, DSM-IV [7] stipulated as a necessary criterion for diagnosing both somatization disorders and conversion disorder: 'The symptoms are not intentionally produced or feigned (as in Factitious Disorder or

Malingering)' (p. 462). This requirement was given up in DSM-5 for *Somatic symptom and related disorders*. Still, the dimension of intentionality delineates a distinction between self-deceit (in genuine mental disorder) and other-deceit (in feigning), as described by Turner [19].

Intentionality (or not) and the nature of incentives are the two dimensions with which various forms of discrepant symptom presentations can be differentiated. The distinction between the three diagnostic entities listed in Table 132.1 critically hinges on the assumption that both intentionality and true motivation can be reliably and, much more importantly, validly ascertained by a third party (that is, the clinician or forensic expert) [20]. Many authors have criticized this assumption [21]. Moreover, in many cases, it appears doubtful whether intentionality and motivation can be reliably dichotomized at all. Diagnostic options such as *Feigning, unspecified* or *Feigning, not otherwise specified* [22], as well as previous attempts to rename somatoform disorders into *medically unexplained symptoms* [23], are reflective of this nosological inconclusiveness. However, the traditional approaches of DSM and ICD stick to the categorical system and have largely ignored attempts to introduce a multi-faceted and dimensional approach [24–26].

Incidentally, Brown's [27] definition of *medically unexplained symptoms* as 'a heterogeneous group of conditions characterized by persistent physical symptoms that cannot be explained by medical illness or injury' (p. 769) would encompass somatoform, dissociative, factitious, and malingered symptom presentations, plus symptoms in the context of a yet unknown physical disease. A more detailed discussion of the conceptual problems of distinguishing between somatoform and feigned disorders and its practical consequences can be found in Merten and Merckelbach [28].

In the descriptions below, we largely ignore the conceptual conundrum surrounding factitious disorder and malingering and depict their ideal-typical manifestations as they are treated in the literature.

Malingering

Definition

Malingering is the intentional false presentation (invention, gross exaggeration, or otherwise gross misrepresentation) of symptoms or health problems with the primary goal of attaining an external reward. External gain may be a financial incentive (for example, compensation), but it may also relate to obtaining drugs, escaping

from formal duty (for example, sick leave, military service, sitting an exam), legal responsibility, or punishment, or obtaining other material or non-material advantage. The specifier *external* indicates that the motivation for false illness presentation does not primarily relate to stress management, internal (interpersonal) conflict, or the sick role. Malingering is not a mental illness and should not be pathologized. Still, pathologization of people who, in a certain context, engage in malingering is not uncommon [29], as indicated by phrases such as *healthy people don't do this; cry for help; you need to be mad in order to fake madness*.

In DSM-5, the term malingering has been deleted from the index and is difficult to find in the text. It is treated under the headline *Nonadherence to medical treatment*, with the code V65.2 (pp. 726–7). DSM-5 lists four criteria that were adapted from DSM-III [30], even though these criteria have repeatedly been shown to be completely inadequate [24, 31, 32]. According to DSM-5, any combination of the following four criteria would be strongly suggestive of malingering: (1) medicolegal context of presentation; (2) marked discrepancy between symptom presentation and objective findings; (3) low degree of co-operation in diagnosis and treatment; and (4) presence of an antisocial personality disorder.

To illustrate the inappropriateness of these criteria, it may suffice to note that any person with a diagnosed antisocial personality disorder who is examined in a medicolegal context should be ‘strongly suspected’ of malingering according to these criteria (when, in fact, the link between antisocial features and malingering is, at best, weak [33]). Also, any patient with a somatic symptom disorder or a conversion disorder should be ‘strongly suspected’ of malingering in any medicolegal context, given the fact that both disorders are characterized by a marked discrepancy between subjective symptom presentation and objective findings and observations.

The DSM criteria for malingering have virtually not changed since 1980. They are based on an outdated (criminological) conception of malingering prevalent in the 1970s (with antisocial personality considered to be a key issue in feigned health problems [34]), and they ignore the vast empirical and conceptual work with several thousands of publications written during the last three decades [24].

In ICD-10, malingering is coded as Z76.5, without further elaboration. Interestingly enough, ICD-10 contains another category of exaggerated or excessively prolonged symptoms that was conceptualized as *Elaboration of physical symptoms for psychological reasons* (F68.0). It corresponds roughly to the older concept of *compensation neurosis* (for a more recent appraisal, see [35]). However, for unknown reasons, it is explicitly limited to physical symptoms and is poorly defined. Cooper’s pocket guide [11] stressed the psychological causation of it (including the aspiration of obtaining financial compensation). Contrary to malingering, F68.0 is conceived to be a mental disorder.

Assessment

Different medical disciplines have developed their own strategies and lists of criteria for the detection of malingered symptomatology. Among traditional medical disciplines, ophthalmology has shown a particularly strong interest in differentiating true visual deficits from feigned impairment [36]. The determination of malingering is usually based on an analysis of plausibility and consistency within the available information or data on a case, with general criteria focusing on discrepancies, such as the following [31, 37]:

- Excessive, overgeneralized symptom report.
- Bizarre symptom presentation.
- Inconsistency in symptom presentation.
- Absence of functional impairment outside the diagnostic setting, unimpaired functional level in the private sphere.
- Disproportionate claimed disability, as compared to the objective severity of illness or injury.
- Implausibility of symptoms and complaints with regard to current medical/psychological knowledge (symptoms *do not make sense*), symptom presentation contradicts the functional–anatomic principles.
- Contradictions between claimed history and documented facts.
- No improvement under treatment with known efficiency.
- Evasiveness.

For different disciplines (for example, neurology, ophthalmology, neuropsychology), lists of special malingering markers have been developed, related to the functional system in question. In psychiatry, such lists are currently *en vogue* with regard to judging the authenticity of claimed symptoms of post-traumatic stress disorder (PTSD). Such red flags may include early and spontaneous patient’s symptom report, the quality of reported flashbacks, the presence or not of observable emotional arousal in the patient, the quality and extent of reported amnesia for aspects of the traumatic event, contents and the frequency of reported nightmares, temporal stability or instability of claimed symptoms, the presence or not of survivor guilt, or blame of others instead of self-blame [38, 39].

The use of checklists for malingering is hampered by a number of difficulties. Firstly, they ignore the conceptual problems. Often, the criteria used for determining malingering equally apply to factitious disorder, making them criteria for feigning, rather than malingering. Also, similar or identical criteria are used for identifying somatoform, conversion, and dissociative disorders [40]. As a consequence, they may rather be called criteria for non-genuine symptom presentation.

Secondly, the criteria on checklists often have been established intuitively, on the basis of what may be called clinical lore, but nobody knows about their reliability and validity or their accuracy of classification (sensitivity, specificity). Usually, they are poorly described and handled in an intuitive, individualized way. They have not been operationalized (that is, there are no rules that describe how to apply and score them). Inter-rater reliability must be expected to be a major problem.

Thirdly, there is no systematic knowledge about decision rules (which and how many criteria should be checked in which context, how many of them must be positive for a positive classification, etc.). A strict application of such criteria may result in an inappropriately low threshold for malingering [41].

For the last two decades, the bulk of research in the domain of malingering has been done by neuropsychologists and published in neuropsychological journals [42]. The reason for neuropsychologists’ prominence is their reliance on test data. Psychological test results are highly dependent upon the individual’s willingness to cooperate. With the development of what was then called symptom validity tests (SVTs), malingering assessment entered a new stage and became a primarily data-driven and evidence-based methodology. A vast number of instruments for practical use were developed, comprising cognitive SVTs (today mostly called performance

validity tests), self-report validity measures (questionnaire approaches), and clinical interviews and ratings. It is beyond the scope of this chapter to give an overview over these psychological test measures; the reader can easily find summary reports in about a dozen of books available in English language [9, 43, 44]. In the past, SVTs were often referred to as malingering tests, but this is misleading because malingering is just one possible reason why individuals may fail on such tests.

Under certain circumstances, some SVTs (those that operate on a forced-choice format) are able to identify response patterns that are indicative of *intentional*, *voluntary* response distortions [45]. In such cases, test results are paramount to the confession of feigning. Accordingly, they occupy a special place in the most noteworthy attempt to formalize diagnostic reasoning about malingering—the criteria proposed by Slick, Sherman, and Iverson [46]. While their original criteria were related to malingered neurocognitive dysfunctions, they were later extended to other conditions, in particular to pain disorder [47].

Prevalence

Available base rate estimates of malingering differ immensely. In clinical contexts, the base rate of malingered symptom presentations is usually expected to be very low. Consequently, the possibility of intentional response distortions is often dismissed at the outset, conforming to the traditional role concept of mental health providers. To illustrate this point, Reuber *et al.* [48] went as far as maintaining that: ‘*Fortunately*, it is rarely necessary for a clinician to determine whether symptoms are intentional’ (p. 308, *emphasis added*). In other settings, malingering appears to be rather common. For the United States military, Morel [49] maintained that: ‘No clinical opinion is more problematic, more weighty, or more pressing for a solution in military psychiatric medicine than differentiating malingering from post-traumatic stress disorder (PTSD)’ (preface).

Potential factors responsible for the wide range of base rate estimates of malingering are the following:

- The exact definition or underlying concept of the phenomenon that is being evaluated (for example, feigning, malingering, symptom exaggeration, negative response bias, suboptimal effort, effort test failure, overreporting, underperformance, symptom invalidity).
- The referral context of the examination (for example, forensic, clinical, rehabilitative).
- Within forensic contexts, the legal issue at stake (for example, diminished criminal responsibility, liability, workers’ compensation, disability, custody).
- The diagnostic group (diagnosed or claimed condition, for example mild traumatic brain injury, moderate or severe traumatic brain injury, PTSD, whiplash injury, chronic toxic encephalopathy, attention-deficit disorder).
- The method used for detecting feigning (for example, unspecified clinical impression, expert rating using specified criteria, rating or questionnaire methods, performance validity tests, application of the Slick criteria [46]).
- The standardized measures or SVTs if any were employed (for example, for questionnaire methods, MMPI-2 Fake Bad Scale, F scale, Response Bias Scale, combination of different scales,

Structured Inventory of Malingered Symptomatology, Assessment of Depression Inventory).

- When SVTs were used, the diagnostic decision rule (for example, based on a score in a single instrument or scores on a whole set of instruments; the number of SVTs administered and the number of positive single indicators necessary to classify the response pattern as feigned).
- The classification accuracy (sensitivity, specificity) of the specific methods used for diagnostic decision-making.
- Which cut scores were used for the single instruments (for a number of SVTs, different cut scores are available and some cut scores underwent modification or refinement in the course of time, after first publication).

Some estimates resort to the criterion of below-chance response patterns in performance validity tests [45, 46]. This is a very conservative criterion with a very high specificity, but low sensitivity in most real-world referral contexts. Consequently, such estimates necessarily result in a considerable underestimation of the true prevalence. In a similar vein, reliance on obsolete screening instruments (for example, the Fifteen-Item Test [50]) or embedded measures with known low sensitivity will yield grossly deflated estimates. Conversely, the employment of larger batteries of validity measures, and particularly of so-called embedded performance validity indicators, with a low threshold of diagnosing negative response bias will yield gross overestimations. Rogers *et al.* [41] pointed out that the influential model of Malingered Neurocognitive Dysfunction (MND) [46] defines a low threshold, in particular for the determination of possible malingering. As a consequence, prevalence estimates based on criteria suggestive of possible MND (and, to a much lower degree, probable MND) will inevitably produce grossly overestimated base rates.

With all these factors in mind, existing prevalence estimates must be understood as very rough approximations for the true base rates to be expected in different contexts. The most frequently cited prevalence data stem from a survey by Mittenberg *et al.* [51]. Probable malingering or symptom exaggeration was judged by 131 participating neuropsychologists to be present in almost a third of all litigating patients (in personal injury, disability, and workers’ compensation contexts). Larrabee [52] identified mild traumatic brain injury as one of the most delicate conditions when it comes to malingering, with a prevalence of about 40% of false or grossly distorted symptom presentations (see a more recent study by Peck *et al.* [53] also reporting a 40% base rate in their sample). For some referral contexts and/or claimed conditions, base rate estimates reaching or exceeding the 50% mark have been published such as: litigating patients after whiplash injury [54]; patients with reported hearing loss, in independent medical examinations [55]; criminal defendants [56]; Social Security disability claimants in the United States [57, 58]; students with claimed attention-deficit disorders, but without learning disability [59]; British personal injury litigation patients claiming memory impairment [60]; or United States veterans claiming mild traumatic brain injury [61]. Adding to these studies, Spanish researchers [62] performed a survey among 161 Spanish medical doctors who were asked to estimate the percentage of malingering patients with different health conditions. Mean estimates of 50% or higher were reported for patients with

claimed whiplash injury, fibromyalgia, chronic cervicgia, depression, and anxiety disorders.

Young [63] performed an extensive literature search on recently published prevalence estimates and also came to the conclusion that 'it is difficult to arrive at one percentage or range of percentages that are definite about the proportion of malingering found in forensic disability and related examinations' (p. 196). He argued that 15% is the most appropriate estimate at the time being, with a large variation of another 15% in both directions, depending on the referral background, the condition in question, and other factors.

Factitious disorder

Definition

Factitious disorder is considered to be a mental disorder characterized by a non-authentic, feigned symptom presentation, either in the form of a voluntary production of symptoms (for example, self-inflicted injury, artificial fever, self-induced wound healing disturbance) or false, misleading, or grossly exaggerated symptom report. DSM-5 [8] describes this condition in the chapter on *Somatic symptom and related disorders*. The key criterion of factitious disorder (300.19) is described as a *falsification* of physical or mental signs or symptoms (instead of false presentation), and it extends to the induction of injury or disease. This behaviour must be deceptive and deception has to be identified. Furthermore, deceptive illness presentation is assumed to be evident, 'even in the absence of obvious external rewards' (p. 324). As with malingering, these diagnostic criteria are judged to be of little clinical validity [64]. Neither do they foster diagnostic reasoning nor do they help to arrive at a reliable diagnosis or assist in differential diagnosis.

In ICD-10, factitious disorder is coded as F68.1 under *Intentional production or feigning of symptoms or disabilities, either physical or psychological*, despite the fact that this description comprises both malingering and factitious disorder. Cooper's pocket guide [11] gives a very short description stressing that false symptom presentation which may include self-harm occurs 'for no obvious reason', with an assumed internal motivation of adopting the sick role. Included are the older concepts of the hospital hopper syndrome, Munchausen's syndrome, and the peregrinating patient. Asher [12], who originated the concept of Munchausen's syndrome, commented: 'These patients often seem to gain nothing except the discomfiture of unnecessary investigations or operations' (p. 339). Munchausen's syndrome is estimated to represent about 5–10% of all factitious cases [65].

Different types of factitious disorder have been described, first the abdominal, the haemorrhagic, and the neurological type by Asher [12] (laparatomophilia migrans, haemorrhagica histrionica, neurologica diabolica), later types like dermatitis autogenica, hyperpyrexia figmentatica, or cardiopathia phantastica. Also, pathological lying (pseudologia phantastica) is being discussed in the context of Munchausen's syndrome [66]. More recently, manifestations of factitious illness behaviour in Internet communities, such as cancer support groups, have been described [67].

Prevalence and assessment

The incidence of factitious disorder in patient groups is estimated to be well below 1%, but using a more liberal criterion, Catalina *et al.*

[68] found in their sample of psychiatric inpatients that 8% exhibited factitious symptoms. These authors further noted that in this group, women were overrepresented, the mean age was below 40, and symptoms became more intense when patients faced discharge. Fliege *et al.* [69] surveyed senior hospital consultants and physicians in private practices. They estimated the 1-year prevalence of factitious disorder at 1.3%. Relatively higher rates were reported by dermatologists and neurologists. Another study reported a prevalence of 1.8% [70]. In contrast, Wallach [71] estimated the base rate of factitious disorders at 5% of all physician encounters. With these estimates in mind, factitious disorder should not be considered a rare condition, having in mind that in any large general hospital in the Western world, several patients with factitious disorder should be expected to be present at any time—mostly going undiagnosed for this very condition.

The diversity of prevalence estimates is partly due to a lack of diagnostic guidelines or assessment procedures. With a few exceptions [72], researchers have employed little effort to develop screening methods for factitious behaviour. In most cases, factitious disorder must be expected to be left undetected. Suspicion is raised in patients with an atypical illness course and marked inconsistencies. Behavioural manifestations may include gratuitous, self-aggrandizing lying, non-compliance with medical prescriptions, disruptive actions, or excessive request for invasive medical procedures [64].

The ample literature on factitious behaviour consists, to a large extent, of case studies. One recent exception is a study by Lawlor and Kirakowski [73] who analysed text communications of two online communities of people who said they engaged in factitious behaviour. One remarkable result was that a large majority reflected upon their motives for playing the sick role, which suggests that factitious behaviour is more consciously motivated than assumed by some workers in the field.

Feigning by proxy

Factitious disorder by proxy has long been discussed as a major problem in childcare, but it may also be present where caregivers exert pressure on persons with intellectual disability, dementia, or mental disease or directly impose symptoms on them. It includes such extreme forms as non-accidental poisoning or non-accidental suffocation [74]. Typical Munchausen presentations would then be called Munchausen by proxy (or Munchausen's syndrome by proxy). Moreover, factitious illness behaviour is sometimes related to animals, in particular pets [75].

In DSM-5, such behaviour is coded as *Factitious disorder imposed on another*, with the code 300.19. The diagnosis is given to the perpetrator, not to the victim.

Little attention has so far been paid to cases in which external gain (such as monetary benefit) is clearly sought by parents or caregivers who exert pressure on the patient (a child or a cared person) to invent or exaggerated symptoms. With a clearly identified secondary gain as the central motive for exerting this pressure, such behaviour is called malingering by proxy [76]. In cases where motivational analysis can favour neither primary nor secondary gain as being central for the grossly distorted symptom presentation, this abnormal illness behaviour may be called feigning by proxy.

Summary and conclusions

Factitious disorder and malingering are two forms of abnormal health care-seeking behaviour [64]. Their common denominator is deception, a conscious intention to deceive medical personnel (or other people), or what Kozłowska [77] called a 'strategic use of illness behaviours in relationships with other individuals' (p. 1368). In the case of malingering, external incentives (such as monetary compensation or sick leave) prevail and health care can be considered to be only the means through which these external goals are expected to be reached. In factitious disorder, health care and the patient role are thought to be central. However, both forms of deceptive behaviour can often not be reliably differentiated from each other and from what has previously been called hysteria. The core feature of all three categories—malingering, factitious disorder, and hysteria (or unexplained medical symptoms)—is the presence of marked inconsistencies, implausibilities, and contradictions within and between different sources of information. While the clinical manifestation may be indistinguishable between these forms of distorted symptom presentation, differential diagnosis requires determinations about both the motivation and the degree of consciousness about the falseness or gross exaggeration of symptoms. However, both dimensions are, in fact, neither categorical nor stable in time nor can they reliably be rated by a third party. This imposes significant limits to the validity of the clinical entities used for the description of non-genuine, feigned symptom presentations. Consequently, the utility of maintaining the distinction between malingering and factitious disorder has been questioned, and the apprehension of factitious disorder as a mental disorder in its own right has likewise been questioned. Both malingering and factitious disorder can be comprehended as expressions of interpersonal behaviour; '... they have no strategic or communicative function except when someone else can observe and respond to the behaviour' [77] (p. 1368).

In a historical perspective, factitious disorder may be conceived of as an attempt of the medical profession 'to acknowledge the deception while pathologizing it. The doctor could make a medical, not legal, 'diagnosis', keeping their medical hat on, and allowing the doctor–patient relationship to remain a therapeutic one' [78] (p. 76).

While factitious disorder is mostly discussed in the context of patient care, most studies on malingering centre on forensic or medicolegal contexts. There may be a bias in this dichotomy. Be that as it may, the bottomline of most prevalence studies is that significant response distortions, substantial symptom exaggeration, and feigning are to be expected in a sizable proportion of patients in medicolegal contexts. Whatever the exact numbers are, the problem of feigning is prevalent enough to proactively test it in any patient with a medicolegal background. Ruling out feigning should also be mandatory practice in clinical patients with a current or foreseeable litigation background, instead of automatically assuming that symptom presentation is genuine under all circumstances (which seems to be the common clinical stance today).

Functional neurological symptom disorder (conversion disorder)

Jon Stone and Michael Sharpe

Introduction

Functional neurological symptom disorder, also called conversion disorder, refers to symptoms of motor and sensory dysfunction which can be positively identified as incompatible or incongruent with neurological disease. Common symptoms include blackouts (that may look like epileptic seizures or syncope), limb weakness, movement disorder such as tremor, dystonia, or jerks, and sensory disturbance, including visual loss. In this chapter, we trace the history of the disorder, especially as it relates to psychiatry, and describe the terminology, classification, epidemiology, clinical features, and treatment.

Historical background

The term 'hysteria' has been used since the time of Hippocrates (around 400 BC) to describe symptoms that were considered to occur only in women, such as choking, and to be caused by a 'wandering womb' exerting its influence throughout the body.

From the early seventeenth century onwards, physicians, such as Lepois (1618), Willis (1667), and Sydenham (1682), located the origin of these 'hysterical' symptoms in the brain and nervous system, rather than the uterus, not only because of changes in neuro-anatomical thinking, but also because of a recognition that the same symptoms also occurred in men [1].

In the nineteenth century, Briquet (1859), Charcot (1880s), and Janet (1890–1920s) pursued a more systematic approach and focused on symptoms that we would now regard as neurological such as paralysis, numbness, seizures, and blindness. Pierre Janet used the clinical study of hysteria to advance his views on 'dissociation' as a way of understanding how a person could lack the ability to control their own voluntary movements.

In 1895, Breuer and Freud's book *Studies on Hysteria* described five case studies in which hypnosis was used to find 'reminiscences' thought to be relevant to the onset of hysterical symptoms. These initial cases formed the basis not only of psychoanalytic theory, but

also of the conversion hypothesis. The conversion hypothesis proposed that symptoms, such as paralysis, were created unconsciously by conversion of intrapsychic conflict. The main benefit or 'primary gain' was considered to be the reduction in the psychological conflict the person experienced. Additional benefits of 'secondary gain' were considered to occur if the symptom provided an escape from the external sources of the conflict, for example by leading to the inability to carry out an act.

Freud's ideas, despite being largely unfalsifiable, had a profound effect on clinical practice over the subsequent century, not least in the adoption of the term conversion disorder in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) of the American Psychiatric Association—the only psychoanalytic diagnosis to remain in the manual to the present day. The effect on practice was that neurologists were able to confidently dismiss the problem as psychiatric and psychiatrists felt an obligation to attempt therapy to make the proposed conflict conscious [2].

Consequently, patients have often ended up falling between neurology and psychiatry, often with neither being sure of what the correct treatment is. To add to the uncertainty, Eliot Slater's influential, but flawed, study on 'hysteria', published in 1965, suggested incorrectly that many such patients had misdiagnosed neurological disease [3].

There has been progress and in the last 20 years, it has been established that patients with neurological symptoms unexplained by an identifiable pathophysiological process are, in fact, common (the second most common reason to see a neurologist). It has also become clear that they can be reliably diagnosed using positive clinical features identified predominantly on physical assessment (and not only as a diagnosis of exclusion). Studies have also suggested that the symptoms have an inconsistent relationship to trauma and stress (that is, some have it, but some do not). In summary, after a long period of confusion and ignorance, we are starting to see progress. We are hopefully now entering a more optimistic era of clinical science which builds on the notion that a brain-and-mind approach is required to understand its aetiology and to deliver effective treatment.

Terminology and classification

Terminology can be difficult for both doctors and patients. Broadly, the current terms can be categorized as follows:

- Psychogenic/somatization/somatoform/conversion—implying that the symptoms are essentially physical manifestation of a psychological problem.
- Non-organic/non-epileptic/medically unexplained—defining the problem as not being due to disease.
- Functional—suggesting a disorder of bodily or nervous system functioning without aetiological presumption.
- Dissociative—suggesting a disconnection between nervous system component functions.

These terms each have advantages and disadvantages. We will use the term ‘functional neurological disorder’ here for the scientific and pragmatic reasons outlined in this chapter.

The classification of functional neurological disorder has been through several iterations in DSM. In DSM-I, it was Conversion Reaction (DSM-I), in DSM-II Hysterical Neurosis—Conversion Type, and in DSM-III and IV Conversion Disorder [4]. In DSM-IV, conversion symptoms were also listed under somatization disorder, a relatively tightly defined long-standing vulnerability to ‘somatoform’ symptoms starting before the age of 30, involving symptoms which were neurological (≥ 1 symptoms), pain (≥ 4 symptoms), gastrointestinal (≥ 2 symptoms), and sexual (≥ 1 symptoms). In the latest iteration of DSM (DSM-5), the disorder is now called Conversion Disorder (Functional Neurological Symptom Disorder) (300.11).

It should be noted that wilfully manufactured or grossly exaggerated symptoms which are deliberately feigned to obtain medical care (factitious disorder, which is considered a mental disorder) or material gain (malingering, which is simply a behaviour, not a mental disorder) are classified separately.

There have also been important changes in the diagnostic criteria in DSM-5 [5] (Table 133.1).

Firstly, it has been recognized that it is not simply a diagnosis of exclusion—patients with this diagnosis should have specific findings on neurological examination such as Hoover’s sign of leg weakness or a positive tremor entrainment test (see Examination, p. 1352). Importantly, this allows the diagnosis to be made even in patients with a coexisting neurological disease, as long as that condition is not a better explanation for the symptom. For example, a patient

may have both epilepsy and dissociative (non-epileptic) attacks/seizures, or multiple sclerosis and functional limb weakness.

Secondly, there is a recognition that stressors are not always identifiable [6]. Sometimes this is because they only emerge later, but sometimes this may simply be because they are not present.

Lastly, the specific requirement to positively exclude feigning has been removed. While it is rarely possible to obtain positive evidence of feigning, it is arguably impossible to positively exclude it.

The World Health Organization (WHO)’s International Classification of Diseases, tenth revision (ICD-10) has, to date, preferred the term ‘Dissociative Disorder’, ‘Dissociative (Conversion) Seizures/Paralysis’, etc. Moreover, as with all ICD diagnoses, there are no operationalized diagnostic criteria.

Epidemiology

Most of the data on functional neurological symptom disorder (FNSD) are from clinical settings, rather than the general population. It has been diagnosed from early childhood to the ninth decade but is rare before the age of 10. Patients with dissociative (non-epileptic) seizures have an average age of onset in the twenties, with a second late onset group, often in relation to the development of physical disease. Patients with functional movement disorders have a mean age of presentation in the late thirties. Most presentations of FNSD occur more commonly in females, with a ratio of 2–3:1.

Patients with FNSD are commonly encountered in neurological or general medical settings. In a study of 3781 new neurology outpatients in Scotland, 16% had a primary diagnosis of a functional disorder and 6% a primary diagnosis compatible with FNSD. Patients with functional limb weakness are probably as common as patients with multiple sclerosis, with an incidence of around 5/100,000 [7]. Patients with dissociative (non-epileptic) seizures have a similar incidence of around 5/100,000 [8]. Up to 50% of patients presenting to accident and emergency with apparent epileptic status may have dissociative (non-epileptic) seizures.

Studies of FNSD have consistently found severity of disability similar to that of patients with equivalent disease [7, 9, 10], and usually a higher rate of psychiatric disorder [11]. Health care costs are also high, especially with respect to repeated investigations and referral [12].

Epidemiological factors related to aetiology and mechanisms are discussed further later in this chapter.

Table 133.1 A summary of the main changes in DSM-5 in relation to functional neurological symptom disorder (conversion disorder)

	DSM-IV	DSM-5	Comments
Motor or sensory symptom ...	✓	✓	Includes limb weakness, movement disorder, gait, blackouts, vision, speech, and hearing symptoms. Not pain, fatigue, dizziness, or memory symptoms
... causing distress or difficulty for the patient	✓	✓	
Positive physical signs of internal inconsistency or incongruity with recognized disease	✗	✓	Not a diagnosis of exclusion. Emphasizes how these disorders should be diagnosed
Patient must have an identifiable psychological stressor	✓	✗	Often not present. Therefore, many patients without stressors were previously rejected by psychiatrists
Intentional feigning must be excluded	✓	✗	This applies to all psychiatric disorders. It is impossible to exclude feigning

Clinical features

History

Patients with FNSD commonly have many symptoms, in addition to motor and sensory symptoms. These may include fatigue, pain, poor memory and concentration, sleep disturbance, and symptoms of other functional disorders such as irritable bowel syndrome or chronic widespread pain/fibromyalgia. It is therapeutically and diagnostically helpful to make a list of all the patient's symptoms at the beginning of the consultation.

Dissociative symptoms, such as derealization ('feeling disconnected/unreal/cut off/floating') and depersonalization ('my leg doesn't feel part of me'), are also common in FNSD. Patients with acute-onset functional symptoms (both motor symptoms and blackouts) often describe dissociation at the moment the symptoms began. Establishing this sequence can be particularly helpful when explaining the mechanism of symptom production to the patient or, in the case of dissociative (non-epileptic) seizures, targeting the prodromal symptoms during therapy (as for panic disorder).

Enquiry about the patient's beliefs about their illness is important. A patient sent from a neurologist with a very firm belief they have 'chronic Lyme disease' or 'multiple sclerosis' is going to require a different consultation to someone who believes they have a functional disorder. When asking about beliefs, however, it is generally best to avoid getting into an unproductive debate about whether the symptoms are neurological or psychological (since they are best considered as both). It can be more helpful to establish whether the patient sees their symptoms as potentially reversible or as a result of irreversible damage (the analogy here is software vs hardware fault), as the former is less of an obstacle to rehabilitation. It can also be helpful to ask the patient's views about what treatments they think would help them and which would not, before discussing options.

Patients with FNSD may be reticent about reporting psychological symptoms. This may be, in part, because they fear being told that all their symptoms are imagined. Therefore, rather than ask direct questions about depression or anxiety, it can be more helpful to begin the enquiry by asking about the emotional and psychological consequences of having disabling physical symptoms. Panic disorder is also common, but often not recognized as such by the patient experiencing sudden chest pain or shortness of breath with dizziness. Equally, the psychiatrist must bear in mind that the patient may have no obvious psychological symptoms. This does not necessarily mean that there is 'no psychiatric disorder' and that the patient cannot be helped; FNSD remains classified as a psychiatric disorder at the interface with neurological practice and the psychiatrist has an important role, as described in this chapter.

One psychological symptom, so-called '*belle indifférence*', requires a particular comment. This refers to a cheerful indifference to disability and has historically been viewed as a typical clinical feature of FNSD. However, modern studies suggest that while this symptom does occur, it has no discriminating diagnostic value, as it also occurs in patients with organic brain disease, especially those with frontal lobe involvement [13]. When apparently present, in our experience, it most commonly reflects an attempt to 'put on a brave face'. Persistent '*belle indifférence*' may, in fact, suggest factitious disorder, a condition that can only really be diagnosed in a neurological context by finding evidence of marked discrepancy between reported

and observed function (for example, walking normally when they said that would be impossible) or significant deception.

Examination

The assessment must address the wide range of possible neurological diagnoses that may present with the observed neurological symptoms. FNSD is not a diagnosis of exclusion; rather it depends on finding positive evidence of clinical signs, which are strongly suggestive of functional disorder (Table 133.2). The diagnosis can therefore also be made in the presence of neurological disease.

The physical signs are: (1) either to aim to find out if the symptom briefly resolves when attention is directed to another body part (for example, Hoover's sign of functional leg weakness or tremor entrainment test) (Fig. 133.1); or (2) are characteristic of a functional disorder in the correct context (for example, the new onset of a clenched fist or an inverted ankle in an adult, or a sudden episode of motionless unresponsiveness and amnesia with the eyes closed for longer than 2 minutes). Awareness of how these physical signs work puts the psychiatrist in a much better position to explain the illness to the patient. Like all physical signs, none is completely reliable on its own, although published studies have suggested they have good sensitivity and specificity.

Cognitive symptoms are common in association with other presentations of FNSD, although they are not included in the DSM-5 definition [14]. Typical positive features of functional cognitive symptoms include inconsistency between reported symptoms and ability to follow dramas on television or perform a job, difficulty with easy cognitive tasks, compared to difficult ones, ability to answer multiple-component questions, and offering of elaboration and detail regarding memory lapses. Someone with more severe functional or feigned cognition difficulties may perform badly on tests of effort in which patients should score by chance or at least above patients with severe dementia. Rarely, questions such as 'how many legs has a horse got?' may be met with an 'approximate' answer such as 'five'—the so-called Ganzer syndrome that often suggests factitious disorder or malingering.

Another distinct type of cognitive presentation is a pure retrograde or dissociative amnesia. This presents as a 'soap opera style' memory loss in which a portion of retrograde memory is missing, sometimes for years, but with normal anterograde memory. It can sometimes be associated with wandering geographical location when it is called fugue. Typically, there is loss of information about personal identity, which is rare in other amnesic disorders, although other causes such as encephalitis or epileptic amnesia should be considered.

Dizziness can also be a common functional symptom but again is not listed in the DSM5 criteria. Typically, the patient with chronic functional dizziness, now called 'persistent perceptual postural dizziness', reports a continuous sense of movement, often a 'swaying' sensation, worse on standing and walking, which can be mixed with dissociative symptoms. This usually arises after a vestibular trigger, such as labyrinthitis or benign paroxysmal positional vertigo, and becomes persistent through a complex process of abnormally focused attention and alteration of normal postural control [15]. Health anxiety and a daily routine dominated by the experience of dizziness can respond well to treatment with cognitive behavioural therapy and/or treatment with antidepressant medication.

Table 133.2 Examples of positive signs in functional neurological symptom disorder

Symptom	Positive finding of FNSD
Functional limb weakness	
Hoover's sign [44] (Fig. 133.1)	Hip extension weakness that returns to normal, with contralateral hip flexion against resistance
Hip abductor sign [44]	Hip abduction weakness that returns to normal, with contralateral hip abduction against resistance
Other clear evidence of inconsistency	For example, weakness of ankle–plantar flexion on the bed, but patient able to walk on tiptoes
Global pattern of weakness	Weakness that is global, affecting extensors and flexors equally
Dragging gait	A gait in which the forefoot remains in contact with the ground, typically with the hip externally or internally rotated
Functional movement disorder/gait	
Tremor entrainment test [45]	Patient with a unilateral tremor is asked to copy a rhythmical movement with their unaffected limb. The tremor in the affected hand 'entrains' to the rhythm of the unaffected hand, stops completely, or the patient is unable to copy the simple rhythmical movement
Typical 'functional' hemifacial overactivity [46] (Fig. 133.2)	Orbicularis oculis or oris over-contraction, especially when accompanied by jaw deviation and/or ipsilateral functional hemiparesis
Fixed dystonic posture [47] (Fig. 133.3)	A typical fixed dystonic posture, characteristically of the hand (with flexion of the fingers, wrist, and/or elbow) or ankle (with plantar flexion and dorsiflexion)
Distraction during standing [48]	Patient with an apparently positive Romberg's test is asked either to guess numbers written on their back or to carry out a complex motor task (for example, with a phone). In a functional gait problem, their balance will improve significantly
Dissociative (non-epileptic) attacks [49]	
Prolonged attack of motionless unresponsiveness	Paroxysmal motionlessness and unresponsiveness, with amnesia lasting longer than 2 minutes
Long duration	Attacks lasting longer than 2 minutes (but be careful of misleading witness histories)
Closed eyes	Closed eyes during an attack, especially if there is resistance to eye opening
Ictal weeping	Crying either during or immediately after the attack
Memory of being in a generalized seizure	Ability to recall the experience of being in a generalized shaking attack
Ictal hyperventilation	During a generalized epileptic seizure, respiration ceases, but it commonly speeds up during a non-epileptic attack
Presence of an attack resembling epilepsy with a normal EEG	Normal EEG does not exclude frontal lobe epilepsy or deep foci of epilepsy but does provide supportive evidence
Visual symptoms [50]	
Fogging test	Vision in the unaffected eye is progressively 'fogged' using lenses of increasing dioptres, while reading an acuity chart. A patient who still has good acuity at the end of the test must be seeing out of their affected eye
Tubular visual field (Fig. 133.4)	A patient is found to have a field defect which has the same width at 1 m as it does at 2 m
Speech	
Highly inconsistent speech, new-onset stuttering in an adult or telegraphic speech [51]	Patients with neurological diseases also can develop stuttering. Persistent foreign accent syndrome is often functional

Investigations

In the presence of typical clinical features, the role of investigation is primarily to seek comorbid neurological disease, rather than to refute the diagnosis. Patients with arm or leg weakness will typically require structural imaging with magnetic resonance imaging (MRI) or computed tomography (CT). The diagnosis of dissociative seizures can be greatly aided by recording a normal electrocardiogram (ECG) and electroencephalogram (EEG) during an attack (but note that some forms of epilepsy cannot be seen on surface EEG). It is the positive recording of an event with typical features of dissociative (non-epileptic) seizures that matters, rather than merely normal investigations. Smartphone footage from family and friends can be especially helpful. It should be remembered that investigations commonly reveal incidental abnormalities in the brain and spine. Such

abnormalities are found in around one in six on MRI brain scans. Disc prolapses occur in asymptomatic individuals at a frequency similar to the 'age of the patient plus 10' (for example, around 50% of 40-year olds have some disc prolapse) [16].

Psychiatric examination

A skilled neurologist should be able to make a positive diagnosis of FNSD. A psychiatric assessment has an important role in ensuring a complete history has been taken and addressing the psychiatric differential diagnosis.

It may reveal important life stressors and factors inhibiting recovery (such as an insurance claim). But it should be remembered that it is not necessary to make such a finding (or to hypothesize it) to make the diagnosis.

Test hip extension – it's weak

Test contralateral hip flexion against resistance—hip extension has become strong

Fig. 133.1 Hoover's sign of functional leg weakness.

Reproduced from *Pract Neurol.*, 9(3), Stone J, Functional symptoms in neurology, pp. 179–89, Copyright (2009), with permission from British Medical Journal.

The assessment also provides the foundation for treatment and is an opportunity to further develop a shared and positive understanding of the disorder with the patient and carer.

Differential diagnosis

The differential diagnosis of FNSD encompasses many neurological conditions and several psychiatric ones. It should usually be diagnosed by a neurologist or a specialist familiar with neurological diagnosis and a psychiatrist, working either together or sequentially.

A common pitfall in diagnosis is failure to consider the presence of a comorbid neurological disease, especially symptoms in the prodrome of a degenerative disease such as Parkinson's disease.

**Fig. 133.2** Functional facial overactivity can look like facial weakness—typically with platysma overactivity, jaw deviation, and/or contraction of the orbicularis oculis.

Reproduced from *Pract Neurol.*, 13(2), Stone J, Reuber M, Carson A, Functional symptoms in neurology: mimics and chameleons, pp. 104–13, Copyright (2013), with permission from British Medical Journal.

Misdiagnoses of neurological disease as FNSD appears especially likely in relation to an isolated gait disorder with normal examination on the bed (for example, stiff person syndrome and spastic gait from cervical myelopathy can present like this); frontal lobe epilepsy (which can look odd and present sometimes with a normal EEG); autoimmune encephalitis and other neurological disorders where there may be prominent psychiatric symptoms [17].

The psychiatric differential is anxiety and especially panic disorder, depression, obsessive-compulsive disorder, and post-traumatic stress disorder (PTSD). Symptoms of dissociation occur as part of both panic and PTSD. These disorders may be the primary diagnosis and the patient may recover with treatment for them; more often, they are comorbidities that may still require treatment in their own right.

Finally, it is important to consider the possibility that the patient is wilfully manufacturing or exaggerating their symptoms. When this is done for medical care only, it is factitious disorder, classified as a psychiatric disorder which often coexists with a personality disorder. When symptoms are manufactured for material gain only, then it is malingering, and not a psychiatric disorder. Wilful exaggeration can only be detected reliably by the presence of a marked discrepancy between reported and observed function (note that this is not the same as variability in symptoms) or by evidence of lying. Most experts seeing patients with FNSD agree that clinically significant wilful exaggeration is relatively rare outside legal scenarios. These disorders are discussed further in Chapter 132.

Aetiology and mechanism

The 'conversion' hypothesis in which symptoms of FNSD are always presumed to be a physical manifestation of the psychological effect of a recent stressor has been superseded by a more complex model. This explains the considerable heterogeneity between patients and suggests a mechanism of symptom production (Table 133.3). Many biological, psychological, and social factors appear to be relevant,

Fig. 133.3 Functional dystonia with characteristic ankle inversion and plantar flexion.

including childhood sexual, physical, and emotional abuse and neglect as predisposing factors and life events as precipitating factors. Adverse experiences like this can promote a vulnerability to dissociation and heighten the experience of threat produced by minor pathophysiological or physiological stimuli. Reviews of the relative magnitude of these factors in individual patients have demonstrated that although more frequent than in those with neurological disease and in healthy controls, they are not universal [6]. For example,

while a detailed study of life events in FNSD suggested an increase in frequency of events just prior to symptom onset, especially of the ‘escape’ type that Freud suggested, not all patients were found to have experienced severe or adverse events of any type [18].

The ‘conversion model’ of aetiology has also been unsatisfactory in explaining why someone should develop a weak arm or blackouts in relation to stress. The solution proposed was that the symptom was ‘symbolic of the difficulty’ or represented an inability to function. Systematic studies of patients with FNSD have suggested a more prosaic explanation for particular symptoms—that they are simply continuations of acute symptoms that arose for many reasons. For example, patients with dissociative (non-epileptic) seizures commonly experience transient dissociative or panic symptoms just before their blackouts [19]. Studies have supported a model in which the ‘blackout’ occurs as a response to this arousal which then becomes habitual, perhaps through classical conditioning [11]. More recently, evidence has accumulated to support the idea that physical injury or physiological states, such as migraine, commonly occur at the onset of these symptoms, which then become perpetuated via persistent abnormal attention [20, 21]. Cognitive neuropsychological models with their basis in a concept of the brain as a ‘predictive’ organ help bridge the gap between neuroscience and psychological models of this disorder and support new ways of delivering treatment [22].

Functional brain imaging of patients with FNSD has found differences between patients and volunteers pretending to have similar symptoms. In addition, functional imaging of patients in experimental hypnotic states has revealed changes similar to those seen in patients with FNSD, with hypoactivation of cortical and sub-cortical motor areas, without activation of prefrontal areas often involved in motor inhibition. Limbic areas, such as the amygdala, are also commonly overactive in comparison with controls [23]. In addition, some studies have suggested hypoactivation of a network identified with self-agency, including the temporo-parietal junction, in keeping with the notion that the movements do involve the

Fig. 133.4 In patients with functional visual loss, bedside testing may reveal a tubular field defect, which disobeys the laws of physics.

voluntary motor system, but the person genuinely does not have the sense that they are 'doing it' [24].

Neurophysiological studies have also revealed potentially intriguing differences in evoked responses between patients with FNSD and controls and also in a parameter known as sensory attenuation, which measures the person's ability to predict their own actions [25]. Interestingly, FNSD may be a paradigmatic disorder of willed action which has escaped scrutiny because of its clinical similarities to 'willed action of pretending'.

Prognosis and misdiagnosis

The prognosis is highly variable. Symptom duration may be as brief as hours or as long as years. Symptoms may be mild or severely disabling. In general, the outlook for patients with dissociative (non-epileptic) seizures is better than for patients with functional movement disorders. A systematic review of 24 outcome studies of functional motor disorder found that 39% of patients were the same or worse after a mean of 7.5 years [26]. In a review of 25 studies of patients with dissociative seizures, the total weighted remission rate was around 33% (that is, about one-third of patients' seizures stopped). While patients may still have some seizures, social and occupational functioning may improve [27]. Positive prognostic factors noted in these studies included young age (especially childhood), early diagnosis, positive reaction to the diagnosis, and short duration of illness. Negative prognostic factors reported are presence of personality disorder, somatization disorder, or ongoing litigation. Patients with poor prognostic factors can, however, sometimes respond well to treatment, and vice versa [26].

We referred earlier to the well-known follow-up study of Slater in 1965 which suggested that as many as two-thirds of patients with a diagnosis of hysteria actually had misdiagnosed neurological disease. Although methodologically flawed, mainly by selection bias, this study convinced at least two generations of psychiatrists that they

need not worry about this disorder; it was just an example of neurologists getting it wrong. However, a systematic review of 27 studies published since Slater's found a misdiagnosis rate of <5% since 1970 (interestingly, this was long before MRI scans and videotelemetry were in routine use) (Fig. 133.5). This rate of misdiagnosis is similar to that for other neurological and psychiatric disorders. Subsequent large prospective studies have also been reassuring [28], as have follow-up studies of other somatoform disorders [29].

Treatment

The treatment of FNSD should usually be multi-disciplinary. Its foundation is a plausible and agreed explanation of the diagnosis, followed by effective triage to the correct therapy (and in some cases recognizing that the patient is unlikely to benefit from therapy).

The traditional sequence of events has been for a neurologist to tell a patient there is 'nothing wrong' and then to refer to a psychiatrist who is expected to detect the psychological stressor and then treat the patient. It is hardly surprising that this process usually results in frustration for both patients and clinicians. A combined and positive approach to diagnosis is preferable.

Explaining the diagnosis

It is crucial that someone, and preferably every member of the clinical team, can deliver a coherent and consistent explanation of how the diagnosis has been made and how the symptoms can be improved with therapy.

Although there is much debate about whether the patient should be told that their illness is 'psychogenic' or 'functional' or 'conversion', it seems likely that there are other more important ingredients of a useful explanation. These include: (1) taking the problem seriously; (2) giving the problem a positive diagnostic label (rather than just telling the patient what they do not have); (3) demonstrating to the patient the rationale for the diagnosis (showing the patient their

Fig. 133.5 Frequency of misdiagnosis of functional neurological symptoms disorder/conversion disorder/hysteria in 27 studies and 1466 patients, with a mean duration of 5 years.

Reproduced from *J Neurol Neurosurg Psychiatry*, 76(Suppl 1), Stone J, Carson A, Sharpe M, Functional symptoms and signs in neurology: assessment and diagnosis, i2–12, Copyright (2005), with permission from *British Medical Journal*.

positive Hoover's sign or how their tremor stops briefly during the entrainment test, or going through the typical features of a dissociative seizure); (4) emphasizing the potential for reversibility, for example using metaphors such as software vs hardware; (5) providing written information, for example, such as that found at <https://www.neurosymbols.org> or <http://www.nonepilepticattacks.info>; and (6) triaging to an appropriate treatment.

Our personal preference for a diagnostic label is to use the terms 'functional' or 'dissociative'. For us, these are terms most consistent with the current state of our knowledge in that they allow for a bio-psychosocial model in which there can be a discussion of abnormal brain function, as well as a discussion of how symptoms may persist because of psychological 'patterns' or habits. In addition, there is the critical implication that brain function (as opposed to structural damage) can be improved by many interventions, including medication, activity, and psychological treatment.

Physiotherapy

Current evidence suggests that physiotherapy should be a first-line treatment for patients with functional movement disorders and limb weakness, as long as the patient has some confidence in the diagnosis and is motivated to change. In recent years, the nature of physiotherapy for functional motor disorders has become more clearly defined and is being tested in randomized trials. Physiotherapy techniques are based on an understanding of how symptoms in FNSD can be dependent on abnormally focused attention and tend to improve with distraction. There has been a realization that generic physiotherapy, as one would use for stroke, may, in fact, be counterproductive. Consensus recommendations have been published for the various motor symptoms with which patients present [30]. A case series and randomized controlled trial found evidence of efficacy for this approach in patients selected for their understanding and motivation. Despite a symptom duration of 5.8 years, 72% had a good outcome with specific therapy, compared to only 18% who had physiotherapy of a non-specific nature [31]. Another trial found sustained benefit from 3 weeks of inpatient rehabilitation [32]. Further studies of inpatient treatment are also encouraging [33, 34].

Psychological and psychotropic drug treatment

Psychiatric assessment and formulation have a key role to play in the management of many patients with FNSD. A bio-psychosocial formulation can put together the factors seen in [Table 133.3](#) and present them back to the patient as an explanation of what may have led to the development of their symptoms and what may now need to be addressed to achieve recovery.

Comorbid and psychiatric disorders, such as panic, anxiety, and depression, often contribute to FNSD and may need to be targeted in treatment, whether pharmacological or psychological.

A tailored cognitive behavioural therapy (CBT)—an informed guided self-help programme—was found to be better than treatment as usual for patients with a range of functional neurological symptoms in a randomized trial [35]. Another specific form of cognitive behavioural psychological therapy has been developed specifically for dissociative (non-epileptic) seizures [36, 37]. In a pilot trial of this CBT-based approach, developed from therapy for panic disorder, the number needed to treat for seizure remission was 5 [36]. This therapy involves: education about the disorder and setting of goals, teaching specific distraction techniques for episodes, learning to make connections between emotions and seizures, using graded exposure to change behaviour restricted by the events, and looking more widely, if necessary, at psychological antecedents or perpetuating factors. A large multi-centre trial is currently under way [38]. There is some evidence for a role of psychodynamic psychotherapy in other functional somatic disorders [39], but little specifically for FNSD [40].

Other treatments

Other treatments used since the nineteenth century may still have a place. Hypnosis may have some efficacy, especially in those keen to have it [41]. Electrical stimulation of the arms and legs has been used for centuries to treat patients with functional disorders but lost popularity after the First World War. More recent studies of transcranial magnetic stimulation have suggested it may have a role, especially in demonstrating reversibility of symptoms, but trial evidence is lacking [42]. Finally, abreaction and therapeutic sedation, which were used as long ago as the First World War, may still have a role for patients with fixed dystonia, mutism, or deficits, where transient improvement cannot be demonstrated using bedside manoeuvres [43]. There is, however, no specific evidence for the use of psychotropic drugs in FNSD, although they may be required to treat comorbid anxiety or depression.

Stopping treatment

While the prognosis for established FNSD is poor without treatment, we may have been too pessimistic about the response to treatment. However, not all patients can be successfully treated and it is at times useful to share this conclusion with the patient, where appropriate, emphasizing that this is something that can be revisited.

Conclusions

Functional disorders are common in neurological practice and are one of the most common reasons for referral to psychiatrists working in that setting. Significant advances over recent years have improved

our understanding of both aetiology and treatment. The modern clinical assessment emphasizes the primacy of diagnosis based on typical characteristics of the physical symptoms themselves. Joint neurological, psychiatric, and multi-disciplinary teamworking is the cornerstone of management for most patients.

Public policy and service needs in mental health

Martin Knapp

Introduction

In policy terms, mental health problems are among the most complex of all health issues, characterized by a number of pervasive challenges. Seen as a group, prevalence rates are high and onset is often relatively early in life. Most mental health problems are chronic, often with life-long negative impacts. Aetiology represents a mélange of genetic and environmental influences. People who have mental health problems will often experience stigma, discrimination, and victimization—opportunities available to other people are often closed off. Psychological well-being—to be separated from psychiatric symptoms—is often very poor for people experiencing mental illness.

There are close links between mental illness, self-harm, and suicide. There are also strong links between some mental health problems, antisocial behaviour, and crime. Consequently, most countries have legal powers of compulsory detention and treatment to protect individuals from themselves or to protect other people. Mental health problems may have other negative collateral effects, including on siblings, parents, peers in schools, and work colleagues, and perhaps also in local communities.

Responses to mental health problems are many and various, and often lead to high public sector and privately borne costs that may extend over many years. Young people with mental health problems are at above-average risk of failing to achieve their educational potential. In adulthood, there are often considerable employment-related difficulties—long spells of unemployment, high rates of absenteeism, and under-par performance when at work—which can lead to substantial productivity losses for the economy and income losses for the individual and family.

It is the combination of these often very challenging characteristics and experiences—for individuals, families, and communities—which require careful, multi-dimensional, far-sighted policy responses. Mental health policy-making that concertedly aims to address these challenges will necessarily be complex. The focus of this chapter is such policy-making. I will briefly consider the main drivers of mental health problems (in Section 2) as a platform for identifying the domains where policy action might be needed to

prevent or ameliorate illness and the distress associated with it. I will then turn to the main consequences of mental health problems, emphasizing how widely spread those consequences will often be (Section 3). Societal responses to those consequences will be discussed. The focus of Section 4 is on the main dimensions of a good mental health policy, providing some illustrations. A brief concluding section pulls together the main arguments.

Drivers of mental health problems

There are many factors that can precipitate, prolong, or reignite mental health problems, representing a set of complex interactions between genes and the environment; although some mental illnesses have high rates of heritability, there are very strong environmental effects. Age and gender are relevant factors in understanding the incidence and prevalence, and demographic trends over time can affect the patterns of mental illness and the nature of the policy challenge. Traumatic experiences, lifestyle choices, and other health problems (acute or chronic) are important, and economic conditions can play a major part. Other chapters in this book have discussed many of these ‘drivers’ in more detail, and here I briefly summarize some of them as a way to identify individual, family, and societal consequences, which, if recognized, will then often be prompts for policy action.

Three-quarters of mental health problems (except dementia) have emerged before age 24, and perhaps as many as half by age 14 [1]. Psychoses most commonly emerge in late adolescence and early adulthood, which is precisely the age when most individuals would be making key decisions that will shape the rest of their lives: finishing their education, moving away from the parental home, taking their first steps into the world of work, and having their first serious relationships. A mental health problem that is not adequately treated can have life-long personal and economic consequences. Later in life, Alzheimer’s disease and other dementias are highly prevalent; as populations age—as they are doing rapidly across the world—overall numbers of people with these disorders will grow too and will clearly need concerted policy attention, especially given that there is currently no cure.

The influences of traumatic experiences on mental health are often pernicious and persistent—experiencing war, military combat, terrorism, rape, or sexual abuse can bring on a range of mental health problems, including post-traumatic stress and depression. Bullying victimization in childhood is known to be still affecting someone's mental and physical health many decades later [2, 3], with sizeable impacts on mental health care systems.

Numerous lifestyle choices are known to affect mental health. For example, excessive cannabis use in young people is a recognized risk factor for developing schizophrenia [4]. Being breast-fed, on the other hand, can be a protective factor—not being breast-fed for very long independently predicts poor mental health during childhood and early adolescence, even after adjusting for other factors [5].

There are well-known links between other health problems and mental illness. People with long-term conditions, such as diabetes, cancer, and coronary heart disease, have above-average risks of psychiatric morbidity, which often affect how their physical health develops and is managed, with consequences for quality of life and costs [6, 7]. For example, it has been shown that the health care costs of treating 11 different chronic health problems are significantly higher when a patient has comorbid depression, while there can also be considerable impacts on workplace performance and absenteeism from work [8]. Individuals with neurodevelopmental conditions can also be at high risk; the prevalence of anxiety is as high as 42% among autistic children [9].

Economic conditions in a country and the economic status of an individual can affect mental health, and in fact, there are multiple and two-way links between economic factors and mental illness. 'Social causation' arguments suggest that core aspects of economic disadvantage, such as poverty and long-term unemployment, increase the risk of mental illness by initiating or exacerbating financial stress (particularly unmanageable debt), social exclusion, stigma, and poor diet, and also by undermining protective factors such as social capital, education, and personal resilience. An alternative explanation is the 'social selection' or 'drift' argument that people with mental health problems have higher risks of remaining or falling into poverty because of the (privately borne) costs of their treatment, disrupted employment, and reduced earnings [10]. A general economic recession, such as the recent global financial crisis, can have profound effects on employment, job security, productivity, earnings, and social cohesion, with knock-on effects on mental illness, as shown most immediately by suicide rates [11].

Consequences and societal responses

Most mental health problems are complicated and distressing. They can cause temporary incapacity, abject misery, self-loathing, and personal shame, and lead to public stigma and discrimination in many different settings. They can prompt violent behaviour, self-harm, and suicidal ideation, causing societies to impose restrictions on individual liberty because of assumed or confirmed incapacity or dangerousness. They are associated with poor health behaviours and premature mortality. But there may occasionally also be some positive aspects; a mental illness may give an individual new insights, help them to embrace change, or energize their creativity. Overwhelmingly, however, the negatives outweigh any positives.

This wide-ranging mix of (largely negative) consequences also makes mental illness look 'economically expensive' in the sense that scarce resources must be devoted to respond to them, often over long periods of time. As a result, decision-makers in health and other systems must think carefully about how they use the resources under their control in order to meet needs and preferences associated with mental illness or—better still—how these illnesses can be prevented in the first place.

Economic and social exclusion

As already noted, people with mental health problems have above-average rates of economic difficulties, particularly linked to employment (especially finding and keeping a job, and chronic unemployment), rent and mortgage arrears, other unsecured debt, low earnings, low household income, poor social networks, loneliness, and social isolation [12].

An authoritative commentary on some of these issues from the Organisation for Economic Co-operation and Development (OECD) drew on national statistics and robust studies [13]. It illustrated the multifarious links between mental health problems and work; people who have experienced mental health problems find it harder to acquire and retain paid employment, have higher rates of absenteeism and presenteeism (reduced productivity when at work because of symptoms), earn lower salaries, and are more likely to take early retirement [14]. The typical age of onset of serious mental health problems often prevents individuals from completing their education. For most people, employment is their primary source of income, and so long-term employment difficulties can propel people into unmanageable personal debt and poverty, which, in turn, can worsen mental health [15]. Employment is, of course, more than just a source of income—it influences social position and community roles, fosters social participation, and, for many people, is a key source of self-concept.

At a national level, these employment difficulties damage productivity and economic growth. For example, a study in eight very different countries found that the extent and costs of depression-related absenteeism and presenteeism in the workplace were considerable, both in absolute monetary terms and in relation to the proportion of the country's gross domestic product (GDP). Absenteeism had a large impact across all countries, but the costs associated with presenteeism were 5–10 times higher [16].

Employment issues mean that many individuals with mental health problems are reliant on social security (welfare) payments. The OECD report cited earlier found that between one-third and one-half of new disability benefit claims in the countries they studied were made for reasons connected to mental illness. Benefits systems need to be designed so as to provide appropriate compensation, but not to make people feel trapped—anxious, perhaps, about losing their benefit entitlements if they 'take the risk' of moving into a paid job that might prove stressful and reignite an otherwise stable condition. But benefits systems that leave people at risk of poverty could create a different kind of downward spiral—their economic circumstances could exacerbate their symptoms, which then make it harder to secure employment and lead to further social and economic exclusion. If an individual struggles to keep up their rent or mortgage payments, then homelessness might even be the result [17].

Crime

If not treated effectively, some mental health problems can result in either antisocial or violent crime [18–20]. Drug and alcohol misuse might prompt acquisitive crime, as individuals seek to find the resources to purchase their substance of choice, and there are also associations between such misuse and violent crime. Conduct disorder—the most common childhood psychiatric disorder, with a UK prevalence of 4.9% for children aged 5–10 years [21]—is associated with antisocial behaviour (and substance misuse) in adolescence and criminal activity in young adulthood, with high costs for both criminal justice bodies and victims. Indeed, an 18-year follow-up study in London found that these crime-related costs dominated all other economic consequences of conduct disorder [22]. However, people with mental health problems are also at above-average risk of being *victims* of crime, particularly violent crime [23].

Self-harm and suicide

According to the World Health Organization (WHO) [24], globally there are more than 800,000 suicides each year, each of them potentially preventable. Suicide and self-harm are major public health issues, and because there are links with mental health problems (especially depression, eating disorders, and alcohol misuse), some governments have included suicide prevention strategies within their mental health policy frameworks. Generally, however, WHO argues that insufficient strategic attention is paid to suicide prevention. Another obstacle is the taboo surrounding suicide. Suicide is one of the priorities in the WHO Mental Health Gap Action Programme (mhGAP) launched in 2008 in low- and middle-income countries. In high-income countries, there is strong evidence that economic difficulties are associated with higher suicide risks. For example, the global financial crisis led to significantly higher suicide rates, particularly for men [25], and an earlier recession in South Korea widened income-related inequalities in depression and suicidal behaviour, especially in lower-income groups [26]. Some authors have further argued that government ‘austerity’ measures have exacerbated the situation [11].

Premature mortality

It is not only suicide rates that are higher for people with mental health problems; premature mortality for other reasons is another major challenge [24]. This is particularly so for people with more severe (schizophrenia, bipolar disorder, and moderate to severe depression). Life expectancy for people with schizophrenia is 20 years lower than for the general population [27], while for people with depression, the risk of death is 1.8 times higher than for the general population. Cardiovascular disease and type 2 diabetes are quite prevalent among people with schizophrenia, and other physical health problems commonly experienced by people with mental health problems that can shorten their lives include respiratory diseases, hypertension, and infectious diseases such as HIV, hepatitis, and tuberculosis.

Many of the reasons for poor physical health and premature morbidity are not hard to identify, linked to lifestyle, poor health behaviours, and, to some extent, the side effects of treatment. Tobacco use is high [28]. Obesity is also an issue, linked to poor diet [29], physical inactivity, and weight gain brought on by some medications (particularly some antipsychotics) [30]. Infectious diseases, such as

HIV and hepatitis, are more common among people with mental health problems, linked to socio-economic disadvantage and behaviours such as intravenous substance abuse. The symptoms of mental illness might make it hard for individuals to seek medical treatment, and social isolation and homelessness will add to the barriers. Stigma and discrimination associated with severe mental illness might also result in poorer physical health care. Every one of these risk factors is, in principle, preventable and ought to be part of any mental health policy strategy.

Transmitted impacts on the family and others

The negative effects of mental health problems can be experienced by people other than the person with the illness. One obvious transmitted effect is the ‘burden’ of being a family carer; for example, supporting someone with moderate to severe dementia can be stressful, with a high risk of anxiety or depression [31], as well as requiring out-of-pocket payments for services and transport costs and missing opportunities for paid employment or social activities [32]. On the other hand, good family care for someone with dementia can greatly improve their well-being and delay nursing home admission [33]. Supporting someone with schizophrenia can be distressing and costly, and the effects on parents of a child with externalizing behavioural problems, such as conduct disorder, can be considerable [34]. Postnatal depression can affect the birth-child’s emotional, behavioural, and intellectual development, with attendant long-term economic consequences [35]. Attention-deficit/hyperactivity disorder can affect classmates at school, work colleagues, and members of the local community [36].

Stigma and discrimination

Stigma and discrimination are deep-rooted, pervasive challenges. The consequences for individuals include social isolation, bullying in schools, discrimination in the workplace, active hostility or neglectful indifference in communities, and a consequent reluctance on the part of mentally ill individuals to seek the help they need [37]. Evidence from a seven-country European study in workplaces showed that managers’ attitudes, employers’ policies on flexible working arrangements, and national benefits systems can have significant effects on individuals with lived experience of mental illness [38]. Negative attitudes can have serious knock-on effects on health, especially mental health, quality of life, access to opportunities, services, and welfare entitlements [12]. Stigma may stem from lack of awareness but often reflects a more insidious suspicion and hostility. A mature mental health policy framework will include concerted anti-stigma efforts, as well as intervention to tackle discrimination and victimization.

High and wide-ranging costs

As is already clear, mental health problems generate high and wide-ranging costs, not only for the health care system, but also for public and other agencies responsible for welfare benefits, social care, education, employment, criminal justice, and other systems. There can be substantial productivity losses associated with mental illness; indeed, the costs of unemployment, absenteeism, and presenteeism tend to dominate any service-related costs. For some disorders, such as dementia, the costs directly or indirectly borne by the family and other carers are, in aggregate, larger than the costs of health and social care services that people with dementia will use [39]. Many

childhood disorders will continue to generate substantial private and public costs many decades later, in terms of employment disruption [40] and earnings, criminal behaviour, and high use of health services [41].

Policy dimensions

What is a mental health policy?

According to the WHO, 'A mental health policy is an organized set of values, principles and objectives for improving the mental health and reducing the burden of mental disorders in a population. It defines a vision for the future and helps to establish a model of how action should be taken' [42]. Typically, a policy document will range over a number of key domains, responding to the kinds of challenge and negative consequences described in the previous section. These could include: human rights and advocacy; financing (such as taxation or insurance); payment mechanisms for providers (such as fee-for-service or capitation); organization and co-ordination of services within the health care sector and across other sectors; prevention of illness and promotion of well-being; treatment and rehabilitation interventions, including access to medicines and other services in different country contexts; quality of services and performance monitoring; information systems; recruitment, training, and retention of skilled human resources; and commitment to research and evaluation.

A recent example can be given from England—a comprehensive policy framework from the 2010–2015 Coalition government (**Box 134.1**) [43]. More recently, an independent Taskforce was commissioned by NHS England. Its report summarized developments in mental health treatment in England over recent decades and set out a number of 'priority actions' for the National Health Service (NHS) for the next 5 years [44].

Financing

There are numerous reasons why a formal mental health policy is needed. There are too many distressing, damaging, and durable consequences for any civilized society to ignore. There are collateral damages for communities and the national economy. Another reason is that families cannot be left to address the issues alone, and there is only so much that relatively informal, locally initiated, and sustained community action can go. There is often market failure, which manifests itself in policy terms in an emphasis on *collective* responsibility for managing, delivering, and/or financing mechanisms.

Most high- and middle-income countries—and gradually a number of low-income countries—rely on prepayment systems of revenue collection as the basis for financing health care. In those countries, the most common methods of financing are tax-based (37% in OECD countries), mandatory (social) insurance (36%), out-of-pocket payments (19%), and voluntary (or private) insurance (6%) [45]. Prepayment through social health insurance, private health insurance, or taxation is preferable to out-of-pocket payments because each individual's need for health care is uncertain, but when that need arises, it can generate enormous (perhaps 'catastrophic') economic impacts in terms of treatment costs and lost earnings.

Box 134.1 Closing the Gap: Priorities for Essential Change in Mental Health (UK Government, January 2014)

This policy document set out 25 priorities for change in how children and adults with mental health problems should be supported and cared for:

- 1 High-quality mental health services with an emphasis on recovery should be commissioned in all areas, reflecting local need.
- 2 We will lead an information revolution around mental health and well-being.
- 3 We will, for the first time, establish clear waiting time limits for mental health services.
- 4 We will tackle inequalities around access to mental health services.
- 5 Over 900,000 people will benefit from psychological therapies every year.
- 6 There will be improved access to psychological therapies for children and young people across the whole of England.
- 7 The most effective services will get the most funding.
- 8 Adults will be given the right to make choices about the mental health care they receive.
- 9 We will radically reduce the use of all restrictive practices and take action to end the use of high-risk restraint, including face-down restraint and holding people on the floor.
- 10 We will use the Friends and Family Test to allow all patients to comment on their experience of mental health services—including children's mental health services.
- 11 Poor-quality services will be identified sooner and action taken to improve care and where necessary protect patients.
- 12 Carers will be better supported and more closely involved in decisions about mental health service provision.
- 13 Mental health care and physical health care will be better integrated at every level.
- 14 We will change the way frontline health services respond to self-harm.
- 15 No-one experiencing a mental health crisis should ever be turned away from services.
- 16 We will offer better support to new mothers to minimize the risks and impacts of postnatal depression.
- 17 Schools will be supported to identify mental health problems sooner.
- 18 We will end the cliff edge of lost support as children and young people with mental health needs reach the age of 18.
- 19 People with mental health problems will live healthier lives and longer lives.
- 20 More people with mental health problems will live in homes that support recovery.
- 21 We will introduce a national liaison and diversion service so that mental health needs of offenders will be identified sooner and appropriate support provided.
- 22 Anyone with a mental health problem who is a victim of crime will be offered enhanced support.
- 23 We will support employers to help more people with mental health problems to remain in or move into work.
- 24 We will develop new approaches to help people with mental health problems who are unemployed to move into work and seek to support them during periods when they are unable to work.
- 25 We will stamp out discrimination across mental health.

Prepayment systems pool risks, thereby potentially redistributing benefits towards people with greater health needs, and can also be made progressive, so that poorer individuals pay less than wealthier people for equivalent access to health care. Obstacles to the use of prepayment mechanisms in low-income countries include the state of the economy, unstable governance structures, and the informality of much employment, making revenue collection impracticable.

Financing arrangements for *mental health* services vary considerably from country to country, with out-of-pocket payments (which are both inefficient and unfair) still dominating in most low-income countries [46], but actually still fairly common in some other countries [47]. As far as mental health systems are concerned, almost every country has a mix of public and private funding. Mental and physical health care needs are generally not treated with parity [48]; some insurance or managed care arrangements exclude mental health coverage in an attempt to cap expenditure, but this will then have predictably undesirable consequences for access, knock-on costs, societal inefficiencies, and inequity [49]. The so-called Obamacare in the United States (centred around the Affordable Care Act 2010) made important breakthroughs in expanding access to health insurance, including mental health coverage [50], and illustrates well the need for strategic policy efforts to be made to address financing issues.

The revenue collected from taxes or insurance premiums reaches service providers via various *commissioning or purchasing* routes. Provider reimbursement can be retrospective (such as fee-for-service) or prospective (capitation and fixed budgets). Fee-for-service arrangements encourage productivity but also perversely encourage resource consumption through unnecessary visits, diagnostic investigations, and hospitalization ('supplier-induced demand') and so can push up overall costs. Prospective payments are therefore increasingly being used to encourage cost-consciousness among providers. Capitation is a fixed payment for a defined set of benefits (treatments or health gains). It encourages efficiency but has some risks, including adverse selection and cream-skimming (where providers have no incentive to treat 'complicated or expensive' patients), which could shift costs onto other providers or sectors or lead to undertreatment [51]. A commonly used mode of prospective payment is by case-mix, for example using diagnosis-related groups (DRGs)—patients are categorized by clinical diagnosis and treatment process and a standard payment is made to the provider. DRG-based pricing is not always straightforward to implement in mental health contexts.

Prevention and risk reduction

Reducing the number of people who develop mental health problems and delaying or avoiding relapse and symptom exacerbation must surely be high policy priorities—to head off or reduce distress and suffering for individuals and families, and potentially avoid substantial future streams of expenditure and productivity losses. Prevention and early intervention therefore figure prominently in many policy frameworks and may require action outside the health sector. Such actions can be highly effective and cost-effective, as the following examples illustrate.

Postnatal depression (PND) has high prevalence but is often undiagnosed and untreated. The effects for women and their children can be considerable. A recent systematic review looked at a range of interventions developed to prevent PND [52], finding a number of

beneficial interventions, including midwifery-redesigned postnatal care, person-centred approaches, and cognitive behavioural therapy—which are intended to be universal—as well as some interventions targeted on high-risk women such as interpersonal psychotherapy (IPT). The study also compared interventions in terms of cost-effectiveness, compared to usual care, and although there was uncertainty about what might be the 'best buy', the accumulated international evidence clearly shows how prevention can have considerable benefits for mother and child and make economic sense.

School-based interventions can also be effective at preventing some mental health problems and also cost-effective such as those that aim to develop social and emotional development [53], build resilience and thereby reduce the risk of later depression [54], or instil positive behaviours to reduce tobacco use and improve well-being [55].

Suicide prevention is possible, but complex. The WHO recommends reducing access to the means of suicide (pesticides, guns, certain medications), more responsible media reporting, policies to reduce alcohol misuse, early identification and treatment of people with mental or substance use disorders who could be high risk, training of health workers to recognize, assess, and manage suicidal ideation, and follow-up support for people who have attempted suicide [56].

Another area where there is good evidence of the potential for risk reduction is in relation to dementia. Mid-life risk factors for developing Alzheimer's disease and other dementias in late life are physical inactivity, smoking, diabetes, hypertension, obesity, depression, and lower educational attainment [57]. These risk factors are clearly interconnected, but even after adjusting for correlations, almost a third of Alzheimer's disease cases might be 'attributable' to risk factors that are potentially modifiable [58].

Effective treatments

An obvious element within any policy framework would be to ensure that effective treatments are available to people who are ill. There is not a bottomless pit of resources, however, and so a policy framework will also need to be clear about how to prioritize needs and target treatments and ensure that resources (public and private) are not wasted on treatments that are ineffective or expensive, relative to their outcomes. The extent to which a mental health policy engages in the details of prioritization, targeting, evidence generation, or cost-effectiveness recommendation depends heavily on a country's overall political approach to health policy. In England, with its central 'command-and-control' NHS, policy documents in mental health and other areas have often been quite prescriptive about the treatments to be delivered and the people who should receive them. In contrast, the health system in the United States is dominated by the private decisions of citizens (for example, in relation to the insurance plan they purchase), the independent case-level decisions of clinicians, and state-level decisions about priorities and funding generosity.

In England and Wales, much of the responsibility for evidence appraisal and prioritization has been devolved by the government to the National Institute for Health and Care Excellence (NICE). With its thorough technology appraisals and its transparently developed clinical guidelines, NICE aims to help individual clinicians and other professionals to choose the best treatments, defined as those of proven effectiveness and also cost-effectiveness in the context

of NHS structures and resources. Some other countries also have health technology appraisal (HTA) mechanisms, varying in structure from country to country and leading to variation in decisions too [59].

One of the most impressive policy initiatives of recent years in some countries has been the closure of the old psychiatric asylums. In most European countries, and for many decades, large mental institutions dominated the landscape. Although originally built with some good intentions (to group people together to make best use of scarce skilled professionals, achieve economies of scale, and protect vulnerable individuals), these asylums were also convenient ways to allow families to hide away their 'disturbed' or socially embarrassing relatives and, in some countries, were instruments of political oppression. Many institutions provided appalling, abusive care, breaching internationally accepted human rights [60]. Where evaluations have been conducted, they demonstrated clearly the *potential* to replace institutional care with good-quality community-based care, so long as it is adequately funded [61].

There are areas where effective treatments are simply not reaching people who need them and where mental health policy has failed. Youth mental health is one area where there is an enormous treatment gap in many countries, with people aged 16–25 with mental health problems having low contact rates with services. Another failure is the frequent neglect of the physical health needs of people with mental health problems, leading to significantly truncated life expectancy. A third example of common policy failure is in relation to dementia where evidence on interventions is now accumulating rapidly [62], but where few countries have yet pulled together a coherent overall strategy, although with some notable exceptions [63]. But even these failings pale into insignificance when compared to the huge mental health treatment gap in most low-income countries of the world [64]. The WHO's mhGAP initiative mentioned earlier seeks to scale up services for mental, neurological, and substance use disorders for all countries.

Because mental health problems often affect families and other community members, a policy framework should include attention to the needs of family members, especially if they are regular (but unpaid) carers. Some countries have already developed formal carer strategies.

Treatments are not necessarily delivered only through the health care system, as conventionally defined, but could be delivered in schools and colleges, workplaces, prisons, and community services.

Tackling inequity

There will always be inequalities, but not necessarily all of them are unfair. Inequality and inequity are not the same; the latter refers to an allocation of resources or responsibilities that is deemed to be unfair by reference to some external criteria, such as a decision-maker's preferences or society's agreed priorities, while inequality simply describes the difference between two or more things. According to the WHO, 'Equity is the absence of avoidable or remediable differences among groups of people, whether those groups are defined socially, economically, demographically, or geographically' [65].

What is meant by 'fair' is a value judgement, and hence likely to be reflected (though perhaps implicitly) in political statements or positions. Most people would probably agree that it would be equitable to allocate more treatment resources to people with greater needs, and fewer resources to people with less needs. But there might not

be such ready agreement that it is equitable for poorer individuals to pay less for their treatment than wealthier individuals; not everyone supports redistributive policies of this kind.

It is abundantly clear from many studies that the risk of mental illness is not equally or fairly distributed across the population, and neither is access to effective treatment. Socio-economic status plays a big part in these unequal distributions. Both absolute and relative poverty affect the development of emotional, behavioural, and psychiatric problems [10, 66]. It is not only socio-economic status that can influence incidence, prevalence, and treatment, but also race, ethnicity, gender, age, language, religion, sexual preference, and place of residence [67].

As noted earlier, there is a vicious cycle linking mental illness with social and economic disadvantage. For any mental health policy to be successful, it must surely find ways to break into that cycle. It needs to ensure that effective treatment and support are accessible to everyone, regardless of individual characteristics, social position, or the ability to pay. It should support efforts to build resilience and invest in mental health literacy. It needs to support wider efforts to tackle poor housing, unequal access to education and employment, and basic material poverty. It must protect and promote human rights [68]. In countries without prepayment financing mechanisms (tax- or insurance-based) or where such arrangements are only affordable by the wealthy, introducing funding reform would make an enormous difference to access and better mental health [46].

Opportunities, choice, and control

When people with mental health problems were contained in large, remote asylums, they were denied the most basic of liberties and rights, often for many decades. A prominent feature of most mental health policies today is to broaden the range of opportunities that are available, tackling the endemic inequities that damage so many people's lives. Indeed, there are a number of different, but connected, themes that feature in policy discussions today, including opportunities, choice, control, personalization, and recovery.

One important area is employment; creating better opportunities and breaking down attitudinal barriers can help to socially integrate someone with a history of mental health problems, make them economically independent, and potentially head off exacerbation of their illness. Widening choice is seen as intrinsically desirable; it leads to greater autonomy and arguably better well-being. Giving people more choice and control over their lives, including the support services they use, can benefit both health and well-being and also prove cost-effective. Experiments in England in devolved funding through personal budgets for social care and continuing health care achieved encouraging results [69, 70].

The concept of recovery—not in the clinical sense of symptom alleviation or cure, but in a broader, personal sense—is attracting growing attention. It is associated particularly with arguments propounded by Bill Anthony some years ago:

'[Recovery is] a deeply personal, unique process of changing one's attitudes, values, feelings, goals, skills, and/or roles. It is a way of living a satisfying, hopeful, and contributing life even with limitations caused by illness. Recovery involves the development of new meaning and purpose in one's life as one grows beyond the catastrophic effects of mental illness.' [71]

The top priority in the English government's 2014 mental health policy statement was 'High quality mental health services with an emphasis on recovery should be commissioned in all areas' (Box 134.1). Specific recovery-focused initiatives might include peer support arrangements, opportunities for self-managing treatment, supported employment, advice on welfare entitlements and how to manage debt, advance treatment directives, health promotion, personal budgets, and recovery colleges [72].

Attitudes and discrimination

At a strategic or societal level, policies are needed to raise awareness of mental illness, improve knowledge about prevention and treatment, tackle prejudice and stigma, and directly combat discrimination. In terms of individual experience, policies are needed to stamp out bullying and victimization. In these ways, it is hoped that there will be a number of gains—more supportive attitudes will lead to less treatment avoidance by people experiencing poor mental health, and so fewer delays in their taking up appropriate treatment, and hence better health and well-being. National anti-stigma programmes have been successful [73] and can be cost-effective [74]. More targeted anti-bullying interventions can certainly help too.

Co-ordinated action

Policy intentions and actions must be co-ordinated, given that people with mental health problems, especially if severe or enduring, often have needs that span a number of different service systems. Their needs could require action and support from health, social care, education, housing, employment, welfare benefits, criminal justice, and other systems, and these will need co-ordination to ensure that vulnerable people do not 'fall through the cracks.' A mental health policy therefore needs to include a strategy for bringing together the various local, regional, and national bodies and processes that are involved, directly or tangentially, in supporting individuals and families. It needs to resolve funding issues (especially given the propensity for silo-budgeting), co-ordinate assessment procedures, and agree on both short-term and longer-term objectives. Co-ordination is needed not just across the public sector, but also with non-public entities such as employers, schools, and community groups.

Concluding comments

As noted at the outset, mental health problems represent or combine a number of complex issues and characteristics. Incidence is commonly early in life, and prevalence of many conditions is enduring over much of the life-course. The distress associated with mental illness can be immense, and there can be adverse consequences for family members and friends. People with severe and enduring problems may face enormous difficulties in securing and retaining paid employment. Many will face discrimination in employment and other areas of everyday life: education, participation, citizenship, and access to community resources. It is still common in many countries today for people with mental health problems to be locked away in large institutions that deny basic human rights and offer little active treatment. People with mental health problems have shorter lives because of their poor physical health, due in large part to their lifestyle, and they are at much higher risk of self-harm and suicide. The symptoms of illness or needs for material resources may lead a

minority of people to commit violent or acquisitive crimes. All societies have the legal powers to compulsorily detain and treat people.

The policy challenges of mental illness therefore are many and huge. A policy framework needs to recognize the complex aetiology of illness and respond to the wide range of individual, social, and economic impacts that often follow. It also needs to tackle some wide inequalities, many of them representing gross inequities in individual experiences and opportunities. Commitment to social justice should be a core part of any mental health policy.

A good mental health policy would invest significant resources in prevention and risk reduction and ensure timely diagnosis and early intervention. It would include a strategy for developing, delivering, and ensuring access to effective and cost-effective treatments. Parity with physical health treatment is essential. Barriers to treatment and services need to be removed, whether due to ignorance, inability to pay, funder prejudice, or provider discrimination. The symptoms of an illness may themselves contribute to access difficulties.

A good mental health policy would adopt a life-course perspective, intervening early enough to prevent more serious symptoms and their consequences. It would promote co-ordinated multi-sector efforts to identify, assess, respond, and fund appropriate actions. Families and communities may need to be involved in some decisions and may themselves have needs that should be addressed. But through it all, the individual with a mental illness should be at the centre and should be given as many opportunities and as much choice and control as is possible and appropriate, given their circumstances and state of health. Finally, a good mental health policy should include ongoing commitment to change societal attitudes to mental illness, promoting recovery in its modern interpretation.

Planning and providing mental health services for a community

Tom Burns and Tony Kendrick

Introduction

The aim of this chapter is to assist clinicians and managers review and plan services effectively for their local population. Severe psychiatric disorders manifest themselves in social relations and often disrupt social structures; they have wide-ranging consequences, so services need to be comprehensive, providing both health and social care. Neither can be ignored in the wider context of their management.

Planning mental health services rarely starts with a clean sheet. Where there is one, Tansella and Thornicroft's 'matrix' model [1] is a particularly thorough and structured guide. It outlines service principles and needs assessment (at national, regional, and local levels) through to monitoring the cycle of planning and provision. Their hierarchical approach reflects the level of spend [2]. Case identification and outpatient treatments in primary care are the priority for low-income countries, and only with increased resources the establishment of a secondary care mental health service [usually a form of generic community mental health team (CMHT)]. Not until these are well established are specialist and inpatient services indicated. This process must, however, take account of what is already in place.

The range of spend and local cultures in mental health services is enormous, and attempting to address all of these would result in a series of unhelpful generalized statements. In this chapter, we will focus on the UK because it is an example of a relatively coherent, developed system with a culture of research. The specificity of many of the descriptions should not be interpreted as a prescription, but as a platform for local consideration and decisions.

Mental health services research

The last 40 years have seen an explosion of mental health services research, alongside the shrinking and closure of mental hospitals (see Chapter 134). The research agenda is disproportionately anglophone, testing innovative alternatives to institutional care. More routine practices, crucial for safe and effective care, have been relatively neglected.

Scope of chapter

This chapter will describe the essential components of a mental health service. It will cover how they relate to one another, how they are linked into other essential services, and how their evolution should be monitored. Services for adults of working age (18–65 years) will be used as template. In many settings, these may be the only services. In better-resourced systems, a range of specialized services have evolved which are described elsewhere (see Chapter 138).

Prevalence of mental illness within the community

Mental illnesses are common, and it is estimated that around 25% of people will suffer from a mental disorder at some point in their lives. However, most of these people will not see a psychiatrist. A useful starting point in service planning is to use any available prevalence figures to estimate the number of people with particular conditions in the community. In the UK, the periodic national Psychiatric Morbidity Survey [3], run by the UK Office of National Statistics (ONS), revealed the following prevalence of disorders among adults in England in 2007 [according to the criteria of the World Health Organization's *International Classification of Diseases*, tenth revision (ICD-10)] [4]:

- Mixed anxiety and depression, 9.7%.
- Generalized anxiety disorder (GAD), 4.7%.
- Depressive episode, 2.6%.
- Phobia, 2.6%.
- Obsessive–compulsive disorder (OCD), 1.3%.
- Panic disorder, 1.2%.
- Psychotic disorders (including schizophrenia and bipolar disorder), 0.5%.

In the UK, the first six of these disorders are termed common mental health disorders (CMHDs), and the last severe (or serious) mental illness (SMI). The overall prevalence of CMHDs, which are not mutually exclusive, was found to be 17.6% [3], while the

prevalence of SMI was likely to have been underestimated by the community survey, and other estimates range between 0.5% and 2%, with higher rates found in the inner city [5].

Treatment in primary care

In the UK, around 70–80% of people with CMHDs are treated only in primary care by general practitioners (GPs), usually with SSRI antidepressants [6], while 10–15% are referred, or refer themselves, for psychological therapies offered by the Improving Access to Psychological Therapies (IAPT) programme [7]. That means only the remaining 5–10% of people with CMHDs receive care from multi-disciplinary mental health services, although they will be the most severely affected people. GPs may also be involved in the mental health care of people with SMI in the UK, although the majority, at least two-thirds, will be receiving care from mental health services [8].

This means at any one time, around 15–20 adults per 1000 will be in contact with mental health services in the UK, of whom the large majority will be suffering from SMI. It also means that a relatively small increase, of say 5%, in the proportion of people with CMHDs referred from primary care to mental health services would increase the workload of those services by around a third to a half!

Referral from primary to secondary care

Ideally, there should be a clear understanding between psychiatrists and their local GPs, to ensure that only the more needy patients who really require a specialist opinion are referred. **Box 135.1** lists suggested referral criteria for patients with depression.

Agreeing referral criteria like these, however, does require the psychiatrist to accept referrals which meet them. The psychiatric team needs to offer treatments which are not usually provided by the GP, including intensive support with or without hospital admission, electroconvulsive therapy (ECT), prophylactic lithium or other mood stabilizers, etc. Simply prescribing another antidepressant and returning the person to their GP's care is not an adequate response to a GP who has already tried three courses of antidepressants combined with psychological therapy.

Building blocks of secondary mental health services: care and treatment

Most mental health treatments (whether psychological, pharmacological, or social) involve face-to-face interviews and require no

sophisticated equipment. Asylums provided social care, protecting disabled individuals while they recovered and, sometimes, protecting society from them. Patients needing long-term institutional care are now very few, but psychiatry is still judged on how they are cared for and services must pay them due attention.

Inpatient beds

No comprehensive service can survive without access to 24-hour nursing supervision for acute episodes of severe illness. They are needed for patients at risk from neglect or suicide, usually lacking sufficient insight to co-operate with treatment. Wards usually accommodate 10–20 patients. It is rarely possible to effectively staff and run stand-alone units of fewer than 3–4 such wards (30–60 beds). Ward size is a trade-off between privacy and domesticity against safety and effective supervision. Single rooms afford privacy and, while initially expensive, improve flexibility and reduce conflict.

Smaller, more flexible units, such as 'crisis houses', offering 24-hour care are a useful complement to inpatient wards, but not an effective replacement. Ward design and management are increasingly crucial as improved community care means that inpatients are mostly involuntary and highly disturbed.

How many acute beds?

'How many beds do we need for our local population?' is often the first question asked by planners or managers. Unfortunately, there is no reliable or precise answer to this. Supply will drive use (perceived as need) and beds are rarely left empty despite enormous variation in their availability. International comparisons are complicated by differences in methods of reporting and a profusion of overlapping ill-defined local terms (for example, night hospitals, crisis homes, step-down wards). Levels of hostels and day care also impact the need for acute beds, which reduces as community services become more comprehensive.

European provision of general acute mental health beds in the public sector in the early 2000s ranged from 64 beds per 100,000 in Germanic settings to 6 per 100,000 in Italy and Spain [9]. However, these figures tell us relatively little unless we know the levels of private and social services care provision. In the UK, with little parallel private care, overall provision has shrunk by 62% between 1988 and 2008 [10].

Current low bed usage in the UK reflects recently established home treatment and crisis resolution teams and the expansion of forensic care, but also a shift in practice. The duration for admissions has steadily reduced over the last four decades. Mean durations are heavily skewed by short (1- to 2-day) crisis admissions, but patients with uncomplicated psychotic relapses usually stay between 3 and 6 weeks.

Longer inpatient care

Acute inpatient wards are designed to admit patients for weeks or, at most, a couple of months, with rapid discharge anticipated, but some patients require longer or more secure care because of either illness severity or legal restrictions. Modern long-stay and rehabilitation

Box 135.1 Indications for referral of patients with depression

- Poor response to antidepressants (three different drugs sequentially) and psychological therapy (if available).
- Recurrent episode within 1 year of last episode.
- Self-neglect.
- Postnatal depression.
- Assessment for possible bipolar disorder.
- Suicidal ideas and plans (urgent referral).
- Psychotic symptoms (urgent referral).

wards are essentially restricted to patients with behaviour that is persistently unacceptable to local communities. Forensic and secure services are usually a regional or national, rather than local, responsibility.

Diagnosis-specific wards

Alcohol and substance abuse wards are common in much of Europe, and diagnosis- or disorder-specific wards in academic services. Specialized wards for patients with anorexia nervosa or resistant schizophrenia provide highly specific regimes, but usually alongside acute admission wards, rather than as an alternative. Some services now organize wards by care pathway clusters (for example, a psychosis unit, an affective disorders ward), instead of general wards. Such specialization is still experimental and not particularly feasible in comprehensive services for smaller populations, as they reduce flexibility and absorb energy in 'boundary disputes'.

Day care

Day care is provided either in day hospitals or in day centres. The two terms and their practices overlap and vary enormously. Attendance generally ranges from half a day to 5 days a week, and many now remain open in the evenings and at weekends.

Day hospitals are provided by the health service, include medical and nursing staff, and provide treatments such as medication and psychotherapies. They figured prominently in the plans to move to district general hospital psychiatry. However, their role shrank as CMHTs expanded, taking over much of their anticipated role. Day hospitals were scaled down or even closed, shifting ongoing support to social services day centres. However, they have recently been re-invigorated as a key ingredient in home treatment teams.

Day centres, provided by social care organizations, do not usually provide complex treatments or employ clinical staff. However, their practice is highly specific to local context. A drop-in day centre may provide psychiatric assessment and treatment in deprived areas with high levels of homelessness. Generally, day centres provide long-term social support, and day hospitals focused interventions and treatments [11]. The 'Club House' is a specialized rehabilitation day centre, popularized in the United States, where members run the centre with minimal supervision.

Acute day hospitals in Europe and partial hospitalization in the United States have been trialled as alternatives to inpatient care [12] but did not catch on, although they have been recently revitalized as bases for crisis resolution teams. Specialized therapeutic day hospitals serve specific groups such as personality disorders [13] or eating disorders. Day care is problematic in rural settings, but adaptations such as travelling day centres or open days run by CMHTs have all been tried successfully.

Supported accommodation and residential care

Many patients can only survive outside hospital with support and supervision to ensure self-care and continued medication and to anticipate and defuse crises. This can be provided by voluntary agencies,

social services, or health services. Voluntary agencies tend to be more efficient at providing long-term residential care [14], but they may be reluctant to accept high-risk patients with a history of violence or substance abuse. A mixed economy works best, and the need for health services provision will depend on the vigour of local voluntary and social services. Purpose-built units do exist, but shared adapted houses are more common and promote integration and reduce stigma.

Supported or sheltered accommodation can be classified by levels of increasing need:

1. *Group homes* have no regular staff and are reserved for relatively independent patients, with visits by CMHT staff.
2. *Day-staffed hostels* have one or two day staff to support and monitor patients (encouraging cooking and cleaning, etc.). Specific treatments are provided by the CMHT.
3. *Night-staffed hostels* have non-clinical staff sleeping over, providing safety and support.
4. *24-hour staffed/nursed hostels* have on-site clinical staff overnight either sleeping in or, sometimes, awake. They are expensive, generally for patients with long-term severe illnesses, sometimes including involuntary patients ('hospital hostels'). They tend to be larger, usually with 10–20 residents.

Most comprehensive local services provide levels 1 and 2, and most social services undertake to provide level 3. Level 4 hostels are relatively rare.

Office-based care and outpatient clinics

In insurance-based systems (the United States and much of Europe), psychiatrists may run individual office practices and manage patients on their own. In directly state-funded systems, this is rare and most psychiatrists work in outpatient clinics or CMHTs. Financial considerations can inhibit integration and service developments if they pose a threat to practitioners' livelihoods. Office-based practice is neglected in academic and policy publications. It is usually focused on either psychotherapy or pharmacotherapy and is poorly equipped for managing severe disorders.

Outpatient clinics are increasingly replacing office practice. Psychiatrists and psychologists may still operate independently within them, but with access to enhanced resources and second opinions. In the public sector, outpatient clinics may operate either alongside CMHTs or as part of them (which works better for severe illness) [15]. They provide for efficient assessment, treatment, and monitoring.

Community mental health centres

Mental hospitals, for all their faults, had no problems co-ordinating care; what little was available was all in the same place. Community mental health centres (CMHCs) were established in the late 1960s, initially in the United States, to provide a wide range of services located in shared buildings (for example, depot clinics, a day hospital, psychotherapy services). Early CMHCs in the United States failed to engage psychosis patients because they lacked any outreach, and this, with an ideological down-playing of the 'medical model', made it impossible to recruit psychiatrists.

Now CMHCs provide accommodation for CMHTs and other services such as day care. This shared accommodation helps sustain clinical standards by reducing professional isolation with dispersed community services otherwise risking becoming idiosyncratic and rigid in their practice.

Multi-disciplinary community mental health teams

Most community mental health services consist of one form or another of multi-disciplinary CMHT. This comprises psychiatrists, nurses, and social workers plus other specialist staff such as psychologists, occupational therapists, employment specialists, etc. Regular meetings to assess and review the management of patients incorporate a wide range of professional perspectives and allocate tasks based on skills and needs.

The sector CMHT ('the CMHT')

Who it is for

The CMHT is the fundamental building block of most modern community mental health services. Mental hospital catchment areas, which often covered a whole city or county, were divided into sectors of 50,000–100,000 inhabitants to facilitate continuity of care. The team could gain familiarity with most of its long-term patients and also some personal knowledge of the referring doctors and community resources. Western European sectors now range from 20,000–50,000 population, determined both by resources (shrinking as investment and specialization increase) and by local characteristics. With more specialized teams, CMHT responsibilities shrink and sector size may increase, but keeping its caseload fairly constant. Two hundred or so patients is about the maximum manageable to exploit multi-disciplinary working effectively.

CMHTs offer assessment and care for patients who cannot be adequately treated in primary care, so they prioritize severe mental illnesses. A trial of community mental health nurse care for people with CMHDs [16] showed no benefit over usual GP care, even when the nurses were trained in problem-solving therapy (a brief CBT-based therapy for CMHDs). Diversion of mental health staff away from a focus on people with SMI does not appear to be a cost-effective strategy. However, diagnosis is not all—social adversity, personality difficulties, or substance abuse can make secondary mental health care necessary, even for apparently 'minor' disorders. Instruments to clarify this threshold have been tried and, indeed, introduced in some countries [17] but are of questionable value. Refusal to assess a patient, not surprisingly, irritates referring GPs and most teams rely on clinical assessments.

CMHTs can be remarkably inefficient if little thought is given to their structure and procedures. Agreement is needed on their purpose, clientele, and systems of management, and they have often suffered from a lack of clarity and leadership.

Staffing and management

CMHT staffing varies enormously and there is no uniform model, although the general trend is towards bigger, better-staffed teams.

Small teams of less than six can rarely provide comprehensive care or cross-cover, while teams of more than 15 or so, or with many part-time workers, become unwieldy, overwhelmed with management and information transfer. CMHTs emphasize skill-sharing and a degree of generic working and have evolved an informal, democratic style [18]. This often generates confusion about clinical leadership (originally provided by senior medical staff). With increased staff numbers and treatment complexity, 'team managers' now co-ordinate procedures, varying from being purely administrative to setting clinical priorities and supervising staff. Establishing a clear understanding of clinical leadership in CMHTs (without inhibiting initiative and creativity) is essential for effective functioning. If leadership and management are separated, the roles need to be well defined and the relationships good.

Assessments

The key to good care is accurate assessment (see Chapter 137). Traditionally, psychiatrists conducted all initial assessments (usually in an outpatient clinic) and involved team members in treatment. Increasingly, other disciplines have taken a role in assessments, either individually or jointly with the psychiatrist. This issue generates strong feelings, but there is surprisingly little research into it. With highly developed primary care, non-medical assessments may be effective, but otherwise medical staff should prioritize time for assessments. With severely ill patients, home-based assessments pay considerable dividends [19].

Case management

Most CMHT staff act as clinical case managers [20, 21] with responsibility for the co-ordination, delivery, and review of care for their patients. Caseloads should be explicitly limited (usually 15–25), and reviews systematic and recorded. In the UK, this has been formalized as the Care Programme Approach (CPA) [22]. Fig. 135.1 shows a care plan indicating a patient's needs or problems, the interventions proposed to meet them, who is responsible and who is informed, plus an agreed date for review. Such concise structured paperwork (as with the risk assessment and contingency plan) (Fig. 135.2) can be adapted to any team. It co-ordinates complex care and serves as a natural focus for clinical reviews. The level of detail needs to be clinically (not managerially) determined.

Team meetings

Many of the newer, specialized teams meet daily. For generic CMHTs, it would be an inefficient use of time. They generally have 1–2 regular meetings of 1.5–2 hours each per week to cover clinical and administrative business. The degree of structure depends on team style and remit.

Allocation of referrals

Referrals can be allocated by who is first available or by matching the clinical problem against available skill and training. Time discussing

allocations before assessment is wasteful, and most well-established teams delegate the task to the manager or a senior clinician.

Patient reviews

Reviews should be held for: (1) new patients; (2) routine monitoring; and (3) discharge. Reviews can range from simply reporting the

problem and proposed treatment in uncomplicated cases through to detailed, structured, multi-disciplinary case conferences, including other services (for example, GP, housing, child protection). New patient reviews are an excellent opportunity for providing a broad, experienced overview and ensuring rational and fair allocation to caseloads. Routine monitoring is often overlooked yet is probably the most important for team efficiency. It should be systematic, and not only responsive to crises and problems. It shapes and redirects

Fig. 135.2 Risk assessment and contingency plan.

treatment and identifies patients ready for discharge, and monitors the burden on individual staff members. Routine monitoring is a requirement of the CPA. Discharge reviews are an excellent opportunity for audit and learning within the team.

Managing waiting lists and caseloads

Effective CMHTs need to guarantee prompt access. Routine assessments should be within 2–4 weeks. Sooner is rarely productive, and delays above 3 weeks result in a rapidly rising rate of failed appointments [23]. Urgent assessments (most psychotic episodes) need to be seen within a week, usually within a couple of days. Emergency assessments for those at immediate risk (for example, hostile behaviour or suicidal intent) need to be seen on the same day. These pragmatic guidelines may soon be superseded by imposed targets.

A practical approach to waiting lists is to count the assessments in the preceding year and allocate routine appointments for 20% more. Thus, for a team with 400 assessments in the preceding year, allocating nine slots a week will have one slot available weekly for emergencies. Rapid routine assessment reduces pressure for urgent and emergency referrals much more efficiently than emergency rotas.

Communication and liaison

Team meetings ensure internal communication, but CMHTs need good links with a wide network of professional colleagues. Structured liaison is advisable with primary care and general hospitals. Hospital links may be between specific CMHTs and wards,

or CMHTs may provide input to patients from their sectors in the absence of dedicated liaison psychiatry services.

General practice liaison

As so much mental health care is delivered in primary care, effective co-ordination is essential. 'Consultation-liaison' also represents efficient use of a specialist team's time if it increases the capacity of primary care through improving GPs' skills and knowledge. However, there has been little systematic research evaluating consultation liaison interventions and this model would apply only in those countries with more developed primary and secondary care services [24]. GP liaison systems range from informal contact through to shared care and co-location of CMHTs in GP health centres [25]. An effective system need not be time-consuming but requires regular, timetabled meetings between the two teams or a 'link' CMHT member. Monthly meetings where shared and complex patients are discussed facilitate prompt problem-solving and crisis anticipation. However, it is important to be clear about responsibilities; fudging boundaries is risky.

Liaison with other agencies

The same principles apply to liaison with other agencies (social services, housing, etc.). Whether regular meetings are feasible and cost-effective will depend on the volume of shared work, but showing up and meeting people (even just once) pays enormous dividends.

Assertive outreach teams

The most replicated and researched specialist CMHT is the assertive outreach (AO) team. The original US model [26] substantially reduced hospitalization without increased cost. AO teams (Box 135.2) are staff-intensive and reserved for the most difficult ('hard-to-engage' or 'revolving-door') psychotic patients. These have frequent, often dangerous, relapses and poor medication compliance, complicated by alcohol or drug abuse.

AO emphasizes proactive outreach—visiting patients at home, even when they are reluctant. It exploits enhanced teamworking with daily meetings and several staff involved with most patients both for safety considerations and to meet patients' extensive needs. The culture is very practical (taking patients shopping, sorting out accommodation, delivering medicines daily if need be), often well beyond traditional professional boundaries.

AO brought much needed clear thinking and research to CMHT practice. However, they failed to deliver the same expected benefits in the UK as in the United States [27]. Similar results were found without slavishly following the original model [28, 29]. Detailed examination of AO studies [29] showed that CMHTs delivered equivalent outcomes at much less cost. Consequently, the UK requirement for these teams has been abandoned, with intensive care provided within the CMHT. A more structured approach to identifying and monitoring patients in CMHTs needing intensive care has been proposed as FACT (functional assertive community treatment) [30].

Crisis teams

Crisis teams play a crucial role where local services are poorly developed (they may be the only community services). They prioritize rapid response and accessibility. Early crisis services often had a short lifespan as they either evolved into more durable CMHT services or became overwhelmed by inappropriate referrals.

Crisis resolution/home treatment (CR/HT) teams

The CR/HT team model implemented in the UK and Europe reflects increased public demand for access in crises plus a drive to reduce inpatient care costs. It draws heavily on AO practice with limited shared caseloads, flexible working, extended access, and an emphasis on outreach. Reduction in hospitalization is believed

Box 135.2 ACT core components

- Assertive follow-up.
- Small caseloads (1:10–1:15).
- Regular (daily) team meetings.
- Frequent contact (weekly to daily).
- *In vivo* practice (treatment in home and neighbourhood).
- Emphasis on engagement and medication.
- Support for family and carers.
- Provision of services using all team members.
- Crisis stabilization 24 hours a day, 7 days a week.

to offset much of their cost [31]. How they integrate with generic CMHTs varies markedly, but they work with patients who would otherwise be in hospital—either by supporting them in early discharge or seeking alternatives to admission. They offer intensive visiting (usually daily for a limited period) and considerable practical support and work with patients' social networks. Many are based in a crisis day hospital, and input is limited to a few weeks. Such intensive teamworking requires highly effective communication and the teams meet daily (often twice at shift handovers). Information transfer can be burdensome and liaison with CMHTs complex, requiring absolute clarity on local arrangements for clinical responsibility.

Variations in practice and sustainability

The CR/HT teams may reduce the need for hospital care [31, 32]. The UK model is precisely specified (including who it should and should not care for) (Box 135.3), but practice varies considerably. A full 24-hour service is rarely provided; most rely on established on-call services. Strict observance of the prescribed patient group 'otherwise in hospital' is difficult to achieve, and engagement may be longer. The main criticism is of multiple repetitive visits from endlessly changing staff members. Good medical staffing is needed, and CMHT responsibilities need to be carefully negotiated, mutually agreed, and crystal clear if confusion is to be avoided.

Crisis houses and respite care

Crisis house admissions involve a minimum of formality with less intense supervision than hospitals. They are usually small (4–8 beds) in a relatively domestic setting and admit for days, occasionally a week or two. They are favoured for vulnerable women and early intervention services. Most have one staff member overnight and a couple during the day, with input from patients' case managers. They improve acceptability and access but do not replace inpatient

Box 135.3 Remit of UK crisis resolution/home treatment teams

'Commonly adults (16 to 65 years old) with severe mental illness (schizophrenia, manic depressive disorders, severe depressive disorder) with an acute psychiatric crisis of such severity that, without the involvement of the CR/HT team hospitalisation would be necessary.'

'The service is not usually appropriate for individuals with:

- Mild anxiety disorders.
- Primary diagnosis of alcohol or other substance abuse.
- Brain damage or other organic disorders including dementia.
- Learning disabilities.
- Exclusive diagnosis of personality disorder.
- Recent history of self harm but not suffering from a psychotic or serious depressive illness.
- Crisis related solely to relationship issues.'

care and need careful management to avoid becoming chaotic or blocked.

Early intervention service

Concern that a long duration of untreated psychosis (DUP) confers poorer prognosis [34] spurred the development of early intervention service (EIS) teams which have now become standard in the UK. Developed mainly from Australian and UK models [35, 36], they vary remarkably. Some down-play diagnosis in favour of easy access; others restrict to schizophrenia; some emphasize a 'youth service', while others take all first-episode patients, irrespective of age [18]. Even more confusing, there are three quite different activities which may, or may not, be part of the service (Box 135.4).

The core of EIS is a specialized CMHT based closely on AO team practice which case-manages first-episode psychosis patients. EIS emphasizes protecting social networks and functioning, aiming to keeping patients at college or work, and assuming a return to premorbid functioning. Crisis and respite houses are preferred to hospital. Some EIS teams go beyond this basic model and conduct public awareness campaigns, lecturing in schools and colleges [37]. A minority of research teams attempt to identify and treat 'ultra-high-risk' patients to prevent progression to psychosis [38]. EIS teams are highly popular with families, staff, and commissioners. They are generally better staffed and funded than other CMHTs, and inevitably problems arise with 'step-down' to routine services.

Adjunct or replacement for CMHTs?

The four teams outlined comprise the fundamental building blocks of most community services. AO EIS and CR/HT teams were originally proposed as replacements for CMHTs. However, both experience and research evidence [39] suggest that they are better considered as additions to improve the quality of care from otherwise well-functioning CMHTs, rather than as cost-saving alternatives.

Highly specialized and diagnosis-specific teams

Several specialized teams are generally organized at a regional level. They impact on local services, removing some of the CMHT's clinical load, but need clear and negotiable thresholds if confusion is to be avoided.

Forensic and rehabilitation teams

Community-focused services face particular difficulties with treatment-resistant patients, particularly those with socially

unacceptable or offending behaviour who fit poorly into open wards. Specialized forensic teams provide secure care. Increasingly, they also run community teams to provide intensive case management of dangerous patients. Integrating them with general services can be problematical, and boundaries are invariably controversial.

Rehabilitation

A significant number of patients remain disabled and require long-term management of disability, rather than episode-based care, despite optimal treatment. Rehabilitation teams generally serve patients who cannot survive without supervised accommodation, even when at their best. They comprise a disturbed 'new long-stay' population, characterized by comorbid substance abuse and behavioural disturbances.

Diagnosis-specific teams

Highly specialized teams for individual disorders (for example, eating disorders, personality disorders, bipolar patients) concentrate on specific skills and provide specialized treatments and are usually provided at a regional level. They provide settings for intensive academic research and treatment refinement, but their opportunity costs need careful thought.

Compulsion and ethics in community mental health care

Balancing patients' welfare with their autonomy and balancing their individual rights with those of their families and the wider community have both become more complex as CMHTs have developed. The introduction of community treatment orders (CTOs) [40] highlights these dilemmas. Compulsion and coercion (either explicitly in the form of legal requirements or informally through professional or social pressure [41–43]) are now a pervasive feature of practice. Improved clinical provision and legal scrutiny make compulsory treatment possible in the community.

Most developed countries have enacted forms of CTO ('mandated community treatment', 'outpatient committal'). Their introduction has generally been controversial, and this is heightened by mounting evidence of their ineffectiveness [44]. CTOs have the advantage of legal scrutiny, unlike most of the ethical dilemmas facing CMHT staff in their day-to-day work which require case-by-case discussion. How proper is it to inform neighbours if a patient may pose a risk to them but will not give consent? Is it right for a patient to deny information on his or her treatment to parents on whom he or she is heavily dependent? Guidelines exist only for extreme circumstances, and teams need regular discussions of these issues.

Stepwise planning and adaptation

Local population needs assessment

Psychiatric morbidity varies considerably with social deprivation and is much higher in cities than in stable rural or suburban settings

Box 135.4 Components of early intervention teams

- Case management—ongoing care of identified patients.
- Early identification—awareness-raising campaigns for psychoses.
- High-risk and prodromal patient identification and treatment.

(see Chapters 134–136). At regional and national levels, comparative need can be predicted fairly well from established indexes incorporating age profiles, number of migrants, overcrowding, poverty, etc. [45]. Catchment areas should broadly reflect these differences. At the local level, however, these figures are of limited value. How can one factor in travelling time or differences in the quality of primary care? A process of negotiation is best to agree on local allocation following these general guidelines. However, a concentration of hostels for the mentally ill or homeless or the presence of a railway station or an international airport may swamp these differences. Such local factors should be provisionally estimated in the planning process, but regularly reviewed.

Opportunity costs and unintended consequences

Planning mental health services is driven by political and policy considerations, at least as much as on international evidence, often including cost-effectiveness analyses. However, these analyses rarely address the opportunity costs across a whole system. A study may demonstrate that one acute day hospital is more cost-effective than another, but does the whole system gain when considering diverting the inpatient nurses redeployed to staff it? Rigorous intervention studies of large systems are formidably difficult to conduct and even more so to interpret.

The impact of enthusiasm and the migration of the best staff to such research services can be especially misleading [46]. Successful new services are always reported, but not when they lose their edge or are abandoned [15, 47]. It is best to visit examples of services that you are considering, and not to assume automatically that what works for them will necessarily work for you [28].

Skilled manpower is as significant a resource limitation as funding is, hence the need for a system-wide appraisal. Although costs are usually cited, planning decisions reflect wider values and expectations, rather than simply outcomes [2].

Cultures and funding

Health care cultures, their structures and their funding systems vary enormously. Services must be congruent with them otherwise they will not survive. The current emphasis on the 'recovery' model [48], while it may not make any major differences in practice, has to be incorporated into service planning proposals if they are to be funded. Occasionally, service planners can influence the culture but more often have to adapt to it. Obtaining relatively small changes in funding arrangements (or external governance) can deliver quite major improvements. However, caution is needed as the risks of unintended consequences and perverse incentives are ever present. Enthusiastic clinicians are often blind to the risks of overprescription which can lock in outmoded practices (for example, a highly specific form of day hospital or crisis facility) that may not meet local needs but are too rigidly prescribed to then be adapted.

How 'integrated' mental health care should be is a highly local decision. Well-established systems often strive for integration with general medicine or with social services to reduce both discrimination and administrative barriers to integrated care. The current emphasis on 'parity of esteem' for mental health is sometimes taken to

imply such integration. For many services, the value of a distinct, separate identity can be considerable—not least the ability to protect its resources.

The task of integration is easily underestimated, particularly the energies required to accommodate contrasting health and social care cultures. Compromises need to be agreed before such integration and the negotiations can be exhausting, but they are infinitely preferable to fudges and misunderstandings. The costs and benefits will depend very much on the local situation, relationships, and history.

Relationships with the voluntary sector and patients movement

Current policies emphasize outsourcing, where practical, any welfare provision for which there is a 'suitably qualified provider'. Relations with local non-health statutory services (housing, education, police) and with the voluntary sector will determine much of the success of mental health services, and their strengths need to be exploited. Non-statutory services are usually well adapted to local needs, but less comprehensive or reliable long term. Patient and carer advocacy and support organizations are now a major force; effective working with them will significantly enhance both the design and the delivery of services.

Monitoring and review

Careful monitoring and review are as important as careful planning, probably more so. Services can easily drift to those who demand them from those who most need them; delivery of treatments (particularly psychological and psychotherapeutic treatments) may become mechanical, losing their effectiveness. The most needy patients are rarely the most demanding or well informed, and engaging them in long-term treatments is often difficult.

A consistent effort to deliver even the most basic proven interventions will make a substantial difference to patient welfare. The PORT study in the United States demonstrated how schizophrenia care was strikingly inconsistent and fell below accepted standards [49]. Regular audit, particularly of national guidelines such as those produced by the National Institute for Health and Care Excellence (NICE), ensures that services remain targeted and quality is maintained. Monitoring can vary in sophistication—from a simple head count of who is getting what (for example, clozapine treatment) through to careful evaluation of care pathways. The audit review process feeds back into the development process. Audit invariably rewards its investment.

Routine outcome measures (ROMs)

Audit and measurement bring rigour and reflection, which are often lost in the immediacy of the therapeutic relationship. Measurement also serves a training purpose by benchmarking interdisciplinary understandings of symptoms and outcomes. Systematic, periodic recording of patients' clinical or social status is increasingly used in both planning and research. Structured outcomes can be generic

[for example, Health of the Nation Outcome Scales (HoNOS) [50]] or for specific disorders (for example, the Brief Psychiatric Rating Scale [51]) or even locally developed. Their value lies in their consistency of use.

Physical health care of people with SMI

In the UK, GPs take responsibility for health promotion and care of the physical health of people with SMI. They are incentivized through the GP contract quality and outcomes framework (QOF) to review the needs of their SMI patients annually and ensure a care plan is in place [52]. This proactive care is crucial, as mortality rates for people with SMI are 2–3 times higher than for the general population. While this is partly due to suicide, two-thirds of the excess mortality is a result of physical disorders, especially smoking- and obesity-related cardiovascular and respiratory diseases [53–55].

The annual review of physical health for people with SMI includes:

- Use of alcohol and drugs and smoking behaviour.
- Blood pressure.
- Body mass index.
- HbA1c blood test for diabetes.
- Cholesterol.
- Cervical screening, if appropriate.
- Medication review.

In addition, GPs in the UK check blood lithium levels and monitor thyroid and kidney function of people with SMI taking lithium.

Mental health service planning should take into account the physical health care needs of people with SMI. It will have to provide that care in countries with less well-developed primary care systems or residential mental health care settings. Even in the UK, the primary care of people with SMI varies widely in quality, and one cannot assume their physical health needs will automatically be met through registration with a GP. An audit of the care of schizophrenia in mental health services in England and Wales revealed only 29% received a fully comprehensive assessment of important cardiometabolic risk factors. Among those with high blood pressure and high cholesterol levels, there was frequently no evidence of appropriate investigation or treatment [56]. The authors recommended all health professionals working with such patients should have training in physical health problems and interventions for treating them, including access to the correct monitoring equipment. They also stressed that mental health services and primary care services need to work together to agree who will monitor and treat these physical health problems [56].

Conclusions

Planning and providing mental health services require flexibility and compromise. Epidemiological and service statistics provide a framework for local planning, but it is still primarily a practical and ‘political’ activity. The scientific evidence is dominated by anglophone alternatives to hospital care studies, but local history, culture, mental health law, and political imperatives cannot be ignored.

Box 135.5 Developing local community mental health services

- Make a careful inventory of what services exist and any special local needs.
- Consult locally and invest heavily in building coalitions with policy-makers, statutory services, and voluntary groups.
- Test research evidence for durability and relevance. If possible, visit established services and ask ‘around the service’.
- Monitor and review regularly. Improved consistency of current practice often delivers more than introducing new treatments.
- Consider carefully opportunity costs. Include both the impact of a specific improvement across the whole service and the costs of system change itself.
- Avoid excessive reorganization—not all change is innovation.

A high-profile patient homicide, or a strong public endorsement of services by a politician or celebrity, can derail months of careful planning.

This chapter has attempted to draw out some principles (Box 135.5) for the process, but these can only be guidelines. Inevitably, the decision will be based on what is possible locally. Most solutions rely on the tried and tested structures described here, but their configuration will depend on what is available and local values. Above all, the mentally ill and their families deserve reliable and predictable services. Not all change is innovation. Research findings should be judged in terms of their sustainability and translation from research efficacy to clinical effectiveness more than on the *P*-values in individual trials.

Health economic analysis of service provision

Judit Simon

Introduction

Resources available in the health care system are limited and are exceeded by needs. Public health and long-term care expenditures have been rising steadily, relative to national income, for several decades. Among the Organisation for Economic Co-operation and Development (OECD) countries, they increased by more than a fifth to approximately 6% of the annual national income or gross domestic product (GDP) between 2000 and 2010, and are predicted to more than double, increasing to almost 14% of the GDP by 2060 unless active cost containment efforts are put in place [1]. Currently, the costs of mental ill-health account for up to 14% of health spending in OECD countries and this proportion is also expected to rise further [2]. Worldwide, costs due to psychiatric diseases are expected to double by 2030 [3]. Decisions on how best to allocate scarce resources are therefore becoming increasingly prominent among health policy-makers.

This chapter summarizes the health economic methods used to inform the key questions of decision-makers in health care related to efficiency and equity, which are ‘*Who gets what, where, and how?*’. It provides an explanation of the underlying economic and analytical frameworks and gives a summary of the different techniques of health economic analyses, supported by a selection of recent relevant published examples from the mental health field.

Health economic analyses

Health economic analyses are concerned with the efficient (and equitable) allocation of limited resources for the promotion of health and the prevention, treatment, and care of diseases to maximize the health of the population. *Cost descriptions* [for example, cost-of-illness studies (COIs)] assess the cost of interventions, services, or illnesses with no comparison in place. When information on outcomes is also described, but no comparison to status quo or other alternative is given, the analysis is called *cost–outcome description*. *Cost analyses* compare two or more alternatives, based only on their costs. To assess the overall value of a health intervention, however,

decision-makers need information on the effect, the resources used to generate the effect, and the cost of these resources incremental to the next best alternative action. The value of the next best alternative forgone is known as the opportunity cost. *Economic evaluations* are the comparative assessment of both costs and outcomes of alternative health care interventions. They provide an explicit economic framework for the systematic identification, measurement, and valuation of the resource inputs and outcomes of alternative activities, and the subsequent comparative analysis of these based on the evidence available [4] (Table 136.1).

Cost descriptions

Mental health disorders are common, often recurrent or chronic, have major impacts on individual and social well-being, cause excess premature mortality, and therefore pose great disease burden. Worldwide, the burden of mental and substance use disorders increased by 38% between 1990 and 2010, driven mostly by population growth and ageing [5]. In 2010, they were among the ten leading causes of total disease burden in terms of disability-adjusted life years (DALYs) (7.4% of the total) and were the leading cause of years lived with disability (YLDs) worldwide (23% of the total) [5]. Depression particularly is considered the third leading cause of disability due to morbidity and mortality in Europe, causing 3.8% of all DALYs [6]. By 2020, depression is predicted to become the leading cause of disease burden, alongside cardiovascular diseases, worldwide [7]. COIs estimate the economic burden of an illness in terms of its costs either for a year based on its prevalence or for a lifetime based on its incidence. They may use top–down methods by disaggregating health (and possibly other intersectoral) expenditure data according to disease, or a bottom–up approach by projecting population-level cost of an illness from patient-level data. They are useful in providing information on resource allocation in health systems, analyse time trends, make projections of future health expenditure, and help make international comparisons. Comparability of top–down calculations between countries has improved substantially since the introduction of the System of Health Accounts (SHA) method by OECD in 2000, which provides a framework for a family of inter-related tables for standard reporting of expenditure on health [8].

Table 136.1 Health economic analyses

		Is there a comparison?	
		NO	YES
Is evidence only available on costs?	YES	Cost description	Cost analysis
	NO	Cost-outcome description	Economic evaluation

COIs can also greatly contribute to the identification of discrepancy between epidemiological and health service use data and identify unmet needs. For example, a pan-European cost of brain disorders study from 2010 concluded that less than one-third of all cases received treatment and suggested a considerable level of unmet needs [9]. There are several potential reasons for this, besides the general underfunding of mental health services. Issues such as availability of trained personnel, poor geographical distribution of services, and other access and utilization issues (language, socio-economic status, stigma, low weight of individual needs and preferences), lack of long-term thinking at decision-making level, provision of cost-ineffective services, bureaucracy, and, last but not least, fragmented funding and provision all play a role.

Cost categories

The *direct medical costs* of mental ill-health include medical expenditure of all goods and services related to the prevention, diagnosis, and treatment of an illness (for example, physician visits, hospitalizations, medication) due to an increased need for health care. Poor mental health also drives up the cost of treating other health problems. It is more expensive to treat physical ill-health conditions when the patient is suffering from a mental illness (for example, depression), and people with mental ill-health are more likely to suffer from physical comorbidities (for example, cardiovascular diseases) (Box 136.1).

Direct non-medical costs refer to the cost of other goods and services related to the disorder, including social services, long-term care, special accommodation, and costs to the patients and their families (for example, travel costs, out-of-pocket payments). Mental illnesses also have broader societal impacts that lead to significant *indirect costs*. People with mental ill-health experience higher rates of unemployment. According to OECD estimates, people with severe mental health disorders are 6–7 times more likely, while people with mild to moderate disorders are 2–3 times more likely, to be unemployed than people with no mental health disorders [2]. In addition, people with mental ill-health retire earlier, have more

absences from work (absenteeism), and also suffer more from presenteeism, meaning reduced productivity at work. In the case of depression, for example, lost productivity costs due to presenteeism are five times as high as those incurred due to absenteeism [13]. Indirect costs also include economic costs attributable to lost resources, but not involving direct payments such as informal care provided by family members and friends. A full accounting of the costs of poor mental health should include relevant *intersectoral costs* of lower educational achievements, increased homelessness, and crime. The *intangible costs* of mental ill-health are considerable and include the monetary value of reduced well-being, emotional distress, pain, and other forms of suffering (for example, stigma). Due to difficulties in quantifying the latter costs, however, they are often neglected in COIs, resulting in an underestimation of the true disease costs (Box 136.2).

COIs, however, are limited regarding their interpretation and policy use in resource allocation. Bias towards already costly disease areas is likely to occur without further consideration of whether the current allocation is optimal and what kind of trade-offs may be done that represent good value for money and may contribute to the reduction of both the disease and the economic burdens effectively. As mental health services are usually complex with multiple impacts, it is difficult to estimate their real cost-saving potentials without relevant considerations in a full economic evaluation framework.

Cost analyses

Comparative cost analyses are seen as partial economic evaluations [4]. Although, without information on outcomes, they are not useful in determining the cost-effectiveness of alternative options, cost analyses may be used to highlight the difference in costs between two alternative interventions or services and are useful tools in health services research and planning. The perspective of the analysis depends on the included cost categories. *Budget impact analyses (BIAs)* are specific cost analyses that address the expected changes in the expenditure of a health care system after the adoption of a new intervention or service in comparison to status quo. They present information on the relevant monetary impact and its diffusion, depending on the time horizon of the analysis and the included cost categories. BIAs are used for budget or resource planning by those who manage and plan health care budgets (for example, administrators of national or regional health care programmes, private health

Box 136.1 Costs of medications

Often direct medical costs that are easy to estimate, for example medication costs, are in the focus of resource allocation debates. Antidepressant consumption has at least doubled in the OECD countries between 2000 and 2013 [10]. Globally, antidepressant medications were ranked ninth among all prescription drugs, with sales of over US\$20 billion in 2011 [11]. Despite the general trend of increasing consumption, drug costs only have limited effect on the total direct costs (between 6% and 29% of the total), with hospitalization remaining the main cost driver (between 30% and 79%) in terms of the economic burden of depression and other mental illnesses internationally [12].

Box 136.2 Costs of mental health in Europe

The total European cost of brain disorders in 2010 was estimated at €798 billion, of which direct health care costs accounted for 37%, direct non-medical costs for 23%, and indirect costs for 40%. The average cost per inhabitant was €5550. From these, the aggregated economic costs of depression were calculated at €92 billion, attributing to one-third of the total cost of brain disorders, and therefore being the most costly brain disease in Europe. The average total cost per patient for depression was estimated at €3034, of which direct health care costs amounted to €797 (26%) and direct non-medical costs at €454 (15%). With €1782 (59%), indirect costs were responsible for the highest proportion of costs per patient, making lost productivity the greatest contributor to the overall economic burden of depression and emphasizing its large societal cost [14, 15].

Box 136.3 Costs of mental health in the UK

A recent UK cost analysis estimated the mental health service use and cost impacts of remote mood monitoring of patients with bipolar disorder introduced in a specialist mood disorders clinic via the *True Colours* system over 1 year before and after engagement with monitoring. Average compliance with monitoring was over 80%. No significant changes in the annual use and costs of mental health services were found, except for patients who were newly referred to the clinic during the pre-monitoring period. Annual psychiatric medication costs increased, however, on average by £235 across all patients due to more frequent changes to psychiatric medications and higher levels of multi-drug use as a possible consequence of a tighter medication regime [17].

insurance companies, health care providers). A BIA can be an independent analysis or part of a comprehensive economic assessment of a health care intervention, alongside an economic evaluation of its cost-effectiveness [16] (Box 136.3).

Economic evaluations**Techniques of economic evaluations**

The main question an economic evaluation tries to answer is: 'Is an intervention or service cost-effective, that is, meaning 'good value for money', in comparison to an alternative use of resources, based on the available evidence?' For this, both costs and outcomes of competing alternatives have to be compared and an *appropriate comparator* should be chosen. For example, when the cost-effectiveness of a new antidepressant medication is investigated, it is not sufficient to compare its outcomes and costs to that of a placebo, but rather to the current gold standard active antidepressant treatment options.

Depending on the resource allocation question at hand, different *types of economic evaluations* applying different types of outcome measures are appropriate [4] (Table 136.2). When there is good evidence that the compared alternatives are equally safe and effective, and therefore have identical outcomes, the question of finding the least costly option can be answered within a so-called *cost-minimization analysis* (CMA). Because of the inherent uncertainty around both the cost and outcome estimates, however, it has been questioned whether CMA can be seen as the correct approach in any decision situation [18]. When competing alternatives within the same disease area are compared, it is appropriate to use

outcome measures that are common natural units meaningful for the given disease within a *cost-effectiveness analysis* (CEA). For example, for people with depression, meaningful outcomes could be expressed as relapse prevented or depression-free days. The preferred outcome measure for economic evaluations that allows comparison across disease areas is the generic quality-adjusted life year (QALY) used in a *cost-utility analysis* (CUA). QALYs combine both quantity of life and quality of life outcomes into a single metric. For this purpose, quality of life is measured in terms of the utility value of a given health state. The length of time an individual spends in a given health state is weighed by its utility value to calculate the QALY. Utility values of 1 indicate full health, and 0 indicate a health state value equivalent to being dead. Health states considered worse than being dead can be represented by negative values. Whether patients, experts, or the general public are best suited to perform utility valuations is an ongoing debate. From a social perspective, the general public is considered as the most appropriate group due to the dominantly public financing of health care systems and the need for unbiased valuations across a wide range of different disease areas and health states. Other generic outcome measures predominantly used in international CUAs are disability-adjusted life years (DALYs) and healthy year equivalents (HYEs) [19]. When the relevant resource allocation question crosses the boundaries of public policy sectors (for example, investment in better health care vs investment in better education), outcomes necessarily need to be measured in a metric that is common to all sectors, that is, in monetary terms within a *cost-benefit analysis* (CBA). It is also possible to report costs and outcomes of an economic evaluation in a disaggregated way in a tabulated format within a *cost-consequences analysis* (CCA) framework. In these cases, while information on the relevant ranking of alternatives is possible alongside different criteria, no single cost-effectiveness ratio is presented, leaving the overall synthesis and trade-off between different outcome attributes for the decision-maker thereby less explicit. More recent attempts for eliciting weights by analysts for different criteria are emerging within a *multi-criteria decision analysis* (MCDA) framework [20].

The resource allocation question at hand also determines the appropriate *perspective of an economic evaluation*, which, in return, defines the categories of costs (and types of outcomes) that need to be included in the assessment. Many stakeholders require an economic evaluation to be conducted from their relevant perspective (for example, provider perspective, payer perspective). In the evaluation of mental health services (particularly with their typically fragmented financing arrangements), such an approach is usually considered insufficient as large proportions of the relevant costs and consequences fall outside the health care sector, with impacts on social care, patients and their families, and other sectors of the economy (for example, employment, justice, education). The broadest possible perspective of an economic evaluation is the societal perspective, which includes all possible costs (and outcomes). Alternative perspectives can result in different conclusions concerning the cost-effectiveness of interventions and services. Therefore, it is not uncommon for an economic evaluation to present results from several perspectives (Box 136.4).

Randomized clinical studies are a great source of collecting relevant cost and outcome data at individual patient level. Often, however, data for all relevant comparisons are not available directly. Furthermore, unless an economic evaluation is prospectively

Table 136.2 Types of economic evaluations

	Costs	Outcomes
Cost-minimization analysis (CMA)	Monetary unit	(Preliminary evidence of equal outcomes)
Cost-effectiveness analysis (CEA)	Monetary unit	Natural units (for example, relapse prevented, life years gained)
Cost-utility analysis (CUA)	Monetary unit	QALY, DALY
Cost-benefit analysis (CBA)	Monetary unit	Monetary unit
Cost-consequences analysis (CCA)	Monetary unit	Multiple outcomes tabulated

Box 136.4 Costs of community treatment orders in the UK

A recent economic evaluation carried out alongside the OCTET Trial assessed the cost-effectiveness of community treatment orders (CTOs) for revolving-door psychiatric patients in the UK over 12 months [21, 22]. The primary cost-utility analysis used QALYs as outcome measure, while a secondary economic evaluation explored the OxCAP-MH capability index as outcome measure. The study found no evidence that CTOs have any significant impact on individuals' health-related quality of life or capabilities, in comparison to the non-CTO group. The mean total health and social care costs per participant were also found not different (£35,959 in the CTO group and £36,003 in the non-CTO group). Participants in the CTO group, however, had significantly higher indirect care costs than those in the non-CTO group (£6138 vs £2993) and significantly higher legal procedure burden. The overall results of the economic evaluation did not support the original hypothesis that CTOs result in reduced hospitalization costs or other health or social care cost savings, and showed that CTOs are unlikely to be cost-effective either from a health and social care perspective or from a broader societal perspective [22].

planned *alongside a clinical trial*, information on important outcomes or costs is frequently not collected. It is also important that the analytical time horizon of an economic evaluation is long enough to capture all important cost and outcome impacts of the compared alternatives. This aspect becomes extremely influential when costs and outcomes occur at different time points, for example, when assessing the value for money of preventative programmes. The time frame of clinical studies is often too short to provide all the necessary evidence. A fourth potential limitation of clinical studies as data sources is the representativeness of their investigated patient populations to real life. Due to these limitations, evidence synthesis of cost and outcome data from multiple sources, including literature, routine administrative databases, and expert opinions, within a *decision analytic modelling* framework often becomes necessary for economic evaluations [23].

Identifying, measuring, and valuing costs

Costing in economic evaluations include the identification of the resources used as inputs in the provision of an intervention or service (for example, medications taken, days spent in hospital, GP visits), measurement of the actual *resource use* for each relevant category, and the valuation of these amounts by their respective *unit costs* (for example, cost per usual defined daily dose of an SSRI, cost of 1 day in hospital, cost of a GP visit).

Information on individual-level resource use can be derived from routinely collected data (for example, hospital records). In addition, linkage of different routine databases across multiple providers may become necessary. Alternatively, patients, caregivers, or professionals may be asked via specifically designed resource use questionnaires and diaries. A comprehensive collection of such resource use measurement instruments is publicly accessible via the DIRUM (Database of Instruments for Resource Use Measurement) database (<http://www.dirum.org/>). When patient-level variability of resource use is of lesser importance, relevant estimates may be taken from the literature or expert estimates are used.

Unit cost information for the valuation of health and social care resources may come from specific unit cost libraries, if available (for example, <http://www.pssru.ac.uk/project-pages/unit-costs/>), or be estimated anew using top-down or bottom-up (also called

micro-costing) approaches, depending on data availability and perspective. Unit cost estimates usually include relevant cost categories for staff costs, capital costs, and overhead costs [24].

Identifying, measuring, and valuing outcomes

In clinical practice, *disease-specific and symptom-specific outcome measures* [for example, Beck Depression Inventory (BDI), Brief Psychiatric Rating Scale (BPRS)] are routinely used to monitor and evaluate outcomes focusing on a particular disease or symptom area. For the purposes of economic evaluations where often outcomes have to be measured and compared across different disease areas or patient populations or within the general population, there has been a growing interest in more *generic outcome measures* that are able to capture health or broader social functioning and well-being [for example, Short Form Health Survey 36 (SF-36), EuroQoL (EQ-5D)].

Both disease-specific and generic instruments can be further classified as *patient-reported outcome measures (PROMs)* when values for health state descriptions are directly reported by individuals who experience them, vs *assessor-reported outcome measures* when someone else, often a doctor, nurse or carer, reports the values. PROMs do not include biomedical measures or are used as specific diagnostic instruments in clinical practice. A great compilation of different PROM instruments can be found at <http://phi.uhce.ox.ac.uk/home.php>.

Outcome measures can also be classified as non-preference-based or preference-based instruments. *Non-preference-based instruments* measure symptoms, disease progression, or health-related quality of life, alongside a predefined profile, and yield profile scores on the relevant domains without assessing the value individuals place on the different domains. Their applicability in economic evaluations is restricted, as their comparability is frequently limited, they are not linked to any underlying valuation of health states, the trade-off across different domains in the profile is difficult to interpret, and they do not provide a single score usable for the development of a single cost-effectiveness ratio. In contrast, *preference-based instruments* combine different dimensions of health to generate quality of life estimates for multiple health states, which are then valued to yield a single summary utility score [25]. When utility values from generic preference-based outcome measures are not directly available for economic evaluations, statistical methods, known as 'mapping', can be applied to predict health state utilities from disease-specific scales, given there is an overlap in content between the measures of interest [26].

There are several instruments and elicitation methods to estimate health state utilities. Among these, the EuroQoL EQ-5D is the most widely recommended tool for quantifying utilities and conducting economic evaluations [27]. There is, however, growing concern whether generic preference-based measures, including the EQ-5D, capture all important aspects of health-related quality of life for specific mental disorders [28]. Although there are studies that have reported that the EQ-5D demonstrates construct validity and responsiveness for common mental illnesses, such as depression, the results for severe mental illnesses, including schizophrenia and bipolar disorders, are less convincing [29, 30].

In the light of the ongoing discussion on the appropriateness of the existing outcome measures for certain disease areas, including people with mental health problems, new approaches of measuring well-being based on the capability approach have emerged and been

increasingly applied in general outcome measurement in health economics. Instruments, including the ICECAP (ICEpop CAPability) and ASCOT (Adult Social Care Outcome Toolkit) questionnaires, have been developed to use in the health and social care sectors [31]. The OxCAP-MH (Oxford CAPabilities questionnaire-Mental Health), a 16-item PROM, has been specifically designed for outcome measurement in mental health [32]. The validation of the instrument with patients suffering from severe mental health problems showed good feasibility, acceptability, content, and construct validities, including significant correlations with psychiatric symptoms, social functioning, and other quality of life measures [33].

Cost-effectiveness decision framework

Economic evaluations compare the difference in costs to the difference in outcomes (effects) between two competing alternatives (alternative A vs alternative B) in the form of an *incremental cost-effectiveness ratio (ICER)*.

$$ICER = (CA - CB)/(EA - EB)$$

Depending on the type of economic evaluation, the ICER may be expressed as the 'incremental cost per case prevented' (CEA) or as the 'incremental cost per QALY' (CUA). Including the inherent uncertainty in estimating the difference in costs and outcomes, there are nine possible decision scenarios that can emerge. These scenarios are listed and depicted on the cost-effectiveness plane in Fig. 136.1.

- Scenario 1: The new intervention/service is more effective and less costly than the control one; the new intervention/service dominates and should be accepted.
- Scenario 2: The new intervention/service is less effective and more costly than the control; the new intervention/service is dominated and should be rejected.

- Scenario 3: The new intervention/service is more effective and costs the same as the control; the new intervention/service dominates and should be accepted.
- Scenario 4: The new intervention/service is less effective and costs the same as the control; the new intervention/service is dominated and should be rejected.
- Scenario 5: The new intervention/service is equally effective and less costly than the control; the new intervention/service dominates and should be accepted.
- Scenario 6: The new intervention/service is equally effective and more costly than the control; the new intervention/service is dominated and should be rejected.
- Scenario 7: The new intervention/service is more effective and more costly than the control; no clear decision.
- Scenario 8: The new intervention/service is less effective and less costly than the control; no clear decision.
- Scenario 9: The new intervention/service is equally effective and equally costly as the control; no clear decision.

In case of scenarios 7 and 8, the cost-effectiveness decision depends on the *threshold value* (T) society is willing to pay or can afford for a unit of outcome. In England, the National Institute for Health and Care Excellence (NICE) established a range between £20,000–30,000 as the relevant cost-effectiveness threshold for one QALY gained [27]. According to this, interventions/services with a cost per QALY of below £20,000 would be funded; between £20,000–30,000, the funding decision would depend mostly on other decision factors (for example, availability of alternative treatment options, burden of disease); and above £30,000, it would be funded only in rare cases. Similar affordability criteria have been set

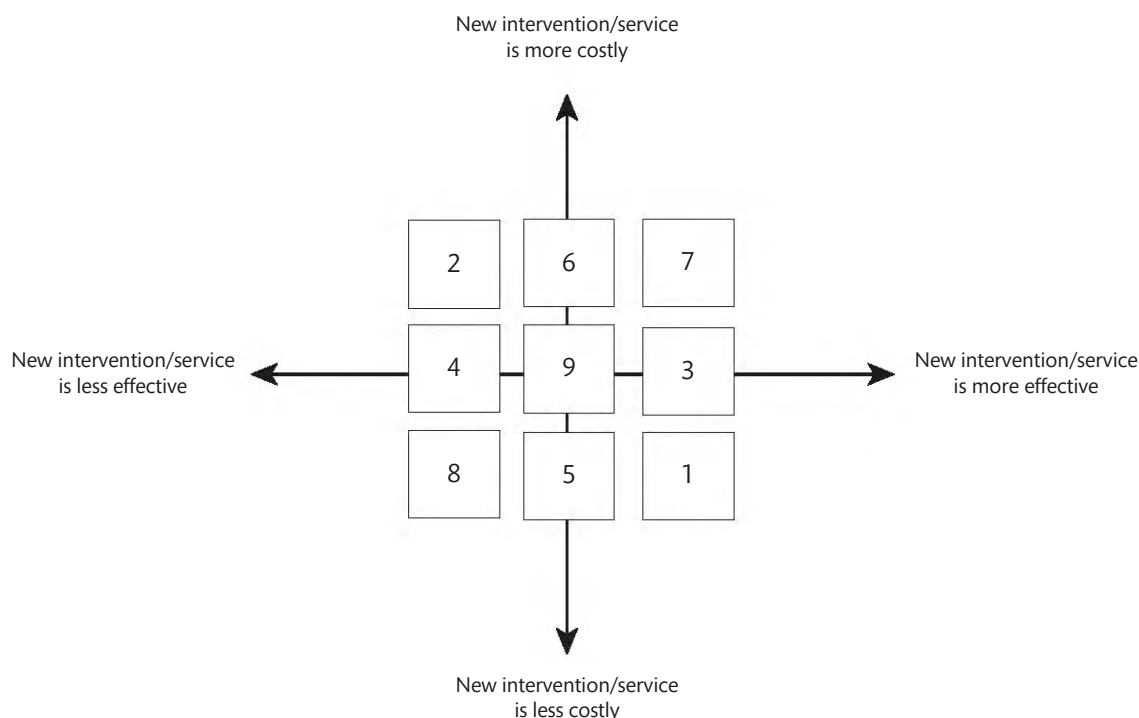

Fig. 136.1 Cost-effectiveness plane with possible cost-effectiveness decision scenarios.

Fig. 136.2 Cost-effectiveness acceptability curve.

up for developing countries by the WHO [34]. Here, interventions are considered very cost-effective if a DALY averted costs less than the GDP per capita, and cost-effective if a DALY averted costs less than three times the GDP per capita. *Cost-effectiveness acceptability curves* show the probability that an intervention is cost-effective, dependent on the threshold value (Fig. 136.2). These curves are based on the *net benefit (NB)*, an alternative summary measure of the value for money of interventions/services derived at by the following cost-effectiveness decision rule:

$$NB = T \times (EA - EB) - (CA - CB)$$

If $NB > 0$, the new intervention/service is cost-effective. If $NB < 0$, the new intervention/service is not cost-effective. If $NB = 0$, there is an indifference between the alternatives. A similar decision rule applies to the results of CBAs.

Applications

Economic evaluations are seen by decision-makers as useful tools with growing importance due to the increasing need for resource allocation decisions. Many countries have now established organizations to develop economic evaluations to inform policy-making either within or outside a health technology assessment (HTA) framework (for example, NICE for England, CADTH for Canada, IQWiG for Germany, CVZ for the Netherlands). A comprehensive list of relevant HTA organizations can be found under the umbrella organizations of the International Network of Agencies for Health Technology Assessment (INAHTA) (www.inahta.org), Health Technology Assessment international (HTAi) (<https://htai.org/about-htai/>), and European Network for Health Technology Assessment (EUnetHTA) (<https://www.eunetha.eu/about-eunetha/>). Furthermore, the requirement to demonstrate cost-effectiveness evidence, in addition to quality, safety, and efficacy, for the reimbursement of pharmaceutical, medical technology, or biotech products has been introduced as a 'fourth hurdle' in many health care systems [35].

It is therefore not accidental that a rapid review of evidence on the costs and benefits of interventions in the area of mental health from Australia found that among the included 50 studies, pharmacological treatments were the most commonly studied interventions, followed by psychosocial interventions [36]. Only a few studies investigated the cost-effectiveness of employment programmes, art programmes, internet strategies, electroconvulsive therapy, discharge models, and

joint crisis plans. Most studies were from the UK and adopted a health sector perspective, with only a small number considering other sectors (for example, housing, education, employment, or (criminal) justice sectors) and relevant intersectoral aspects. In terms of disease area, depression was the most frequently studied, followed by schizophrenia, anxiety disorder, conduct disorder, attention-deficit/hyperactivity disorder (ADHD), and panic disorder [36].

Another systematic review of published economic evaluations that compared antidepressant treatments in depression, based on database analyses and prospective clinical studies, identified 40 papers that met the inclusion criteria [37]. Among these, a relatively large number of industry-sponsored evaluations of escitalopram were identified, which found escitalopram to be potentially cost-effective in depression treatment. Evidence of cost-effectiveness differences between other individual SSRIs was not unequivocally established. Inconsistent findings further emerged concerning the cost-effectiveness of SSRIs vs tricyclic antidepressants between retrospective database analyses and prospective studies [37].

Incorporation of economic analyses in evidence-based clinical guidelines is also becoming common practice. One of the first decision analytic models developed for this purpose relates to the 2004 NICE depression guideline [38, 39]. This evaluated the outcomes and likely costs of the first-line use of combination therapy of antidepressant medication with psychological therapy for moderate and severe depression in the UK. The study found that combination therapy is likely to be cost-effective for severe depression, with an average cost per QALY gained of £5777 (95% CI: £1900–33,800), while its cost-effectiveness is much more uncertain for moderate depression (average cost per QALY gained: £14,540; 95% CI: £4800–79,400).

Economic evaluations may also be used to evaluate mental health programmes for whole populations and show how much of the burden may be averted by selecting cost-effective interventions. A comparative cost-effectiveness analysis of interventions for reducing the burden of major neuropsychiatric disorders formed part of the WHO CHOICE project (CHOosing Interventions that are Cost-Effective) [40]. The project assembled databases on cost-effectiveness of key health interventions in 14 epidemiological subregions of the world, using a generalized cost-effectiveness framework in which costs and outcomes of current and new interventions were compared to 'doing nothing'. The costs and effectiveness of pharmacological and psychosocial interventions in primary

care or outpatient settings for psychiatric disorders were compared in a population model. Effects were measured as DALYs averted and costs in international dollars. Compared to no treatment, the most cost-effective strategy for averting the burden of psychosis and severe affective disorders in developing regions of the world is a combined intervention of first-generation antipsychotic or mood-stabilizing drugs with adjuvant psychosocial treatment delivered by community-based outpatient services. For more common mental disorders treated in primary care settings (depressive and anxiety disorders), the single most cost-effective strategy was the scaled-up use of older antidepressants due to their lower cost, but broadly similar efficacy to newer antidepressants. However, as the price difference between older and generic newer antidepressants continued to narrow over time, generic SSRIs may represent the current treatment of choice. Proactive disease management, including long-term maintenance treatment with antidepressant drugs, also represents a cost-effective way of significantly reducing the enormous burden of depression in developing regions. As the authors point out, these findings provide relevant information regarding the relative value of investing in neuropsychiatric treatment and prevention, and so may help to remove one of many remaining barriers to a more appropriate public health response to mental health needs [40].

In addition, economic evaluations can highlight the potential economic benefits of improved service and care provision at the population level. A global return on investment analysis for scaling up depression and anxiety treatment focusing on the benefits of increased productivity found a benefit-to-cost ratio of 2.3–3.0 when only economic costs and benefits were considered, and a ratio of 3.3–5.7 when the intrinsic value of health gains were also included across the different country income groups [41].

Due to the growing number of published economic evaluations to guide resource allocation decisions, it is of utmost importance that the methods used and the standards of reporting are harmonized. International checklists to support the *critical appraisal* of the robustness of methods and results have now been developed and are used to guide publications standards as well [42, 43].

Conclusions

Health economic analyses of mental health services are aimed to support needs assessment, service development, budget planning, and resource allocation decisions. Among these, economic evaluations provide information on the cost-effectiveness of competing alternative interventions and services. They are seen as useful decision-making tools with increasing importance worldwide.

The rising disease and economic burden of mental health problems, together with the growing economic evidence on simple cost-effective interventions with great return on investment potentials, put the scaling up of some mental health services high on the political agenda. Availability of current cost-effectiveness information reflects the increased submission requirements for the reimbursement of new technologies. As a consequence, evidence on the cost-effectiveness of preventative measures for mental health disorders remains limited, potentially shifting away the attention from such options.

Although the rigour of the methods and reporting standards of economic evaluations have considerably increased since the

introduction of relevant checklists, several methodological questions persist. Outcome measurement for the evaluation of mental health services remains a major challenge. Recently growing concerns about the validity and responsiveness of common, generic quality of life measures for people with severe mental disorders point towards the need for alternative, broader well-being measures to be implemented in this context. Novel instruments using the capability approach as their underlying framework have now emerged as promising new concepts. Due to the important broader societal consequences of mental health problems, including their negative impacts on families, it is also imperative to shift standard outcome evaluation from individual patients towards family units and progress relevant methods. For the same reason, economic evaluations of mental health services require broad costing perspectives. Although the methodology of costing in economic evaluations may seem more straightforward than that of outcome measurement, internationally harmonized methods and tools for the identification, definition, measurement, and valuation of costs have received considerably less attention, and comparability among economic evaluations is often lacking in this respect. Not only is there a need for increased availability of harmonized national unit cost compendiums for health and social care services internationally, the lack of similar comprehensive intersectoral unit cost information also remains a major challenge.

Organization of psychiatric services for general hospital departments

Proactive and preventive interventions in psychiatry

William H. Sledge and Julianne Dorset

Introduction

There are many proactive health care interventions that have proven to be effective with acceptable risk–reward ratios. Organized Western medicine, however, continues to focus on administering health care resources, particularly in hospital-based psychiatry, to those patients with advanced illnesses despite knowing about early manifestations of mental illness and associated disorders of personality and addiction. Consultation-liaison psychiatric services, where treatment may be considered reactive and minimalist, relative to what consult services within other disciplines believe is adequate care, are particularly vulnerable to glossing over early signs of illness due to the lack of mental health professionals in general hospitals and the gulf of understanding between hospital staff and psychiatric service providers. A variety of problems flow from this type of practice. Practitioners from other medical disciplines and specialties are rarely well versed in accurately recognizing subtle and/or early signs of mental illness and emotional suffering. This is a matter of training and skill, but also a product of the way that many mental illnesses are conceptualized as a continuum of traits and qualities. As such, there is no clear line of demarcation between illnesses and normality. Consequently, medical practitioners may not understand or have adequate experience utilizing psychiatric treatments that may be appropriate for their patients. This may result in ‘psychiatric treatment nihilism’ or a phenomenon in which the non-psychiatric practitioner feels that there is little that can be done to help the patient, partly because treatments are limited, but also because of a lack of skills and knowledge to deal with the clinical presentation accurately [1]. A sense of futility may ensue so that the practitioner calls for a psychiatric consult late in the hospitalization or does not call a mental health specialist at all.

The appropriateness of the consultation request does not always match the putative patient. Some requests for services are inappropriate such as in the case of a normal reaction to bad news or physical suffering that does not require the specialized skills and knowledge of a mental health professional. This may happen while the

undetected mentally ill patient suffers in silence in the absence of appropriate care. Nursing staff members are left to use ‘common sense’ to manage these patients, which may suffice when distress, and not mental illness, is the cause of a patient’s symptoms. Common sense in the face of mental illness, however, is often uncommon among non-psychiatric hospital clinical workers. Therefore, it is inappropriate for practitioners in disciplines other than mental health to decide whether mental health services should intervene during an episode of care for a somatic ailment. Non-psychiatric physicians do not always understand mentally ill patients nor do they have knowledge of the resources that might be available to both patients and practitioners. It is thus understandable, but not entirely forgivable, why psychiatric patients often do not get maximal care for their psychiatric troubles when they are in a non-psychiatric setting in the hospital.

Part of the responsibility for this lack of awareness about mental health issues redounds to the mental health practitioners who do not educate non-mental health providers and/or lack the ability to deal professionally with their skepticism about psychiatry. In that regard, mental health practitioners may need to be more assertive and proactive in advocating for these services. Chen, Evans, and Larkin [1] reviewed the literature from 1965 to 2015, on the reasons that hospital-based physicians are reluctant to refer to psychiatry. They noted that physicians frequently did not call for psychiatric consultations due to feeling uncomfortable with consultation-liaison psychiatry (CLP). Operant factors that favoured psychiatric referrals were a dedicated CLP service, an active consultant, and physicians who were comfortable with psychiatric patients, as well as with medically ill patients.

In this chapter, we address psychiatric consultation services for early intervention, review conceptual and practical challenges, and present where to find more detail about efforts of early intervention. We distinguish the difference between proactive and preventative services by the following—‘proactive’ refers to activity on the part of the practitioner that is designed to eliminate or arrest the progression of an already recognized condition and/or illness, whereas

'prevention' entails activities that keep an illness or a disability from being established. Common examples of preventative measures are vaccination programmes against infectious diseases, protective gear in athletic endeavours, or mandatory seat belts in automobiles to prevent traumatic injury. We review successful non-psychiatric proactive health care interventions to establish universal structural factors that need to be considered in any kind of proactive or preventative intervention. For ease of presentation, we will use the term 'early intervention' to describe preventative and/or proactive efforts together. While we propose a clear-line distinction between proactive and preventive, in practice, this distinction may not always be discernable.

Prevention as a concept in medicine has been modernized by an Institute of Medicine work group [2], which divides it into three subcategories: *universal* preventive interventions, *selective* preventive interventions, and *indicated* preventive interventions. Universal preventive interventions are targeted to the public or to whole population groups that have not been identified as having the illness in question but perhaps have associated increased risks for the disorder(s) being considered. In this instance, there would be no discernable, definitive evidence of the presence of the condition(s) in question, but there would be a perceived risk or vulnerability. Universal interventions are typically characterized by low risk and low cost. The annual flu shot and other vaccinations urged upon populations would be examples of universal interventions. Psychiatry does not have a disorder that clearly fits into this category.

Selective preventive interventions refer to operations and interventions for subgroups of the population whose risk for developing a disorder is higher due to present known individual traits and characteristics or social risk factors. Such a group might be the non-symptomatic carriers of a recessive gene for the development of a severe disorder such as Huntington's disease or coal miners who, due to their line of work, are at higher risk for developing black lung disease. The risk-reward ratio of the intervention and the likelihood of developing the condition dictate whether an intervention may be worth implementing.

Indicated preventive interventions are for high-risk individuals who are identified as having minimal, but detectable, signs or symptoms which foreshadow the expression of a disorder. Biological markers or symptoms that signal a predisposition for a mental disorder in the carrier, but do not meet diagnostic criteria for the disorder at the current time, would also fall into this group [2]. Indicated preventive interventions may be worthwhile, even if intervention costs are high and the intervention entails some considerable expense or risk to the patient, relative to the possible consequences of not providing the intervention. Interventions for conditions that demonstrate that a disorder is present should be considered treatment, rather than prevention.

Proactive interventions in psychiatry, and perhaps for many medical conditions, fall somewhere between treatment and indicated preventive interventions. However, psychiatric conditions present conceptual, as well as practical, challenges to this cartography of intervention in that the present diagnostic system in psychiatry is largely based on descriptive accounts, rather than precise aetiological, biologically based characteristics. Furthermore, as noted, psychiatric conditions are frequently expressed along a spectrum of the illness in question, so that there may be several conditions that create suffering and disability but do not rise to diagnosable

disease proportions. There may be ambiguity as to whether a person is diagnosable as mentally ill or not. Additionally, some conditions have similar characteristics, which may result in different providers diagnosing a person differently over time. Finally, some normal symptomatic conditions are difficult to discern from mental illness, such as in the case of grief which may, in some cases, be indistinguishable from depression. These conditions can be easily confused with pathological states if the historical data are not clear or understood.

Psychiatric conditions are often chronic, beginning slowly and eventually manifesting as peaks and valleys of symptoms and morbidity, interspersed with periods of relatively normal functioning. Experienced psychiatric clinicians can usually identify prodromal symptoms and recognize deterioration in clinical status and capacity. Yet it may be difficult to differentiate between illness and normal variation in many circumstances, particularly when a clinician is without a longitudinal view of the patient or significant training for recognizing mental illness.

Diagnostic uncertainty in psychiatry has, in part, added to the lack of preventive prescriptions that are feasible in effectiveness, cost, or secondary risk, to which the interventions may expose the patient and/or others. In most of medicine, with the exception of trauma, serious diseases may present with minor symptoms or findings that are frequently ambiguous in terms of their implications. Physicians and patients are left to opt for a wait-and-see approach, to push aggressively for a definitive diagnosis immediately despite economic cost and/or personal risks, or to pursue a course of assessment and treatment somewhere in between these two polar positions. To illuminate the possibility of proactive and/or preventive measures in mental health, we review some of the literature on early interventions in other fields. In doing so, some of the conceptual considerations for proactive and preventive approaches in psychiatry will be brought to light. Desan *et al.* [3] similarly described a new vision of liaison psychiatry for the future, in which psychosomatic medicine will be proactive and increasingly integrated into specialty and general medical care.

Structural examples of 'early recognition' interventions in clinical care

A review of the literature on early intervention revealed some common structural features of successful programmes (including assessment). Certainly, an important feature is a clear concept of the illness/disease in question, both in its treatment as well as in its morbidity and mortality. Of particular importance is its manner of early expression. In other words, detectable features (signs and/or symptoms) must be present for early detection and subsequent treatment to be applied effectively and appropriately. There must also be a means of detecting and recognizing the early signs in the form of a screening process that has acceptable accuracy and ease of use and that poses no threat to the safety of the patient. For some diseases, this may be screening for biological markers, but in psychiatry, markers will inevitably be historical facts, present symptoms, and/or behaviour (which includes thoughts, intentions, emotions, etc.). Standardization of these data is important to understand, as it is through standardization that we can compare outcomes and course, as well as risk and results. Ideally, screening is standardized across a variety of barriers such as time, place, condition, and user.

Review of proactive treatments

One form of proactive treatment that has gained traction is the rapid response team (RRT). Most of these teams are used to counteract extreme illnesses such as cardiovascular events and other medical emergencies that respond to highly specialized technical care. Garretson *et al.* [4] offered that the use of rapid assessment breaks traditional hospital hierarchies or silos that delay care, noting that the role of the team is to assess the patient, assist the bedside nurse in providing the most appropriate care for the patient, and determine whether the patient needs a higher level of care and where that care can be provided. The effectiveness of RRTs has been measured by reduced unplanned intensive care unit (ICU) admissions [5, 6], reduced incidence of cardiac arrest and mortality [7], and increased patient, family, and staff satisfaction [8, 9]. These teams adopt a proactive approach, which contrasts with the reactive nature of conventional care such as traditional cardiac arrest teams [10].

One modification of the RRT is a 'rover team' which identifies at-risk patients and facilitates the prompt administration of time-sensitive therapies [11]. This proactive approach provides a critical care resource and improves clinically important outcomes, at a lower level of cost than a reactive approach. One randomized controlled study measured the efficacy of a proactive infection control team [12]. The team visited patients on the study wards daily and identified risk factors for developing health care-associated infections (HAIs). If risk factors were identified, the team worked with the treating clinicians to eliminate those risk factors, which resulted in a significant decrease in the incidence of HAIs. Another quasi-experimental study [13] found that a proactive response system identified subtle signs of deterioration faster than a control unit without a system of proactivity. This experimental unit used the physiological measures of patients to generate an alert for early warning signs of patient deterioration. These measures were updated regularly throughout the day, and if a patient generated a score above a set threshold, an RRT was activated. This is an example of delivering expedient and appropriate expertise to patients in need. On the back end of hospitalization, when cost and oversubscription become a problem, a proactive palliative care nurse consultation was shown to reduce the length of stay (LOS) in a medical ICU by almost half (8.96 vs 16.28 days; $P = 0.0001$) without any impact on mortality or other salient clinical measures [14]. In yet another study, proactive consultations for geriatric patients undergoing repair of hip fractures resulted in an 18% reduction of post-operative delirium [15]. Additionally, proactivity has been found to affect patient and staff experience, with one proactive approach to hourly rounding by nursing staff resulting in improved patient satisfaction and staff morale [16].

In several studies of medical rounding, researchers pursued a proactive approach through the inclusion of non-conventional professionals. These professionals were sought for their expertise and skills which were employed to help detect signs of problems that might cause complications in patients' hospital stays and to offer solutions. In an innovative proactive approach, investigators found that the inclusion of a clinical medical librarian as a part of the medical team during daily rounds helped to improve the performance of the team, as measured by lower LOS and lower readmission rate [17]. The librarian helped to clarify clinicians' questions immediately during rounds or after through prompt email responses. Shortened LOS

and lower readmission rates were also the outcomes of a multicentre quasi-randomized controlled clinical trial that included a pharmacist on a medical team in two internal medicine and two family medicine services [18]. The pharmacist helped to resolve drug-related issues and make suggestions for improvement by reviewing patients' medication histories and participating in rounds and discharge counselling. Another example is the development of a new system of multi-disciplinary rounds [19]. A team of clinicians from medical wards, as well as other specialty services, designed a new process for performing rounds that targeted care inefficiency, poor communication, and redundant documentation. The new standardized method of rounding increased the frequency to daily, included all disciplines involved in patients' care in the interaction, and made workloads more predictable by requiring orders to be written during the rounds. The new method of rounding resulted in both decreased cost and decreased LOS in the treatment groups, as compared to controls.

This review of proactive services for disciplines outside psychiatry illuminates the critical design features that a proactive service might contain. Fig. 137.1 outlines the eight proposed critical design features. Perhaps the most important design feature for a psychiatric proactive approach is that it must comprise clinicians from various disciplines (at least nurses, physicians, and social workers). Additionally, these clinicians should be flexible and devoted, enquiring practitioners who are looking for the right clinical answers to the patients' troubles. Having multiple practitioners who overlap in tasks and skill sets offers more flexibility and depth in personnel, and knowledge. A second design feature is the availability and clear definition of discoverable facts within the patients' narratives and behaviours that may be harbingers of mental illness. Screening algorithms serve this purpose well. Furthermore, practitioners must have the skills to detect and interpret these signs and symptoms. The third necessity for a successful team is for the clinicians to be well trained, so that they can interview patients efficiently and quickly develop an accurate idea of what may be wrong. The fourth feature is to have a standardized and thorough assessment which helps to ensure accuracy of diagnosis. The fifth feature is the availability and prescription of an effective treatment. The sixth is the follow-up, monitoring, and assessment of treatment delivery and effectiveness and assisting in post-hospitalization care. A seventh feature is that the practitioners should be fluent with each other's disciplines and aware of each other's strengths and weaknesses. This allows for timely and unambiguous communications, as well as on-site education. And finally, there should always be an educational function and goal with non-specialty staff.

Programme descriptions

Desan *et al.* [20] reviewed the literature on the impact of consultation services on LOS and discussed the impact of a proactive approach. In the review, ten studies were identified that demonstrated increased consultation rates, four of which demonstrated improved LOS. Twelve studies examined the salience of consultation to geriatric patients, four of which demonstrated significant improvement in LOS. This review did not include the proactive psychiatric studies from Yale, Columbia, or Birmingham City Hospital. The review

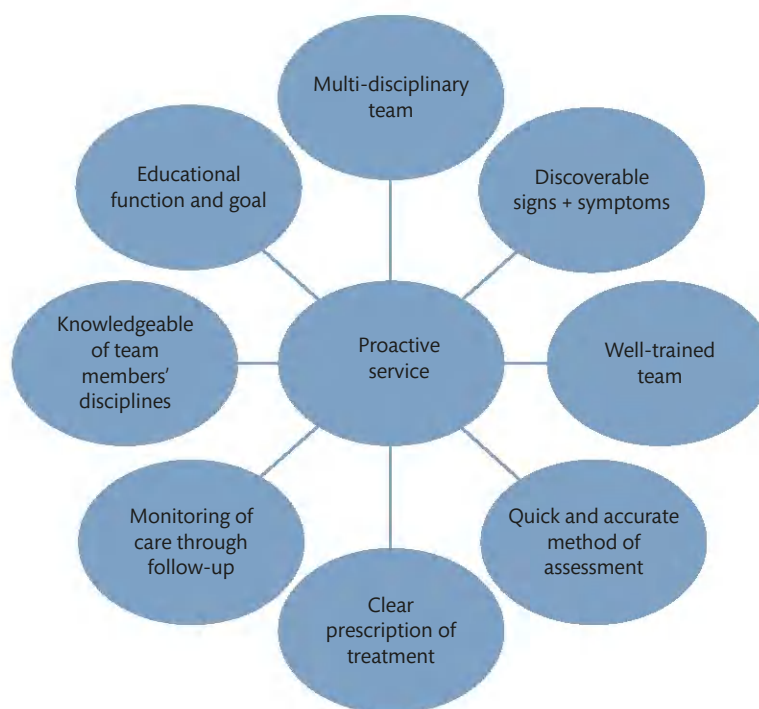

Fig. 137.1 Design features of a proactive intervention programme.

did include the proactive geriatric service described by Sennour *et al.* [21].

Three comprehensive models of proactive psychiatric services have been developed and reported in the literature in the last 7 years. All three models are general hospital-based and would qualify as ‘indicative prevention/treatment approaches’, as all patients within the total inpatient population on or within an organization (service, floor, unit, etc.) are screened for the presence of mental illness, substance abuse, severe character disorders, or situational stressors. One is from the United Kingdom, and two are from the United States. All interventions came into being within a year of one another, though none were aware of the others.

The innovative proactive Rapid Assessment, Interface, and Discharge (RAID) model in the United Kingdom was developed to serve the 600-bed City Hospital of Birmingham [22]. RAID is a rapid-response, ‘age-inclusive’, comprehensive mental health intervention. During the study period, the team responded to 91% of accident and emergency (A&E) service cases within an hour (average of 24 minutes), and 89% of general and specialty ward cases within 24 hours (average of 16 hours). It also provided periodic training to the staff in these settings about the care of patients. The presence of RAID increased the detection of mental illness and reduced readmissions.

The assessment of the effectiveness of RAID entailed a novel approach of comparing populations in a before-and-after trial, in which patients were matched by risk factors and drawn to create three different analytic groups. The first group consisted of patients treated prior to the implementation of the RAID intervention and who had only received standard consultation services. The second group were the RAID recipients, and the third were those who were contemporaneous to the RAID recipients but had not received the intervention and were referred to as RAID-influenced. The clinical

outcome variables were LOS, readmission rate, cost savings, and quality of care, as measured by the percentage of mental health diagnoses detected. The authors noted that they reduced the LOS, which equated to savings of 21–42 beds per day and reduced readmissions, saving 22 beds per day. The economic assessment carried out by the London School of Economics used the estimate of at least 44 beds per day, resulting in an estimated savings of £3.5 million. The authors believed this was a conservative estimate and that the actual savings would have been more like £4–6 million. During the intervention, the City Hospital was able to close 60 beds without cutting down on services.

From the United States, Muskin *et al.* [23] reported on a ‘quality improvement program’ in which psychiatrists and internists co-managed patients with comorbid psychiatric and medical conditions. In a before-and-after trial on a single unit, they found that the intervention resulted in a statistically significant reduction in LOS of 1.19 days among patients, with an LOS of less than 10 days. When annualized, the total number of saved days was 2889. The estimated cost per day was \$600, resulting in an expected annual savings of over \$1.7 million per year. The intervention paid for itself, as the estimated savings were more than three times the cost of the intervention teamworkers’ salaries (2.5 full-time equivalent psychiatrists, in addition to a social worker).

Aspects of the Yale proactive approach have been reported in three different publications from two different, but related, interventions. The first, a pilot and feasibility study [24] demonstrated the value and effectiveness of a psychiatric proactive approach, revealing potential clinical and financial advantages, as well as areas for improvement. This initial study was conducted in a 30-bed general internal medicine inpatient unit at Yale New Haven Hospital. In an A-B-A single case study design, the patients’ average LOS and consultation rates were examined in three different time frames. These were, in order,

the pre-intervention period in which there was an initial study of the LOS in the usual treatment phase of the study for 6 months, the proactive intervention period for roughly 5 weeks, and the 6-month post-intervention period in which the unit resumed the usual conventional consultations as the mode of psychiatric treatment for the patients. On this general service, among patients whose LOS was 30 days or less, the intervention reduced the LOS by 0.9 days (from an average of 3.8 days, chi square = 6.38, $df = 2$; $P = 0.04$). The consultation rate was 22.6% during the 5-week intervention period, and 9.3% and 12.0%, respectively, during the two control periods of before and after the intervention.

The intervention team screened 100% of all admissions, with the initial contact being within 34.6 hours of admission, while the conventional consultations occurred, on average, at 72.5 hours into the admission during the two control time periods (note that the average LOS for the unit which was 3.8 and 3.7, respectively, for the two control times in the A-B-A comparison). The average length of the proactive screening assessment was slightly less than 3 minutes. There were no discernable differences in age, ethnicity, or medical acuity among the three different patient groups upon which the conventional and proactive services consulted ($N = 257, 62, 274$, respectively). The screenings revealed that 51% of patients on the study unit had a psychiatric condition that required treatment or consultation. Substance abuse disorders accounted for 43%, the largest portion of the detected difficulties. Mood and anxiety disorders (30%), psychotic disorders (13%), suicide attempts (7%), and delirium and dementia (6%) accounted for the rest.

After the initial pilot study was completed, and the service was terminated due to a shortage of staff, we used the results and experiences of the staff and patients to create a proposal for an enhanced proactive service. In addition to the reduction in LOS, responses of the nursing staff on a satisfaction measure administered after the initial study described high praise, with 80% of staff giving the service the highest rating possible. The medical team also expressed their pleasure with the increased presence of a psychiatrist [roughly 0.25 full-time equivalent (FTE)] on the unit. The estimated financial benefit was roughly \$828,722 (\$237,286 for cost avoidance by reduction of LOS, and \$591,436 for revenue enhancement from backfilling the saved days). The only added cost was \$56,550 (annualized) for the psychiatrist's extra time during the 5 weeks that the intervention was in place. The annualized net financial benefit was estimated to be \$772,172, with a cost-to-revenue ratio of 4.2 (cost-effectiveness is calculated by adding the expenses of the intervention to usual costs and dividing that into the total dollars received).

Given the promising LOS reduction, high staff morale, and good contribution to the bottomline of expenses and revenues, a case was successfully made for the implementation of another version of a proactive psychiatric consultation service. This version was a team approach that was given the name behavioural intervention team (BIT). This second iteration was implemented on three internal medicine inpatient units (92 total patient bed capacity), with a team of a part-time psychiatrist (0.5 FTE), a full-time nurse practitioner (APRN), and a full-time social worker. We worked with a bio-psychosocial understanding of the patient's hospitalization, and hence the skills and perspectives of the aforementioned various medical professional groups were essential [25–28]. We decided on a team approach, as there were multiple tasks and domains that required different skills and knowledge for a maximally

effective hospital experience. Examples of such tasks are support, encouragement, reassurance, medication when needed, accurate diagnoses and formulation of their problems, education, social and family support, and the mental health practitioners' support of staff. Again, we achieved a good reduction in LOS (0.65 days; $P < 0.02$) in the before-and-after trial from the three general internal medicine units. We ran the comparison for the same 11 months in two successive calendar years. There were 509 patients in the treatment group and 535 in the control group. The team not only screened 100% of the admissions, but also evaluated and cared for the psychiatric patients who could not be effectively managed by the regular medical staff and provided education for the staff about these patients. The multi-disciplinary nature of the team also allowed the treatment team to educate the staff in a practical and individualized manner about the mental health and social issues of each patient. This type of education was termed 'just-in-time education'. The added dimension of education enhanced the satisfaction of the staff and provided more skilful and effective interventions for patients.

The economic benefits of the BIT were characterized by a reduction in LOS, as well as the provision of added services and features associated with caring for patients who were behaviourally challenged. The incremental costs of the team were compared to the incremental economic benefits to the hospital as a result of the team's work. We conceptualized the economic benefit of the team's work in terms of the overall cost of the patient's hospitalization, as measured by the LOS and extra services such as sitters or other types of increased staffing. It was hypothesized that the intervention would have the greatest impact on LOS, readmission rate, and sitter use. There was an additional economic benefit of more filled beds which were made available by the increased efficiency of bed use (0.65 days of reduced LOS) without increased expense. Furthermore, when these patients with mental illness or psychological distress were given the care they needed in a timely, effective manner, both their medical and psychological outcomes improved. At the time of this study, the hospital was reimbursed for medical services almost exclusively by a case rate methodology, as opposed to a per diem rate. We compared the experience of the three medical units in a before-and-after implementation evaluation design of the intervention over successive and same 11-month calendar periods.

The average LOS for patients in the two intervention periods are presented in [Table 137.1](#) [27]. The before-period consisted of treatment as usual with reactive conventional consultation liaison (CCL). The after-period was when the proactive BIT was employed. For the LOS expense calculations, the comparison was based on a blended rate. Included in the expenses were sitter costs, as well as room and medication costs, and associated overhead allocations. For income, a blended rate that reflected the proportion of different payers was utilized. The details of this economic relationship are presented in detail in another publication [27]. In the pilot study of proactive consultation with only a psychiatrist providing the services for one internal medicine unit, the economic benefit or cost-effectiveness ratio was estimated, conservatively to be 4.2. The same ratio in this before-and-after implementation was 1.7, meaning that for every dollar spent over and above usual care, \$2.70 were received.

[Table 137.2](#) [27] shows the direct cost metrics and comparison of the second study. The total saved cost for the intervention (not annualized) was \$107,027 or a case rate of \$210 saved on average per patient. There is also the opportunity for enhanced revenue by the

Table 137.1 Length of stay metrics for the second study

Population	CCL period N Mean (SD)	BIT period N Mean (SD)	Period effect Test statistic (df) P-value
Patients with psychiatric intervention and LOS <31 days	535	509	$T = 2.86$
	7.29	6.65	(1042)
	(5.76)	(5.75)	0.004
All patients with LOS <31 days	5158	5391	$F = 8.39$
	4.98	4.68	(215, 457)
	(4.62)	(4.38)	0.0002
All patients	5251	5490	$F = 6.90$
	5.87	5.58	(215, 755)
	(8.9)	(9.12)	0.001

creation of empty beds. The value of enhanced revenue will vary by institution and setting. For instance, the freed-up bed space due to reduced occupancy from the shortened LOS allows for more revenue. **Table 137.3** [27] summarizes the calculations for increased revenue realized due to the increased capacity created by the LOS reduction over 11 months.

The actual realized income will vary, depending on the mechanism of payment and the amount. For example, a case rate will be potentially more lucrative than a per diem rate, as the case rate incentivizes efficiency and reduced LOS. Furthermore, the magnitude of benefit realized by increasing capacity will vary per rate of backfill. **Table 137.4** [27] illustrates the change of revenue, depending on the percentage of occupancy rate.

It should be clear there will likely be a substantial economic benefit from a proactive psychiatric consultation service, regardless of the payer, unless the utilization of beds is lower than the break-even point which, in our institution, is at 50% occupancy. The same will hold for revenue per case. **Table 137.5** [27] summarizes the expected consequences of various scenarios for revenue per case.

Table 137.6 [27] summarizes the annualized costs of the programme in terms of salary expenses, incorporates the credits of reduced costs and enhanced revenue, and provides an integrated financial return on the BIT.

Table 137.2 Direct cost comparisons

Population	Cases	Direct cost/case
BIT, LOS <31 only	509	\$6550
CC, LOS <31 only	535	\$6760
Total cost per case difference		
BIT minus CL (\$210) times 509 cases	(\$107,027)

Clinical process and considerations for the future

Clinically, in the 11-month trial, there were 5641 admissions to the three units. While we screened almost all patients on admission for the BIT trial, 945 patients, or 17%, were noted likely to be in need of psychiatric services. The incidence of the major diagnostic groups that required the attention of psychiatric services because their psychiatric condition was requiring psychiatric care was 63% (of the 945 screened); 52% required specialized (in mental health) discharge planning; 34% were seen for addiction; 18% were seen for delirium/dementia; and 17% had a behavioural issue that interfered with medical care [28].

The outcome of this study allowed us to implement the BIT on all medical units at Yale New Haven Hospital, York Street Campus, and on half of the medical units at our recently acquired nearby campus of the former Hospital of Saint Raphael. The multi-disciplinary teams perform the various clinical tasks noted in **Fig. 137.1**. Through screening 100% of the admitted patients, BIT staff quickly identify those who will require and/or benefit from a psychiatric consultation. This is accomplished by reviewing the medical and social histories provided in the patients' electronic medical records within 36 hours

Table 137.4 Incremental revenue based on bed demand: alternate estimates of incremental net revenue

Revenue	Backfill (%)	New cases	Annualized
\$723,889	100	57.08	\$789,697
\$651,500	90	51.37	\$710,727
\$579,111	80	45.66	\$631,757
\$506,722	70	39.96	\$552,787

of their admission and discussing the patients with the admitting nurses and/or attending physicians. Those patients who screen positive for the likelihood of being able to benefit from a mental health consult are evaluated by the end of the second day of their stay. The 'treatment' that they receive may be extra support and attention to their mental illness by either the APRN or the doctor, depending on the problem and/or disposition assessment by the social worker who evaluates the various requirements related to different social elements such as family, living arrangements, and work. Those who will be at risk for difficulty at discharge due to their mental health or social issues are evaluated early on in their hospital stay, so that any serious psychiatric issues can be resolved early enough to accept an appropriate transfer to a psychiatric facility or discharge. They are evaluated by the psychiatric social worker on the team who works with the medical-floor social worker to fashion a suitable disposition. The unit's general medical nurses and the medical social workers are encouraged to support the patient in their capacity and look out for problems at disposition. If this is not enough to manage and treat the patient effectively, BIT members provide the mental health services and use that intervention as a teaching exercise for the staff on the units.

The doctors on the BIT oversee the treatment plans and spearhead the resolution of medically related problems for disposition. The doctor is also the leader of the team. However, the team is intensely nurse-oriented, and the medical-floor nurses can ask for

consultations and support from any one of the team members. In terms of our cartography of the interventions for prevention and treatment noted, this is universal in that all patients get screened and may be categorized into a group that needs treatment (at least 25% of the patients have a history of mental illness). This includes our educational efforts with the nursing and medical staff at recognition, diagnosis, and treatment. The next level of preventive intervention that makes this an 'early' or proactive intervention is that those who may have a pre-existing psychiatric condition or who demonstrate some likelihood of disruptive behaviour or suffer from mental illness, such as confusion, irritability, fear, or depression, are treated immediately with no lapse in their care, before their behavioural or mental health condition can become a disruptive factor. For those who are clearly manifesting psychiatric problems, their care is taken on immediately by the mental health professionals and their condition elaborated and explained to the nursing staff as the characterization of the intervention moves from selective to indicated.

The team functions both as practitioners of psychiatric care for patients, but also as educators and assistants for the regular unit staff. BIT team members and floor staff co-monitor patients who are in the selective category of prevention and treat or supervise the care of those who are in the indicated category, while they monitor and teach the treatment given by the medical/nursing team with primary responsibility. The education can take many forms such as: formal and informal supervision, tutorials, case conferences, case reports, and orientation. One common form is the 'just-in-time' education previously mentioned. This is education in which staff observe the experts in action and may informally seek their advice. Tadros *et al.* described a similar interactive education provided by RAID and noted that the instruction of the RAID team members helped junior doctors and nurses to better manage difficult patients and more accurately identify those patients who should be referred to psychiatric services [22]. Typically, the 'just-in-time' intervention will be triggered by a request from a medical or nursing staff member for advice on the care of a patient.

The interventions employed are: (1) the assessment of risks and whether risk categories have reached the level of indicated treatment; (2) the prescription of care in the development of a behaviourally oriented treatment plan, at all times supporting the patient; (3) the provision of just-in-time education that increases the effectiveness of the floor staff in their interactions with patients and encourages them to try out the perspective and skills themselves; (4) the assessment of the family and subsequent discharge; and (5) the actual care itself for those difficult patients. The goal is to produce outstanding clinical care in the most cost-effective manner possible.

At present, we have implemented the BIT only for internal medicine services on two of the hospital campuses. The programme is especially popular with nursing staff, as nurses are the hospital professionals most directly affected by the presence of the BIT. There are plans eventually to expand to cardiology, cancer, and appropriate surgical specialties. In each of these instances, we will take into consideration the dynamics of admission, treatment, and discharge, so that we can design a programme that functions well at the decisional points in the patients' hospital career.

Common sense tells us that proactivity and early intervention are clearly strategies that are effective in the face of the cascade effect [29]. In health care, the cascade effect is the process of deterioration of health when the resources available to the patient do not match

Table 137.6 Summary of net financial return on BIT

Estimated financial benefit	11 months	12 months
Incremental net revenue from backfill (filled at 100%)	\$723,889	\$789,697
Overall reduction in cost/case for BIT cases, including	\$107,027	\$116,757
Reduction in use of sitters		
Subtotal, estimated financial benefit	\$830,916	\$906,454
Estimated additional expenses	\$306,230	\$334,069
Estimated benefit minus expenses	\$524,686	\$572,384

the needs of the patient's environment, so that a feed-forward state ensues, in which unmet demands in one sector (that is, attending to medical appointments) result in an ever more serious and numerous unmet demands in other sectors as the person sacrifices resources from one sector (for example, saving money previously used for transportation) in order to correct unmet other demands (buying groceries). This cycle continues until the patient's health becomes unstable to the point where hospitalization or acute care is warranted. Effective holistic programmes are those that have a clear understanding of the costs and benefits of the intervention programme in its totality, so that the system in which the patient lives can be stabilized and recovery becomes an option for more people sooner in the cycle of their illnesses than would otherwise pertain.

The future

Other features that we intend to investigate and possibly develop are the integration of inpatient and outpatient experiences through the maintenance of continuity of care. We believe that integrating care should make the continuity of care between inpatient and outpatient more effective, which will further reduce the need for, and length of, hospital stays. In addition, we plan to document and better understand the role and value of informal consultations, or 'curbside consultations' which are not typically noted in the medical records and have no income associated with them. Nevertheless, they appear to be effective and valuable to the recipients. We believe that the RAID programme's educational effect is similar to what we call 'just-in-time' education.

And finally, our ambition for the future is to create a consortium comprising a regionally based group of hospitals or other health care entities capable of serving large populations of patients and that can develop this model and share experiences, so that information, data, ideas, and experiences can be shared and a more substantial research programme can be developed to refine and pilot innovation.

Refugees and populations exposed to mass conflict

Mina Fazel, Susan Rees, and Derrick Silove

Introduction

This chapter will consider the mental health needs of refugees and other populations forcibly displaced because of exposure to mass conflict. Migration has been a hallmark of humanity over millennia, the reasons leading individuals or groups to move being numerous and often multi-faceted. Migration can be forced or by choice or a combination of these factors; for example, poverty or natural disasters might lead a person or group to leave their home out of choice, but elements of compulsion can play a role such as severe food insecurity. This chapter will consider those obliged to leave their homelands for reasons of persecution and exposure to mass conflict, populations broadly referred to as refugees. The terms utilized to describe these populations are summarized in [Box 138.1](#) [1], highlighting the different groups to consider; however, for the purposes of this chapter, *refugees* will be used to describe this population, unless reference is made to specifically defined groups.

The mental health of refugees continues to be an important area of clinical work and research, and one that highlights the complex interplay among biological, psychological, social, and cultural processes in determining how individuals vary on a spectrum of adaptation to frank mental illness. The psychological impact on a person, family, and groups forced to migrate because of conflict can be considerable, the effects generally being negative, but, in some aspects, potentially positive. To leave an environment of extreme insecurity in order to reach a new country of safety is likely to enhance the mental health and well-being for many; the focus of this chapter, however, will be on the varied mental health risks associated with forced migration and the factors preceding and following that major event. We will describe the mental health impacts of forced displacement and the essential role that both previous and ongoing exposures to traumatic events, ongoing stresses, and broader psychosocial influences play in generating or maintaining the psychopathology and the appropriate interventions that may assist in overcoming these adverse outcomes. Selective high-risk subpopulations will be described in more detail, including unaccompanied refugee minors, persons living in states of protracted insecurity, such as in refugee camps, women and their children, and those caught in cycles of violence, for example

in situations where post-traumatic anger presents a risk to the individual, those close to them, and the wider community.

The global pressures causing forced displacement show no signs of abating, including the Syrian civil unrest which has caused a substantial movement of forcibly displaced populations. In 2015, the estimated number of people displaced by mass conflict reached 65 million worldwide [2]. A total of 12 million were displaced in 2015, with at least 40 million believed to be internally displaced. The majority of refugees live in protracted insecure situations, often in makeshift settlements in countries neighbouring the site of the conflict, almost all in low-income countries. Only a small portion are able to travel to high-income countries. [Table 138.1](#) lists refugees and asylum seeker populations by country of origin and destination [2], and [Fig. 138.1](#) is a graph showing the changes over the last 15 years in the numbers being displaced across the globe.

Mental health needs

Refugee populations are exposed to a number of stressors that may impact on mental health, many of these factors operating simultaneously or in sequence. Refugees commonly experience personal grief often complicated by the nature of the multiple losses they experience, including murders, disappearances, kidnapping, atrocities, and sex slavery, and more general potentially traumatic events such as violence, torture, sexual abuse, and arbitrary incarceration. As a group, refugees experience major psychosocial and cultural upheavals of having to leave their families, homes, communities, and work to seek personal security. Evidence suggests that two sets of factors are of key importance in impacting on the mental health of refugees: exposure to past and ongoing potentially traumatic events, and the complexities of navigating the post-migration environment as both individuals and groups [3–5]. These inter-relationships have been best described by Miller and Rasmussen (2016), from which [Fig. 138.2](#) has been adapted [3].

The actual rates of mental illness identified among refugees vary by population, their exposures to potentially traumatic events, their current living arrangements (where and with whom they are currently

Box 138.1 Definitions of migrant populations and subgroups

Migrant: A person who has moved across an international border or within a state away from their habitual place of residence, regardless of their legal status, whether the movement is voluntary or involuntary, what the causes for the movement are, or what the length of the stay is.

Refugee: A person who, owing to a well-founded fear of persecution for reasons of race, religion, nationality, membership of a particular social group, or political opinions, is outside the country of his or her nationality and unable or, owing to such fear, is unwilling to avail themselves of the protection of that country; often strictly defined according to the 1951 UNHCR Refugee Convention.

Internally displaced person: A person who has been forced to leave their place of habitual residence as a result of armed conflict, generalized violence, violations of human rights, or natural or human-made disasters, and who has not crossed an internationally recognized state border.

Asylum seeker: A person who seeks safety from persecution or serious harm in a country other than their own and awaits a decision on the application for refugee status under relevant international and national instruments.

Stateless person: A person who is not considered as a national by any State under the operation of its law. As such, a stateless person lacks those rights attributable to protection of a State, no inherent right of sojourn in the State of residence, and no right of return in case he or she travels.

Irregular migrant: A person whose movement takes place outside the regulatory norms of the sending, transit, and receiving countries and increasingly used for a person who has been smuggled or trafficked.

Trafficked: A person who has been recruited, transported, transferred, harboured, by force or other forms of coercion, abduction, and deception, to achieve one person having control over another person, for the purpose of exploitation. Trafficking in persons can take place within the borders of one State or may have a transnational character.

residing), and the long-term security of their place of residence. In general, rates of depression, post-traumatic stress disorder (PTSD), and anxiety disorders are high, compared to non-displaced populations, with some suggestion that the prevalence of psychotic disorders is also increased [4, 6, 7]. Nevertheless, there is considerable heterogeneity in reported rates of mental disorder across studies, most likely because of variation in sampling, measurement, and the characteristics of the groups under inquiry. The sociodemographic profile of the population alone may influence the overall mental health status of individual groups. In a meta-analysis published in 2005 on pre- and post-displacement influences on mental health, refugees who were older, more educated, and female, those who had higher pre-displacement socio-economic status, and persons from a rural background had worse mental health outcomes [4]. Some studies have identified higher rates of somatization [5], and others have suggested an elevated suicide risk among refugees, especially when there are significant post-migration stressors [8]. Several factors have been shown to be associated with suicidal risk among refugees, including lack of employment, access to resettlement services and social support, distress related to separation from families, past trauma exposure, and integration difficulties in the resettlement country. Discrimination against ethnic minorities is also associated with poor mental health among refugees, a society-wide problem that is of particular relevance to contemporary resettlement environments. These factors, along with the stigma that often accompanies mental illness, can complicate efforts to seek treatment after resettlement [8] (Box 138.2).

Long-term outcomes

The complexities of studying refugee populations are most evident when considering the array of long-term mental health implications associated with their experiences; although studies are limited, there is evidence that mental disorders, especially PTSD, tend to be highly prevalent in these populations, even years after resettlement [15]. As identified in a systematic review on studies of populations resettled for more than 5 years, this increased risk seems to be a consequence of exposure to both conflict-related trauma, post-migration socio-economic factors, and more general living difficulties [16]. The systematic review identified 29 studies, of which only 13 were deemed of high quality. Consistent with past findings, there was substantial heterogeneity across studies in the prevalence rates of depression (range 2.3–80%), PTSD (4.4–86%), and anxiety disorder (20.3–88%). Nevertheless, prevalence estimates were typically in the range of 20% and above for any disorder, the lowest rates being found in the higher-quality studies. Descriptive synthesis suggested that greater exposure to pre-migration traumatic experiences and post-migration stressors, the higher the rates of all three categories of mental disturbance (PTSD, depression, anxiety), while a poor post-migration socio-economic status was particularly associated with depression.

Impact of exposure to previous and ongoing traumatic events

Impact of other post-migration stressors

Specific post-migration displacement stressors that have been shown to influence mental health include social isolation resulting

Fig. 138.1 Graph to show rates of newly displaced persons from 2003 to 2015.

from the loss of social networks [17], unemployment (either due to limited rights to work or because of local employment demands [17, 18]), poverty [19, 20], perceived discrimination [21], increased violence against women [22–26], and a lack of safety when living in refugee camps [20, 27]. These post-migration living difficulties prolong pre-existing feelings of insecurity and deplete the capacity of displaced persons to manage ongoing challenges, a compounding of prior conflict-related experiences and ongoing stressors, a combination of factors that increase the vulnerability to disorders such as PTSD [28].

A conceptual model for understanding the refugee experience

When attempting to understand the full range of experiences of refugees, it is important to consider a number of interacting domains: early developmental experiences; the context and culture of origin; and the sequence of changes that have occurred through the phases of mass conflict, displacement, transition, and final resettlement [29]. There are multiple levels of influences (political, social, cultural, familial, and physical/biological) that impact at each phase on the adaptive capacity of refugees, their families, and the wider community; the outcome of these attempts to adapt may be positive

or, in conditions of overwhelming stress, may result in severe distress and ultimately mental disorder. The Adaption and Development After Persecution and Trauma (ADAPT) model identifies five core psychosocial pillars challenged by the sequence of experiences that refugees encounter [30]. These pillars, which form the foundations of stable societies, maintain social cohesion, as well as individual mental health. Specifically, the pillar of *safety* and its maintenance are vital to the person's sense of security and protection, with conditions of pervasive or recurrent threat generating anxiety and fear, the extreme outcome being disorders such as PTSD. Maintaining *interpersonal bonds* (nuclear and extended family, networks) is essential to mental well-being. Multiple threats to attachments and repeated traumatic losses can lead to severe distress, including symptoms of complicated grief and separation anxiety. The maintenance of *roles and identities* (cultural, social, family, personal, work-related) is vital to prevent alienation, isolation, and marginalization, a state referred to in sociology as anomie. Finally, the sense of *meaning and coherence* in life is critical to forming a positive view of the present and future, the existential domain which may be expressed in political values, religious beliefs, social and cultural affiliations, and/or spirituality. All five domains, and the institutions and social rules that support them, tend to be undermined by the refugee experience,

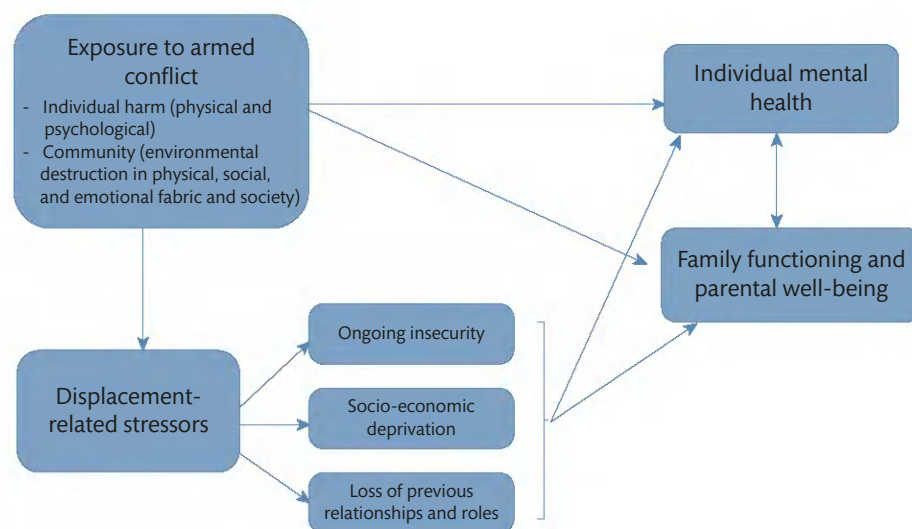

Fig. 138.2 Relationship of armed conflict, displacement, and mental health.

Box 138.2 Assessment of refugees in mental health services

In addition to the usual assessment required of any person referred to mental health services, there are a number of areas that it might be of additional importance to question. These include those identified in the ADAPT formulation described in the text, but the core elements of assessment are detailed here.

Background history

- Description of previous life before difficulties that led to displacement.
- Sensitive enquiry of reasons as to why they had become displaced: any experience of incarceration, torture, abuse directed to themselves or family members and other close associates, including sexual abuse. Significant losses experienced of family members, friends, and colleagues.
- Enquiry as to how they arrived in their current place of residence: how did they travel, were they placed in hands of strangers or traffickers, did they spend time in a refugee camp, experiences and exposure to abuses in these environments.
- Their perceived roles in their families, previous occupation, and communities.

Physical health

- Review of physical health needs is important, as this can be overlooked. It should include chronic health conditions, oral health, and skin. The screening would need to include questions about previous health and exposure to any infectious diseases endemic in the countries of origin and transit, as well as previous injuries [9–11].
- Previous head injury, especially if associated with loss of consciousness, is an important question to ascertain, as studies have demonstrated that this is highly prevalent in torture survivors and can have significant long-term psychological effects, including depression and PTSD [12–14].

Current situation

- Living circumstances: where are they living; with whom; how many house moves have they had since arrival; are they able to afford food, clothing, other necessities; how do they spend their time (as those awaiting more permanent legal status are often not permitted to work); any new family stressors; any family members they are trying to find.
- Immigration status and understanding of the process: these processes can often be complex and hard to understand, as information might not be available in the desired languages; legal representation can be hard to access without financial assistance, and there might be the constant threat of immigration detention and deportation back to either a country of transit or the country of origin.
- Linguistic ability and access to interpreters: this is likely to be apparent in the interview. Mental illness can impact on a person's ability to learn the host language.

impacting at every level on the displaced community and exerting reciprocal effects on the individual capacity to adapt. The extent to which these disruptions can be repaired or accommodated will determine where individuals and their collectives are located on the continuum of adaptation and functional impairment, a failure of adaptation expressing itself in the individual as mental disorder. The ADAPT system can be used as a framework for undertaking a comprehensive assessment of the experiences and psychosocial responses of individual refugees in clinical and other service settings. The model can also provide a framework for assessing the overall needs of refugee families and communities as a first step in formulating effective programmes of psychosocial and mental health interventions.

Specific populations of note

There are a number of subpopulations requiring special attention among the heterogeneous population of refugees.

Unaccompanied minors

An unprecedented number of children and adolescents worldwide are forced to migrate on their own to escape war and persecution [31]. As minors, these individuals face extreme risks to their physical and psychological well-being at an important developmental period [27, 32]. The trauma and hardships that accompany these experiences have potential to create prolonged mental health difficulties [33].

War exposures and ongoing social hardships can be complex and severe in nature for unaccompanied refugee minors. In contrast to single-incident trauma, war-affected youth can experience chronic exposure to traumatic events for weeks, months, or even years, often representing a significant proportion of their life [34]. Among the range of traumatic incidents common in war, children may witness violence, lose family members and friends, experience physical, sexual, and psychological harm, be exploited in various ways (involvement in criminality, prostitution, sex slavery), deprived of food, water, or shelter, or be compelled to inflict harm on others. These exposures have varying impacts for each child, but some experiences are particularly harmful [35]. For example, it is not uncommon for long-term shame and guilt to be experienced by some of these children, responses that are intensified by being forced to serve as 'child soldiers' and either witnessing or participating in breaking cultural taboos such as injuring family members. Managing the social stigmatization and isolation that can follow these experiences adds to the complexities of rehabilitation of these populations.

Studies support the high-risk status of unaccompanied minors. For example, the prevalence of PTSD was increased among unaccompanied minors resettled in Belgium, Norway, and the Netherlands [33, 36–38]. War exposure was positively associated with depression among unaccompanied minors on arrival in Belgium [37] and 6 months post-arrival in Norway [36]. In a follow-up study, unaccompanied minors continued to exhibit high scores on anxiety, depression, and PTSD over an 18-month period, with negative outcomes predicted by the number of traumatic experiences and daily stressors experienced [33].

Living in prolonged insecurity such as refugee camp settings

Refugee camps are settlements, usually built with the intention of being temporary, to receive forcibly displaced populations. However, many settlements have grown and become semi-permanent, requiring the development of systems of governance and civic institutions [39]. Approximately one-third of refugees in protracted situations live in camps, some of which have been in existence for over 20 years. In 2015, the largest camps were in Kenya, with occupants primarily from South Sudan and Somalia (for example, the population of Kakuma exceeds 180,000 and that of Hagadera more than 100,000); other large camps have also been established in Jordan for Syrian occupants [40].

Studies have highlighted the mental health risks of living in refugee camps [41, 42]. For example, among Rwandan and Burundese

refugees in a Tanzanian refugee camp, the prevalence of serious mental health problems was estimated to be 50% [43]. Children and young people living in camps (for example, in Central America, the Middle East, and the Former Yugoslavia) have higher rates of mental illness, compared to young people living in other transitional settings [27]. Refugee camps are often unsafe situations, placing children at risk of violence and abuse and consequent negative mental health outcomes. Neglect of basic needs, such as sanitation, parental distress, high levels of poverty, and lack of access to education increase the risk of mental disorder—even though humanitarian organizations and international bodies, such as UNICEF, provide substantial assistance in these settings [44]. Not surprisingly, therefore, a systematic review of 20 mental health studies of refugee/displaced youth residing in camps highlighted high rates of maladjustment, a large number of these young persons experiencing anxiety, somatic symptoms, depression, and aggression [45].

Women and families

Violence against women is a global public health problem. There is a clear association between exposure to gender-based violence, including intimate partner violence, rape, and sexual assault, and mental disorders including PTSD, depression, and anxiety, as well as adverse psychosocial outcomes such as increased suicidal ideation [46]. Social and cultural factors influence the risk of violence against women. In particular, violence is higher in societies that are patriarchal, that is where authority in the household is reserved for men, and many contemporary settings of mass conflict involve populations with these traditional customs. In these contexts, women are at risk because of the prevailing culture of patriarchy and the disruptive and traumatic effects of mass violence [47]. The sequence of factors that increase the risk of intimate partner violence is complex, commencing with the increased risk among those exposed to early childhood abuse and violence (involving both sexes), experiences of war-related trauma, and conditions of extreme deprivation and poverty in the post-conflict environment, stressors that are common among displaced populations in low-income countries [48, 49]. Laws and customs that promote and protect women's rights and entitlements may also be regressive or undermined by war and conflict. The society as a whole may have lost its regulatory capacity, for example to intervene in situations of family conflict, and the exigencies of survival and the stresses arising from these pressures may reinforce traditional roles, including gender-inequitable practices.

War-specific factors can directly endanger women. The militaristic culture associated with war, for example, can intensify women's subordination and increase the risk of gender-based violence [50]. Rape is commonly used as a weapon of war and intimidation, leading to demoralization, humiliation, and isolation of women survivors and impacting more widely on men, families, and communities [25]. A recent meta-analysis of studies found that one in five refugee or displaced women in complex humanitarian settings have experienced sexual violence [51]. This is likely to be an underestimate, given the multiple barriers associated with disclosure, particularly in such unsafe settings. As indicated, gender-based violence is associated with a range of mental disorders, including PTSD, outcomes that further undermine women's functioning and capacity to manage the immediate demands of the post-displacement environment [46].

Women are critically important to ensuring social stability and recovery after conflict, both in the roles they play within the family and

in guiding societies towards a return to peace and security [26]. Yet, qualitative studies confirm that women are often under-represented in decision-making in situations where they could provide a significant contribution to recovery and development. For example, women's voices concerning the violent episodes in refugee camps are often muted and left unheard [50]. It is crucially important therefore to raise awareness of aid personnel and camp authorities to ensure that priority is given to promoting gender equality and to recognizing and addressing factors that may undermine women's participation such as the presence of mental health-related disabilities as a consequence of gender-based violence. Gender equity promotion programmes and an explicit social and legal infrastructure that promotes gender equality should be prioritized to reduce violence against women and promote gender equality [47].

Cycles of violence and human rights abuses that can be perpetuated in peri- and post-migration settings

There is emerging evidence indicating that under certain circumstances, a post-conflict cycle of violence can occur within families and communities in displaced societies. The proposed cycle of violence, partly supported by a growing body of research, proposes that there is a sequence of events in which adults exposed to trauma related to human rights violations are prone to outbursts of excessive anger in the post-conflict period, a sense of enduring injustice playing an important role in engendering this tendency. As a consequence, there can be inappropriate acts of anger and aggression within the family, triggered by relatively minor frustrations and conflict. Post-migration conditions of poverty and insecurity can exacerbate this tendency (see [Fig. 138.3](#)) for a conceptual model to describe these cycles of violence. In affected families, aggression may manifest as family conflict or in the form of intimate partner violence targeting women, and/or in harsh parenting in the upbringing of children. The long-term outcome may be the initiation of pathways in which the effects of trauma are transmitted to the next generation, impacting on their mental health and their tendency towards aggression and violence. A recent study identified a key pathway in this sequence in which male and female partners of survivors of trauma were more likely to exhibit high levels of grief and anger symptoms. Only women partners of men with high levels of trauma, however, showed an increase in PTSD, an important reason appearing to be that women tended to identify with the injustices experienced by their husbands [52].

Societal factors

Detention

In over 60 countries worldwide, including high-, middle-, and low-income nations, immigration detention is used in inconsistent ways to incarcerate some of the persons who have been forcibly displaced. In high-income countries, these practices are applied to selective groups of refugees such as those who arrive without an entry visa and others who are deemed not to have proved their claim for protection. Existing studies suggested that immigration detention is associated with poor mental health outcomes that can last for many years after release, the overall body of evidence indicating that the relationship is likely to be causal [53–56]. Several studies from the UK and Australia showed that the majority (if not all) children surveyed in detention centres meet criteria for at least one psychiatric illness

interventions, for example based on the principles of the ADAPT model [77, 78]. Specific clinical interventions at the individual level include treatments for PTSD following multiple traumatic events, commonly applied approaches being narrative exposure therapy (NET), eye movement desensitization and reprocessing (EMDR), and trauma-focused cognitive behavioural therapy (TF-CBT) [79–82]. At a more general psychosocial level, several approaches are used focusing on groups, the community as a whole, the school, and the family [83–86] (Table 138.2).

Studies of specific interventions usually targeting culturally homogenous client samples tend to demonstrate moderate to large outcome effects in relation to traumatic stress and anxiety reduction [72]. Further work is needed to ensure that these interventions can be embedded and sustained within primary health care facilities, that workers receive adequate supervision to maintain skills and prevent burnout, and that the long-term effects of treatment are maintained.

In designing intervention programmes, beliefs held by refugees about health care—its role, how to access it, and whether it can help—need to be a primary consideration. For example, a study among Somali women demonstrated how their beliefs focused on situational factors as determinants of mental health, in contrast to biological models that tend to drive interventions in Western medicine [92, 93]. These discordant health beliefs resulted in divergent expectations regarding the process and outcomes of treatment and health care interactions. Experiencing unmet and varying expectations, Somali women and their health care providers reported multiple frustrations, which often diminished the perceived quality of health care. Moreover, during the process, previously silent worries about mental health and reproductive decision-making surfaced. To provide high-quality, transcultural health care, providers must encourage patients to voice their own health explanations, expectations, and worries.

There is a consensus that in the resettlement environment, positive psychosocial outcomes for youth and adults depend to a great extent on the integrity and functioning of families. Yet few

intervention programmes in mental health focus specifically on families in the refugee field. There is a pressing need therefore to devise and test mental health interventions that aim to prevent or lessen the effects of family dysfunction on individual mental health. Weine (2011) described eight characteristics that preventive mental health interventions should address to meet the needs of refugee families, including: feasibility, acceptability, culturally tailored, multi-level, time-focused, prosaicism, effectiveness, and adaptability [94]. To address these eight characteristics in the complex environment of refugee resettlement programmes requires modifying the process of research to introduce innovative strategies that build these principles into mental health services. Important principles are adopting a resilience (rather than an illness) framework; promoting community collaboration, participation, and leadership; and utilization of mixed-methods approaches, including focused ethnography. At a wider systems level, promoting preventive mental health programmes for refugee families requires appropriate supporting policy directives, multi-systemic partnerships, and training in flexible implementation research designs that ensure that innovative programmes are rigorously evaluated and the positive findings are captured and disseminated.

In general, controlled studies among refugees and asylum seekers have reported positive intervention outcomes in reducing trauma-related symptoms [84]. For example, there is evidence to support TF-CBT and NET in certain refugee populations. Findings from other intervention studies are limited by methodological constraints such as lack of randomization, absence of control groups, and small samples. Further evaluations of the array of psychotherapeutic, psychosocial, pharmacological, and other therapeutic approaches, including psychoeducational and community-based interventions that facilitate personal and community growth and change, are needed [72]. In addition, there is a need to test the effectiveness of rehabilitation strategies for more complex cases and interventions for refugees with severe mental disorders such as psychosis. There is a need for increased awareness, training, and funding to implement and assess broader psychosocial programmes (working in

Table 138.2 Examples of mental health interventions for refugee populations

Intervention	How delivered	Study example	Findings
Narrative exposure therapy (NET)	Individual sessions provided by lay counsellors (6–10 sessions)	Rwandan and Somali refugees in a Ugandan camp [79, 87]	Significant reduction in PTSD symptoms for NET and trauma counselling groups. Remission of 70% following NET
Common elements treatment approach	Individual sessions provided by lay counsellors	Burmese refugees in Thailand [85]	Significant reduction in depression, post-traumatic stress, anxiety, and aggression scores
Cognitive behavioural therapy (CBT)	Individual sessions (with or without interpreter)	Mixed refugee group receiving CBT in a London outpatient service [88]	Positive PTSD outcomes in both groups (interpreter or not)
Multiple-family group access intervention for PTSD	Multiple-family group (nine sessions)	Families from Bosnia-Herzegovina in Chicago [89]	Improved access to mental health services
Parenting intervention	Parenting programme (eight sessions)	African migrants and refugee families in Australia [90]	Positive change in all parenting domains tested
School-based theatre intervention to improve mental health and academic outcomes	Classroom-based drama workshop	Multi-ethnic high schools [91]	Significant decrease in impairment score for first-generation migrants and increase for second-generation
Classroom-based intervention (CBI)	CBI for aftermath of exposure to potentially traumatic events (15 sessions)	Trials in conflict-affected settings (Burundi, Sri Lanka, Indonesia, Nepal) [44]	Positive change in coping, hope, pro-social behaviour, and functional impairment

synchrony with clinical services) that collaborate with refugee communities in promoting adaptation during the stages of resettlement, programmes that require an innovative approach to ensuring that both the host and refugee communities actively contribute in reciprocal ways to ensure successful integration.

Notwithstanding the documented risks to mental health that the refugee experience generates, these adverse outcomes must be balanced against the potential positive adaptive outcomes among many displaced populations [95]. There is growing interest in issues of youth resilience and post-traumatic growth in the face of adversity; for example, many war-affected adolescents from Uganda did not display psychosocial distress 4 years after the war had ended, despite witnessing various atrocities [96, 97]. Nevertheless, although the relevance of a resilience-oriented approach is broadly recognized, there is little consensus about the definition of resilience and substantial variation in the operationalization and measurement of that construct, a challenge that is increased in relation to ensuring the cross-cultural equivalence of relevant concepts [95]. A study of 26 qualitative studies exploring resilience in young refugees identified six sources of resilience: (1) social support; (2) acculturation strategies; (3) education; (4) religion; (5) avoidance; and (6) hope [95]. These sources indicated that both social as well as personal factors confer resilience in young refugees. Nevertheless, several fundamental issues need to be clarified, including whether resilience is a latent capacity of the individual or is invested in the social sphere in which the person is embedded; and whether resilience is a unique positive characteristic of active adaptation and maximizing the person's potential, independent of mental disorder or simply the absence of the latter.

Conclusions

Refugee communities and people displaced by mass conflict have been increasing in numbers over the last few decades. They can experience a potent mix of biological, psychological, and social stressors that can lead to increased rates of mental health problems, especially depression, anxiety, and PTSD. Furthermore, these populations have increased exposures to a sequence of experiences of violence and abuse, both in their countries of origin, situations of transition such as refugee camps and even when reaching host countries, within their own families and self-induced, in the form of suicidal acts. Refining a suite of broad psychosocial and more specific clinical interventions to address the varied needs of this population requires much further work, the focus being both on mitigating specific mental health problems and preventing adverse society-wide outcomes, including potential cycles of violence in the family and the community.

Associations between psychiatric disorder and offending

Seena Fazel and Mark Toynebee

Introduction

The perception of an association between mental illness and anti-social behaviour has been widespread historically and influenced changes in mental health services and policy, including the development of secure hospitals and specific laws for mentally disordered individuals in the criminal justice system. Over the last few decades, research evidence has clarified the nature of this association and investigated mechanisms. Most of the high-quality evidence for associations between psychiatric disorders and offending has come from epidemiology. Translating the epidemiological evidence into individual clinical assessment and decision-making remains a challenge for the field.

Historical perspectives

Historically, many cultures have assumed a link between mental illness and criminality [1]. In the 1980s, this view was questioned by some research that suggested that schizophrenia and other psychoses did not, in fact, increase the risk of violence [2]. However, from the 1990s, longitudinal population-based studies showed clear evidence of associations between most investigated psychiatric disorders and offending, and also violent behaviour [3]. The magnitude of this association varied from study to study. The influential MacArthur Risk Assessment study that followed up discharged psychiatric patients from three inner cities in the United States reported no such association for a heterogeneous group of diagnoses without substance misuse comorbidity [4]. However, the MacArthur study did find increased risks of violence for some specific mental illnesses, and in particular severe mental illness, and strong links were reported between comorbidity and violent outcomes [5]. In a 2009 systematic review of 20 studies examining the association between psychosis and violence, all included studies found an increased risk of violence when individuals with psychosis were compared with general population controls, links that were substantially increased by comorbid substance misuse [6]. Additional research using population-based sibling-control studies in Sweden [7] and Israel [8] has further

strengthened the evidence of an association. However, any such reviews of association studies need to be viewed in the context of the risks of violent victimization to individuals with schizophrenia [9, 10], the population impact of a particular diagnosis such as schizophrenia on all violent crime, and how this population impact compares with other more common diagnoses.

In addition, the robustness of the research evidence needs to be considered. Typically in this field, exposures and outcomes have been heterogeneous. For exposures, different psychiatric disorders have been investigated, with varying approaches to determining diagnosis. In relation to outcomes, self-report, informant report, arrest, conviction, and imprisonment have been variously reported. Although the relative risks for self-reported and conviction data do not appear to differ in mental illness [11], absolute risks do. As any association between mental illness and offending is subject to a range of confounders and liable to reverse causality, longitudinal studies are key.

Violent offending

Violent crime is particularly important from a public health and policy perspective, as it is less prone to measurement error than other violence outcomes, is associated with more morbidity and economic costs, and may be more generalizable than other outcomes. A consistent finding from population-based studies is that a significant proportion of violent offending is perpetrated by a relatively small number of individuals [12, 13]. Among the mental disorders, violent offending is strongly associated with substance misuse [14, 15] and personality disorder [16], and less strongly with schizophrenia and related psychoses [6], bipolar disorder [17], and depression [18].

Mechanisms linking these disorders to violence have been proposed [19, 20] that has drawn on research examining damage to certain areas of the brain (especially the orbitofrontal region) [21], genetic research [22], neurochemical investigations [23], and imaging studies [24]. There is consistent evidence from animal models that decreased serotonin transmission is associated with aggressive behaviour [25]. In humans, higher levels of serotonin in

the blood of males (but not females) who have committed violent crimes have been demonstrated [26]. Serotonin is metabolized by monoamine oxidase, and it has been hypothesized that decreased expression of the gene for monoamine oxidase A is associated with an increased risk of violence [27], with a gene–environment interaction [28]. Other genes involved with serotonin metabolism have also been investigated such as the *COMT* gene (involved in the metabolism of catecholamines) [29]. However, this research has been influenced by small studies and has not been replicated. Although violence is heritable [30], genetic association studies have reported no consistent associations [31] and genome-wide association studies are now required. Statistical genetic approaches have found shared genetic liability for schizophrenia, substance misuse, and violent crime [32].

Psychoses

Schizophrenia and other psychoses have been shown to be associated with an increased risk for a number of different crimes, including arson, drug, property, and violence [7, 33, 34]. For arson and homicide [6, 35–37], the relative risks are more than 10, compared with population controls. However, absolute risks are low, and, for example, the annual risk for a stranger homicide in schizophrenia is not higher than one in 11 million annually in Western Europe [37]. For violence, the increased odds of violent crime range between 2 and 6 in men, and slightly higher in women, and remains increased when compared with siblings who do not have schizophrenia and related psychoses [38]. The impact of environmental influences may vary with gender [39]. Overall, around one in 20 violent crimes is committed by individuals with psychosis [40].

Risk factors

The strongest predictor of future violence in individuals with schizophrenia is a history of previous violence, especially convictions for violent crime [41]. Clinical factors include persecutory delusions [42], particular if accompanied with anger [43] (consistent with earlier work [19, 44]). This was attenuated after treatment—a finding consistent with other work using novel within-individual designs that has found a reduced rate of violence in patients on antipsychotic medication [45]. Other possible mechanisms include impulsivity, hostility, and lack of insight [41]. Poor adherence to medication and psychological treatments is another risk factor. A reliable finding is the effect of substance misuse [41], which acts as both a mediator and a moderator of the association and in homicide in individuals with psychosis [46]. Comorbidity with substance misuse increases the risk of violent outcomes 8–10 times, compared with the general population [7, 47]. Substance misuse may directly contribute to the risk of violent offending by decreasing adherence to medication, increasing impulsivity and hostility, and worsening certain psychotic symptoms, and indirectly through social networks and antisocial peers. Consistent with the importance of genetics and early environment, a review of risk factors for violence in psychosis found that a history of childhood abuse (OR 2.2, 95% CI 1.5–3.1), parental criminal history (OR 1.8, 95% CI 1.5–2.2), and parental alcohol misuse (OR 1.6, 95% CI 1.4–1.8) were all significantly associated with an increased risk [41]. No significant association has been found with many neuropsychological factors [41], including intelligence quotient (IQ) [47] (Table 139.1).

Table 139.1 Strongest associations between risk factors and violence in individuals diagnosed with psychosis

Risk factor		Odds ratio (95% CI)*
Criminal history	History of assault	21.4 (5.2–86.6)
	History of imprisonment for any offence	4.5 (2.7–7.7)
	Recent arrest for any offence	4.3 (2.7–6.7)
	History of conviction for violent offence	4.2 (2.2–9.1)
	History of arrest for any offence	3.5 (2.1–5.8)
	History of violent behaviour	3.1 (2.2–4.4)
Substance misuse	Comorbid substance misuse disorder diagnosis	3.1 (1.9–5.0)
	History of alcohol misuse	2.3 (1.7–3.3)
	History of substance misuse (alcohol and/or drugs)	2.2 (1.6–2.9)
	Recent drug misuse	2.2 (1.6–3.1)
Treatment	Non-adherence to psychological therapies	6.7 (2.4–19.2)

* All significant to the $P < 0.001$ level.

Adapted from *PloS One*, 8(2), Witt K, Van Dorn R, Fazel S, Risk factors for violence in psychosis: systematic review and meta-regression analysis of 110 studies, e55942, Copyright (2013), PloS. Reproduced under the Creative Commons Attribution License CC BY 4.0.

First episode

Around a third of offending in schizophrenia occurs before any contact with mental health services [36], and approximately one in three individuals with first-episode psychosis exhibit some violent behaviour [48]. Hence, early diagnosis and treatment are likely to reduce violence repetition. In addition, a longer period of untreated psychosis is associated with increased risk [48]. Risk factors for violence in first-episode psychosis include hostility [odds ratio (OR) 3.5, 95% confidence interval (CI) 2.1–5.9], past violence or criminality (OR 3.3, 95% CI 1.8–6.1), and manic symptoms (OR 2.9, 95% CI 1.9–4.4) [48].

Repeat offending

A systematic review [49] and a recent longitudinal study [50] reported a clear increased risk of recidivism in individuals with psychosis. The latter study confirmed this association using sibling pairs released from prison who were discordant for mental disorders. This is in contrast to a previous review that included studies with heterogeneous comparison groups, including some with personality disorders and substance misuse, and therefore was potentially misleading [51]. Further evidence for mental illness as a risk factor for repeat offending was found in a large study of Texan prisoners [52].

Affective disorders

Studies investigating associations between affective disorders and violence are less frequent than those investigating psychosis [53]. Depression has a high prevalence in forensic populations, with up to one in ten prison inmates clinically depressed [54]. Early studies reported an association between depression and violence, but this relationship was mostly attenuated after adjustment for confounders

[11, 55, 56]. This was not a consistent finding, however—and the MacArthur study [4] and some case register studies [57] found links. New work has more clearly demonstrated an association between depression and violence, utilizing longitudinal designs and siblings and twins as genetically informative controls [18]. The latter research reported the odds of committing a violent crime in individuals with depression, compared with the general population, was around three times higher [18]. When depressed individuals were compared to their non-depressed siblings, the increased risk was 2-fold. The absolute rate of violence in men diagnosed with depression was 3.7% over 3.2 years, higher than the rates of suicide (0.6%) and self-harm (3.3%). Rates in women were significantly lower, with 0.5% of women convicted of a violent crime after a depression diagnosis.

Bipolar disorder is clearly associated with a range of adverse outcomes. A longitudinal analysis and systematic review in 2010 investigated the risk of violent crime and bipolar disorder [17]. The 30-year prevalence of violent crime convictions for people with a diagnosis of bipolar disorder was 8.4%, compared to the general population where it was 3.5%. When meta-analysed with eight other investigations, the increased odds of violent outcomes was 4.6 (95% CI 3.9–5.4). The impact of early environment and genetic factors is important in patients with bipolar disorder, and the rate of violence in unaffected male siblings has been reported to be 6.2% [17]. In terms of risk factors, no difference in violent crime risk was found in bipolar patients if their last episode was psychotic or non-psychotic, nor according to crude markers of disease phases. More sensitive markers of clinical presentation will be required, and some work has shown that links between mania and offending may be mediated by disinhibition, irritability, and impulsivity [58].

Substance misuse

Goldstein proposed three mechanisms through which substance misuse may cause violent behaviour—directly or ‘psychopharmacological violence’, or more indirectly via ‘systemic’ or ‘economic compulsive’ paths where situational and environmental factors ‘impact on behaviour’ [59]. Clinical studies focusing on just the ‘psychopharmacological’ pathways are complicated by confounding, comorbidities, and clarifying temporal and spatiotemporal relationships [20, 60, 61]. Risk factors for substance misuse and psychiatric illness overlap and have varying impacts at different points along the life course, and many studies rely on self-report. Polysubstance misuse is common, especially in individuals with serious mental illness—the odds of having another drug use disorder if also suffering from alcohol use disorder is around 4- to 5-fold, compared to those not using alcohol [62]. Despite all these difficulties, associations between violent offending and a history of substance misuse has been clearly established [20, 63].

The evidence for an association between alcohol use and violence is relatively strong. Studies have shown that the greater the number of symptoms of alcohol dependence, the higher the risk of violent offending [64]. The Dunedin birth cohort study found that 11% of the violence risk was attributable to alcohol dependence, with an adjusted OR of 3.4 (95% CI 2.0–5.9) for violence in those with significant alcohol use, compared to non-drinkers [11]. Other studies suggest a dose–response relationship, with weekly binge drinking associated with an increased risk of crime,

compared to monthly binge drinking [65]. In a case-crossover study, alcohol consumption in the previous 24 hours was associated with a relative risk of violence of 13.2 (95% CI 8.2–21.2) [66]. Individuals with a history of alcohol misuse were responsible for 16% of violent crime in Sweden [67].

Studies looking at individual substances are fewer in number and poorer in quality [68]. A 2016 review of studies of controlled substances and violence identified 22 relevant prospective studies, all of which had a moderate to serious risk of bias [68]. Eight studies investigated marijuana and showed either an increased risk or no change in risk of violence [68]. Studies of other illegal drugs have typically reported similar mixed results, with some with increased risk and others with no association. Data on barbiturates and tranquillizers, however, showed negative associations with some self-reported violence outcomes [69]. In an investigation based on an American inner-city population [69], other illegal drugs (including amphetamine, crack cocaine, opiates, and tranquillizers) were also associated with mixed results, based on self-reported violence outcomes.

There are few studies that have looked carefully at temporal relationships between substance misuse and violence. One report examined the odds of committing an act of serious violence the day after substance or alcohol misuse [70]. Consistent with other studies, it found that violence on day 1 was the largest risk factor for violence on the following day. It also found that alcohol use increased the odds of serious violence on the following day (OR 2.4, 95% CI 1.8–3.2). A possible effect of drug use alone (other than marijuana) could not be excluded (OR 1.5, 95% CI 0.8–2.8). Similar to many studies in this area, information on drug use relied on self-report.

Personality disorders

A number of studies have investigated links between personality disorder and offending [71, 72]. Birth cohorts and population-based studies have shown associations, which tend to be stronger for Cluster B disorders (antisocial, borderline, narcissistic, and histrionic). In a meta-analysis, Yu *et al.* [16] found that 10.7% of individuals with a personality disorder diagnosis were violent over a median follow-up period of 4.5 years, compared to 1.2% of general population controls. This corresponded to an increase in risk (OR 3.0, 95% CI 2.6–3.5) of violent outcomes in individuals with a personality disorder diagnosis. Antisocial personality disorder was associated with the greatest increase in risk, with elevated odds of violence of more than 10, although the individual estimates contributing to this pooled estimate were mostly unadjusted. When studies that excluded patients with antisocial personality disorder were compared, the risk of violence remained significantly raised. There was no significant difference between genders in studies with samples that included all personality disorders. No explanation was found for variations between studies when age band, comparison group, or diagnostic criteria were considered. Overall, it was estimated that around a fifth of all violence could be attributed to individuals with personality disorder if causality was assumed, and the prevalence of personality disorder in the general population is typically between 5% and 10% [16].

Personality disorder is also a risk factor for repeat offending. The odds of any criminal recidivism is doubled in individuals with a personality disorder diagnosis [16], with little difference in risk if the

comparison group comprised individuals with other psychiatric diagnoses or the general population. Studies have found that around two-thirds of individuals with a personality disorder diagnosis will reoffend, with no difference between different personality disorders. As individuals with personality disorder often have comorbid disorders, future research should account more carefully for this.

Neurodegenerative disorders

There are few high-quality studies that estimate the risk of offending and violence in neurodegenerative disorders. One of the most common behavioural manifestations of dementia is aggression, with estimates of over 90% in some patient surveys [73], with plausible mechanisms such as misinterpretation of the environment [74]. Rarely, this aggression can result in a criminal offence, especially prior to a formal clinical diagnosis, and offences committed by patients with dementia are not limited to violence and range from theft [75] to homicide [76]. A case series of first-time offenders aged 65 and over have found higher rates of dementia than would be expected by age alone [77].

Fronto-temporal dementia and Huntington's disease are two disorders where illness onset is earlier than that in other neurodegenerative disorders. A recent review of offending and neurodegenerative diseases found associations with fronto-temporal dementia [behavioural variant (bvFTD)], primary progressive aphasia, and Huntington's disease, all of which have clinical conditions affecting the frontal circuits [78]. In a cohort of 2397 patients seen at a memory clinic in California, 8% presented with criminal behaviour, patients with bvFTD had the highest rates of offending (37%) and those with mild cognitive impairment the lowest (3%), and estimates for vascular dementia and Alzheimer's disease were 15% and 8%, respectively. In 4% of bvFTD patients, violence was their presenting complaint, which compares with 0.7% of Alzheimer's disease patients. Thus, degenerative processes that predominantly affect non-frontal areas, such as Alzheimer's disease, do not appear to be as strongly associated with offending [78].

Neurological disorders

Traumatic brain injury (TBI) can lead to personality change and incident psychiatric and substance use disorders. The odds of a juvenile offender having a history of TBI, compared to a control, is 3.4 (95% CI 1.5–7.5) [79], and a 2010 meta-analysis estimated the prevalence of TBI in offender populations at 60% (95% CI 48–72) [80]. Prisoners appear to have a higher lifetime prevalence at 68% (95% CI 50–86), with more than half of these injuries including loss of consciousness (the diagnostic threshold for mild TBI or concussion). Absolute rates of violent crime in TBI patients are about 6% [81], reflected in an increased odds of 2.3 (95% CI 2.2–2.5) when adjusted for socio-economic confounders and substance misuse. When compared with unaffected siblings, the odds of violent crime remain raised at 2.0 (95% CI 1.8–2.3) [81].

Although epilepsy has been historically linked with crime and higher-than-expected rates in prisoners [82], both of these conventions have been questioned. In a population-based study, the absolute risk associated with epilepsy was slightly higher than in age-matched population controls, but not different to unaffected siblings (OR 1.1,

95% CI 0.9–1.2) [81]. Further, a systematic review found no support for the increased rates in prisoners, and previous findings of increased rates were partly based on using the wrong denominator [83]. The finding that epilepsy itself is not associated with an increased risk of violence is important, given the stigma associated with this condition.

Neurodevelopmental disorders

Up to 10% of the child and adolescent population worldwide have neurodevelopmental disorders [84], and these disorders are overrepresented in the criminal justice system [85]. Of these disorders, attention-deficit/hyperactivity disorder (ADHD) has been consistently associated with an increased risk of offending (OR 4.6, 95% CI 2.2–10.3 in a large epidemiological study) [86]. In some studies, ADHD is a stronger predictor of violence than substance misuse [87], although comorbidity is common. Individuals with ADHD appear to be overrepresented in the criminal justice system, with an estimated prevalence of around 12% in boys in detention [88]. Among those diagnosed with ADHD, earlier onset of ADHD symptoms is associated with a higher rate of recidivism. Individuals with ADHD often have other comorbid psychiatric disorders, most often conduct disorder (17%) [89]. A longitudinal study in Sweden examined four childhood neurodevelopmental disorders and their association with future violent offending, compared to age-matched controls [90]. After adjustment for confounding, a diagnosis of ADHD was associated with an increased risk of violent offending (OR 2.7, 95% CI 2.0–3.8) [90]. When comparing full-siblings of individuals with ADHD with matched controls and adjusting for confounders, an increased risk of violent offending remained (OR 1.3, 95% CI 0.9–2.0), suggesting familial confounding.

It has been hypothesized that autism spectrum disorders (ASD) may be associated variously with higher and lower risks of offending than the general population. Studies based on offender cohorts have suggested a small increased risk of criminality in individuals with ASD [85]. More recently, no association was found between ASD and violent offending in a Swedish sibling control study (OR 1.1, 95% CI 0.6–1.9) [90]. The authors suggested that associations seen in previous studies were possibly due to other comorbid psychiatric diagnoses [90]. A study of individuals with ASD reviewed by the forensic psychiatric service in Norway found comorbidities included intellectual disability (33%), ADHD (15%) and substance misuse (19%) [91]. Risk factors for violence in individuals with ASD included comorbid psychiatric disorder (OR 4.2, 95% CI 1.8–9.8) [92]. A diagnosis of Asperger's syndrome has also been associated with a higher risk of violence than ASD [92]. Other neurodevelopmental disorders associated with offending include tic disorder [90].

Eating disorders

There have been very few studies researching associations between eating disorders and offending. One investigation compared individuals with eating disorders to matched controls and found no difference in aggressiveness [93]. There have been case reports of an association with shoplifting; however, epidemiological data are lacking [94] (Table 139.2).

Table 139.2 Associations between psychiatric disorder and offending (comparison groups used unaffected siblings where possible; if not, systematic reviews were identified, followed by large observational studies)

Psychiatric disorder	Odds of offending/ violence (95% CI)	Comparator	Source
Schizophrenia-spectrum disorders	4.2 (3.8–4.5)	Siblings	[47]
Bipolar disorder	3.4 (risk ratio)	Siblings	[100]
Depression	2.1 (1.8–2.4)	Siblings	[18]
Personality disorder	3.0 (2.6–3.5)	General population	[16]
Substance misuse	7.4 (4.3–12.7)	General population	[6]
Substance misuse (SMI + alcohol + drugs—general)	9.8 (5.2–18.7)	General population	[6]
Neurodevelopmental disorder (ADHD)	1.4 (0.9–2.1)	Siblings	[90]
Neurodegenerative disorder (bv-FTD)	7.2 (P < 0.001)	Alzheimer's disease	[78]
Neurological (TBI)	2.0 (1.8–2.3)	Siblings	[81]
Neurological (epilepsy)	1.1 (0.9–1.2)	Siblings	[81]

SMI, severe mental illness.

Risk assessment

There has been a proliferation of structured risk assessment tools in recent years, which rely on research on risk factors to create a checklist of items that can be scored in an unweighted or weighted manner. Current tools identify low-risk individuals with reasonable accuracy but are less accurate at identifying high-risk individuals who will actually go on to offend [95]. The rates of violence in individuals classified as high risk by these tools vary substantially [96], and trial evidence does not demonstrate improved outcomes using structured clinical judgement instruments [97]. In addition, some of these tools are subject to the prevention paradox—that most individuals with adverse outcomes are categorized in low- or medium-risk categories [17, 49], especially for rare outcomes such as homicide. Furthermore, scalability and simplicity need to be prioritized, as current instruments are time-consuming, suffer from authorship and publication biases [98], and are expensive to use (often requiring training and costs to administer). Recent work has addressed some of the limitations of previous work by using large data sets, pre-specifying risk factors and thresholds in a protocol, publishing a range of performance measures in a validation cohort, and developing a brief, scalable, and free-to-use risk assessment tool (OxMIV) for clinical decision-making in individuals with schizophrenia-spectrum and bipolar disorders [99]. The validation C-index [equivalent to area under the curve (AUC)] for this tool was 0.87, higher than comparative tools that take considerably longer and rely on interviews. Such a scalable tool can be used to screen out low-risk persons with psychosis and act as an adjunct to clinical decision-making.

Conclusions and implications

Offending is a complex human behaviour and has many different causes, often acting at the same time. The links between psychiatric disorder and offending can be further clarified by using clear outcomes that allow for comparability, longitudinal studies to account for temporal relationships between exposure and outcome, and methods that adjust for sociodemographic and familial

confounders. Overall, the data suggest that substance misuse and antisocial personality disorder are most strongly associated with an increased risk of offending, particularly violent offending, in relative and absolute terms. Schizophrenia-spectrum disorders, bipolar disorder, and clinical depression are also associated with offending, but relative and absolute risks are lower, unless there is comorbidity with substance misuse (Table 139.2). Pharmacological treatment of schizophrenia-spectrum and bipolar disorders is associated with a reduction in reoffending in observational studies and with broader violent outcomes in randomized controlled trials, which underscores the importance of early diagnosis and treatment. Violence risk assessment should consider using scalable tools, particularly to screen out low-risk persons and as an adjunct to clinical decision-making.

Developmental approach to understanding the needs of young people in contact with the criminal justice system

Sue Bailey and Prathiba Chitsabesan

Introduction

Over the last decade, studies have highlighted that young people with disproportionately high and multiple needs have clustered in the juvenile justice system. These young people experience higher levels of diagnosable mental health problems and neurodisability than the general population.

Delinquency, conduct problems, and aggression all refer to anti-social behaviours that reflect a failure of the individual to conform his or her behaviour to the expectations of some authority figure or to societal norms, or to respect the rights of other people. The 'behaviours' can range from mild conflicts with authority figures, to major violation of societal norms, to serious violations of the rights of others. The term 'delinquency' implies that the acts could result in conviction, although most do not do so. The term 'juvenile' usually applies to the age range, extending from a lower age set by the age of criminal responsibility to an upper age when a young person can be dealt with in courts for adult crimes. These ages vary between, and indeed within, countries and are not the same for all offences.

This chapter provides a developmental approach to understanding the needs of young people in contact with the criminal justice system. It reviews the prevalence of a range of mental health and neurodevelopmental disorders in young offenders and describes the key principles of assessment and intervention approaches. The policy and legal framework have been illustrated by reference to the system in England but will have relevance to readers from further afield.

Developmental pathways to antisocial behaviour

Adolescence is a transitional stage of development between childhood and adulthood; the developmental tasks of adolescence centre on autonomy and connection with others, rebellion and the development of independence, the development of identity, and the distinction from, and continuity with, others. Many theories of

development are stage theories, in which we pass from stage to stage, completing the developmental tasks appropriate to each stage prior to moving on. However, in reality, progression across domains is not equal and frequently non-linear. Additionally, neuroscience suggests that there is a lack of synchrony in late childhood and adolescence in the development of two of the critical brain systems that enable the development of adaptive behaviour [1]. The mesolimbic system develops more quickly than the frontal system, resulting in the adolescent brain having a heightened need for basic reward, but a lower capacity to manage short-term rewards for greater long-term gains. This discrepancy may be greater for young people at risk of antisocial behaviour where reward-driven behaviour is increased and neurocognitive deficits in executive functioning more common.

Epidemiological studies suggest that the development of antisocial behaviour involves a complex interaction of intrinsic and psychosocial risk and protective factors [2]. Links between early adverse events in the prenatal period and the impact of parenting, family, and peer relationships on behaviour in early childhood have been found [2]. Heritable influences contribute towards a gene-environment interaction, suggesting pathways are complex and some vulnerabilities become increasingly evident in the context of other risk factors. Intrinsic risk factors include socio-cognitive deficits (hostile attribution bias), temperamental factors (callous-unemotional traits), and low autonomic nervous system arousal [2, 3]. The neurocognitive profiles of young offenders include deficits in language skills, attention, and impulse control, as well as low intelligence quotient (IQ) scores. Deficits in executive function can affect the young person's ability to regulate their behaviours and plan and generate alternative strategies. However, antisocial behaviour also shows strong associations with psychosocial adversity. Parental mental illness, family breakdown, parenting style, and association with other antisocial peers influence outcomes [2]. Detachment from school through truancy and exclusion may increase the risk of offending through reduced supervision and loss of any positive socialization effects of school and by creating delinquent groups of young people [4].

Distinctive pathways are described for those with early and late onset of offending behaviour, with some gender differences suggested. Girls have historically been found to have a later onset to their antisocial behaviour, compared with boys [2, 5]. Moffitt [5] proposed a developmental taxonomy whereby early-onset conduct problems were more likely to be associated with individually based risk factors that increase vulnerability to the development of behaviour problems in the context of adverse family and parenting conditions. In adolescent-onset conduct problems, by contrast, individual vulnerabilities may be less marked, and the impact of environmental risk factors, including the influence of antisocial peers, more evident. There is evidence that

early-onset, life course-persistent antisocial behaviour is more likely to be associated with a greater risk of neurodevelopmental impairment [6].

However, it is important to bear in mind that protective or resilience factors for the young person or within the system around them can also modify outcomes (Fig. 140.1). This is particularly relevant for interventions and an important underpinning principle of the risk and resilience approach which focuses on building important 'assets' in the child's health and emotional well-being. Activity can include strengthening children's internal resources, as well as resilience in their families, their communities, and their broader environment.

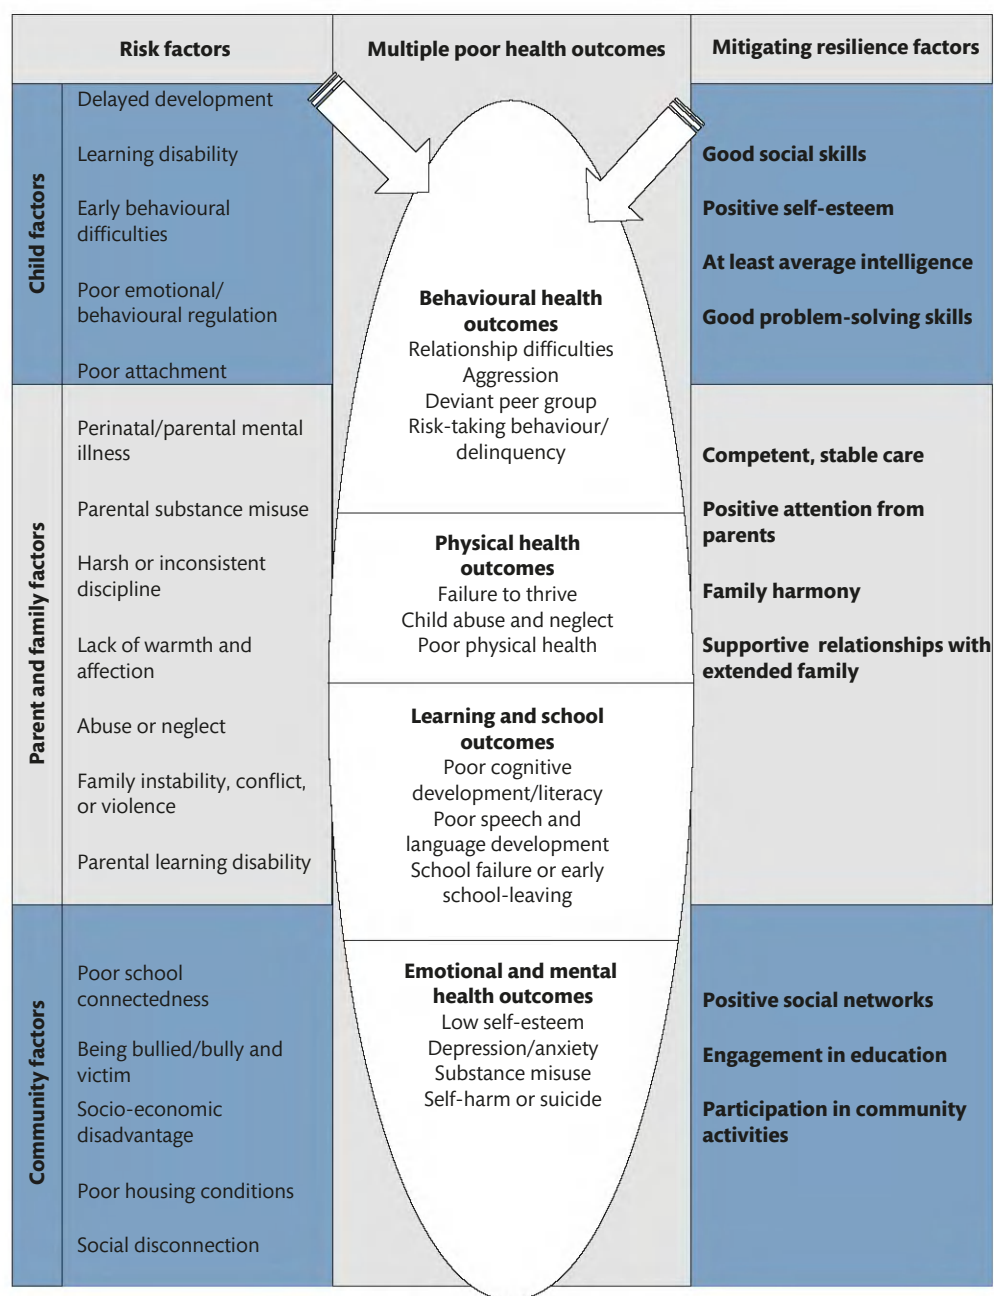

Fig. 140.1 Risk and resilience factors affecting multiple health outcomes.

Prevalence of mental health needs and neurodevelopmental disorders

Mental health needs

Studies have reported the prevalence of psychiatric disorders among young males in custody in the United States (US) to be between 60% and 70%, and between 60% and 80% for young females in custody [8], in contrast to rates of between 7% and 12% in the general population [9]. The high rate of psychopathology in juvenile offenders may be the consequence of shared risk factors in the development of both antisocial behaviour and psychiatric disorders.

Table 140.1 summarizes a range of studies that identify rates of specific mental health needs and neurodevelopmental disorders among young people within the youth justice system and the general population [10]. While it is important to highlight that comparing such rates is problematic due to differences in methodology between studies, prevalence rates found in young offenders are consistently higher than in the general population.

Psychotic disorders

Young people in the secure estate are approximately ten times more likely to suffer from psychosis than the general adolescent population [11]. Fazel *et al.* [11] found that 3.3% of males and 2.7% of females in youth custody were diagnosed with a psychotic illness. A first psychotic episode may have multiple causes, including drugs, brain injury, physical illnesses, or schizophrenia. Schizophrenia is a mental illness characterized by cognitive disruption, delusions (fixed, false beliefs), and hallucinations. Sufferers frequently have comorbid depression, anxiety, and substance misuse. Mortality rates for young offenders with schizophrenia was found to be significantly higher than in non-offending peers [12].

Table 140.1 Prevalence of psychiatric and neurodevelopmental disorders in young offenders

Type of disorder	Reported prevalence rates among young people in the general population (%)	Reported prevalence rates among young offenders (%)
Psychotic disorder	0.4	1–3.3
Depressive disorder	0.2–3	8–29
Anxiety disorder	3.3	9–21
Post-traumatic stress disorder	0.4	11–25
Substance misuse disorder	7	37–55
Learning disabilities	2–4	23–32
Dyslexia	10	21–43
Communication disorders	5–7	60–65
Attention-deficit/hyperactive disorder	3–9	11.7–18.5
Autistic spectrum disorder	0.6–1.2	15
Traumatic brain injury	24–31.6	65

Anxiety disorders and post-traumatic stress disorder

Anxiety disorders include a range of different disorders, from generalized anxiety disorder to phobias and post-traumatic stress disorder (PTSD). In their UK-based study of young offenders, Chitsabesan *et al.* [13] diagnosed anxiety disorder in 16% of cases, consistent with findings from a systematic review [14].

The NWJP study found that the vast majority of offenders had experienced at least one trauma in their lifetime (93%), while 11% met the criteria for PTSD [15]. In the UK, the Annual Report of the Chief Medical Officer stated that 9% of 13- to 18-year-old young offenders in secure care have a diagnosis of PTSD [16].

Many young people within the criminal justice system who present with pervasive and complex presentations often have an extensive history of repeated interpersonal traumatic experiences. Disruption to the early attachment process through interpersonal trauma has a direct impact on the development of a child's brain, attachment style, and emotional regulation systems [17]. Over time, the brain is more likely to develop connections between the parts of the brain based on recognizing and interpreting threat.

Depression

A number of studies in adolescents within the criminal justice systems, both in the UK and internationally, have reported disproportionately higher prevalence rates of depressive disorders in young offenders. Fazel *et al.* [11] conducted a meta-analysis of 25 studies of psychiatric morbidity among children and young people in custody, including studies from the UK, as well as other international contexts. Their findings suggested that around 11% of boys and 29% of girls had a major depressive disorder [11]. Adolescents within the youth justice system experience high levels of psychosocial adversity and are significantly more at risk of developing depression due to both genetic and environmental factors. Additionally, these young people are at greater risk of continued depression, as they have fewer protective influences to compensate for the many adversities they face.

Self-harm and suicidal behaviour

An association between antisocial behaviour and suicidal behaviour has also been demonstrated in research studies. A study of 200 young people sentenced to custody found that 20% were reported to have harmed themselves and 11% to have attempted suicide [18]. Self-harm is more prevalent among offenders, as certain risk factors for self-harm are more common among this group. Predictors of an increased risk include previous attempts, prolonged low mood, attention-deficit/hyperactivity disorder, impulsivity, and substance misuse [19].

Rates of suicide are similarly much higher in the offender population, compared with non-antisocial peers, possibly as a consequence of greater impulsive behaviour and substance misuse, which are more common in this group of young people [19].

Substance misuse

Substance misuse disorders are defined by sustained maladaptive behaviours related to, or caused by, substance misuse. Young people's substance misuse differs from that of adult substance misusing offenders. Cannabis and alcohol are the main substances of choice reported by adolescents, and polydrug use is common. The

mesolimbic dopaminergic system, or 'reward system in the brain', has an important role as adolescent brains appear particularly sensitized to dopamine.

Prevalence rates of substance misuse disorder in young offenders in custody have ranged from 41% to 55% [20]. Childhood exposure to violence and abuse was found to increase the likelihood of violence and problematic substance misuse in adulthood [20, 21]. Reduced parental supervision and the influence of peer relationships play a key role in both experimentation with, and ongoing use of, substances [20]. Mulvey *et al.* [21] reported that the disinhibiting effects of drugs, such as alcohol, can increase the risk of violent or risk-taking behaviour. Positive associations have also been shown between substance misuse and other disorders, including depression and attention-deficit/hyperactivity disorder (ADHD). Longitudinal studies also showed an association with persistent offending and both depressive symptoms and drug use into adulthood [22].

Psychopathy

Psychopathy is characterized by a unique cluster of traits, including shallow affect; lack of empathy, and guilt; irresponsibility; impulsivity; and poor decision-making. A closely related construct to psychopathy is antisocial personality disorder (APD). APD is defined in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-V) as having a pervasive disregard for, and a willingness to, violate the rights of others [23]. While most individuals with APD do not meet the diagnostic criteria for psychopathy, psychopaths are almost invariably diagnosed with APD.

The Psychopathy Checklist Revised (PCL-R) is a well-known measure of adult psychopathic traits, although criticized for its strong focus on criminality. The Psychopathy Checklist: Youth Version (PCL:YV) was developed from the PCL-R to provide a standardized approach to assessing psychopathic-like traits in youth males and females aged 12–17 years and has demonstrated predictive validity for reoffending and violent offending [24]. An alternative approach which is still in its early stage of validation is the Comprehensive Assessment of Psychopathic Personality Disorder (CAPP) which has six dimensions: attachment, behavioural, cognitive, dominance, emotional, and self-styles of functioning [25]. The new measure attempts to encapsulate the 'clinical' construct, as well as capture change [26].

The presence of callous-unemotional (CU) traits has been shown to identify a discrete group of conduct-disordered children with more severe conduct problems and aggression. A biological theory has been proposed that children who develop CU traits have unique neural mechanisms characterized by low cortisol and underarousal, contributing to a temperamental style which has low emotional reactivity and fearfulness to threatening stimuli, poor responsiveness to cues to punishment, and reward-dominant orientation [27]. However, Johnstone [26] argues that there are developmental challenges associated with extending the construct of psychopathy to youth and that environmental factors, such as disrupted parent-child attachments and trauma, are also important risk and mediating factors which can influence neural brain processes and outcomes.

Neurodevelopmental disorders

Neurodevelopmental impairments are expressed through a wide range of symptoms, including deficits in cognitive functions

(reasoning, thinking, and perception) and social-affective functions (the expression of emotion and formation of relationships). Specifically, problems with executive functioning, cognitive empathy, and emotional regulation associated with particular neurodevelopmental disorders can directly influence propensity towards aggressive and antisocial behaviour [6].

Attention-deficit/hyperactivity disorder

A meta-analysis reviewing 25 international studies found a rate of 11.7% for young male offenders [11], in contrast to 3–7% within the general population. Longitudinal studies have suggested that childhood ADHD predicts later antisocial behaviour, although more recent evidence suggests that this association is indirect and mediated through the development of conduct disorder, illicit drug use, and peer delinquency [28]. Young people with conduct disorder and ADHD have been shown to have greater severity and persistence of antisocial behaviour. Co-occurrence with substance misuse is also high, with evidence of increased frequency and severity of institutional behavioural disturbances while in custody [29].

Autism spectrum disorders

Autism is a neurodevelopmental disorder characterized by a triad of impairment in social communication that affects about 1% of children and young people [30]. Certain features of autism may predispose young people to offend, including social naivety, misinterpretation of social cues, and poor empathy [30]. While the National Autistic Society [31] suggests that young people with Asperger's syndrome are seven times more likely to come into contact with the criminal justice system than their peers, many studies demonstrating an increased prevalence rate in the criminal justice system have been conducted on a forensic psychiatry sample of offenders, suggesting further research is required. There is concern, however, about the possible links between autism and particular types of offending. Certain types of offences may raise the suspicion of autism spectrum disorder (ASD), including stalking, arson, sexual offences, inexplicable violence, computer crime, and offences arising out of misjudgement of social relationships [30].

Learning disability

A learning disability is defined as an IQ score of less than 70, together with significant difficulties with adaptive or social functioning and onset prior to adulthood. High prevalence rates (23–32%) have been found in studies of young offenders [32]. The majority of young offenders with a learning disability frequently have an IQ in the 'mild range' (between 50 and 69) and may therefore be less likely to have had their learning needs identified in mainstream schools where those needs are often overshadowed by their challenging behaviour [33].

Communication disorders

Communication disorders relate to problems with speech, language, and communication that significantly impact day-to-day functioning. A study of 72 young offenders attending a youth offending service found that 65% of those screened had profiles indicating that they had communication difficulties, including expressive language difficulties (28%), receptive language difficulties (45%), and articulation difficulties such as a stammer (8%) [34]. Particular deficits in verbal skills may also be highlighted through a discrepancy in verbal and performance IQ scores.

Traumatic brain injury

A traumatic brain injury (TBI) is any injury to the brain caused by an impact, and the severity is typically measured by the depth of loss of consciousness (LOC). The majority of TBIs appear to be mild, although long-term effects on academic performance, behaviour, emotional control, and social interactions can be reported. This is reflected in a range of studies which have demonstrated an association between TBI and antisocial behaviour, including an earlier onset of offending history and more violent offending [35]. Greater severity of TBI was also found to be associated with greater impairment of cognition, earlier onset of criminal behaviour, and increased rates of mental illness and substance use. Identified prevalence rates of TBI among young offenders are variable, however, ranging from 4.5% to 72% [36].

Gender and ethnicity

While studies of mental health needs have predominantly focused on male offenders, gender differences have been reported. The NWJP study found that female offenders were 14 times as likely as male offenders to meet the criteria for at least one mental disorder, including depression and anxiety disorders [8]. Rates of PTSD and self-harm have also been found to be significantly more prevalent in females [13]. Explanatory mechanisms may include greater genetic vulnerability, as well as increased exposure to trauma and chaotic family lifestyles. Female offenders have been shown to experience more abuse, neglect, and a family history of mental illness than male offenders. There are concerns that there is an overrepresentation of some ethnic minority groups within the criminal justice system and that these groups of young people have poorer access to services. However, studies exploring differences in the prevalence of mental disorders among young offenders by ethnicity have been sparse and findings inconsistent. A national study within the United States using the Massachusetts Youth Screening Instrument-Version 2 (MAYSI-2) found that differences in prevalence rates varied across sites and were generally small [37].

Screening and assessment

Studies to date suggest that one of the most common reasons for unmet need is lack of appropriate and timely assessment [38]. Lack of identification hampers opportunities for early intervention and promotion of healthy development and resilience in young people.

Initial assessment is a key factor in the successful treatment of mental health needs for young offenders. Early identification of mental health needs may also reduce the later risk of mental disorders and their related health costs. However, assessment can be complicated by a number of factors, including the non-clear nature of emerging mental health symptoms in children and young people, in comparison to presentations in adults, the minimization of symptoms by young offenders, and the disinclination of young people to engage with mental health services due to fear of stigma.

Historically, screening and assessment tools have been developed focusing on single-problem areas, for example the MAYSI-2, a widely used screening tool for mental health needs within the

US youth justice system [39]. However, young people who offend often have multiple areas of need. In recognition of these difficulties, the Comprehensive Health Assessment Tool (CHAT) was introduced for young offenders in custody across England and Wales [40], supported by the development of Healthcare Standards for Children and Young People in Secure Settings [41]. The CHAT is a semi-structured assessment developed to provide a standardized approach to health screening for all young offenders admitted to the secure estate and includes assessment of mental health needs, physical health, substance misuse, and neurodevelopmental impairment. Assessing and managing unmet health needs can inform individual care plans, help to address offending behaviour, and provide a valuable opportunity to re-engage young people with health and educational services to address unmet needs.

Principles of risk assessment

Risk assessment combines statistical data with clinical information in a way that integrates historical variables, current crucial variables, and contextual or environmental factors. Structured risk assessment instruments have been developed that aim to increase the validity of clinical prediction. These scales typically contain a number of risk items selected from reviews of research, crime theories, and clinical considerations. Items are summed to form a total risk score and may also reveal specific risk patterns (for example, mainly family or child factors). The Structured Assessment of Violence Risk in Youth (SAVRY) [42] is a popular risk assessment tool which assesses 24 risk factors (ten historical risk factors, six social/contextual risk factors, eight individual/clinical risk factors) and six protective factors. The SAVRY has a good evidence base to support its predictive accuracy and clinical applicability in a range of settings.

Risk assessments can vary in the type of risk they assess, for example the Youth Level of Service/Case Management Inventory [43] assesses general offending, while the SAVRY assesses interpersonal violence.

The following five-step approach should be considered when undertaking risk assessments [44]:

- Step 1: collecting case information via interviews and collateral information from informants.
- Step 2: identifying the presence and relevance of risk factors using the structured risk assessment tool.
- Step 3: identifying the presence and relevance of protective factors using the structured risk assessment tool.
- Step 4: risk formulation.
- Step 5: management plan.

For risk and protective factors, consideration needs to be given to the presence and relevance of the factor in relation to a specific risk, as well as its severity and frequency. A rating (low, moderate, or high for risk factors, and either absent or present for protective factors) does not fully inform the subsequent risk formulation or management plans. The aim of a risk formulation is to provide a better understanding of the origins of violence and how it has developed, is maintained, and changes [44]. There are a number of frameworks which can be used to help explain and communicate risk, including the '5Ps' model (problem, predisposing factors, precipitating factors,

perpetuating factors, and protective factors) and the '3Ds' model (which represents drivers, destabilizers, and disinhibitors) [44].

Interventions

A large number of different treatments have been developed to reduce antisocial behaviour. These include psychotherapy, pharmacotherapy, school-based interventions, residential programmes, and social treatments. Meta-analyses of treatment approaches to juvenile delinquency have produced reasonably consistent findings [45]. The best results were obtained from cognitive behavioural, skills-orientated, and multimodal methods. Specifically, treatment approaches that were participatory, collaborative, and problem-solving were particularly likely to be beneficial. Family and parenting interventions also seem to reduce the risk of subsequent delinquency among older children and adolescents.

Cognitive behavioural therapy (CBT) is an effective psychological intervention for a number of mental health difficulties in childhood and adolescence, including depression, social anxiety disorder, and PTSD. Studies that have been conducted with young people engaging in high-risk behaviours indicated that CBT may be useful for young offenders with a range of mental health needs [46]. However, the format and delivery of CBT may require adaptation, taking into account the young person's level of cognitive, social, and emotional development, including neurodevelopmental impairment. Adaptations include use of visual cues, encouraging verbal learning through games, reducing distractions, and using simplified language [47].

More recently, therapies include mindfulness-based cognitive therapy, dialectical behaviour therapy (DBT), and mentalization-based therapies. Overall, the current research base provides support for the feasibility of mindfulness-based interventions with children and adolescents, and there is an emerging evidence base in relation to adolescence with behavioural problems and those in custodial settings; however, there is no generalized empirical evidence of the efficacy of these interventions at present. DBT was developed as a treatment for suicidal adults by developing specific skills in mindfulness, emotional regulation, distress tolerance, and interpersonal effectiveness through individual and group sessions. Over recent years, DBT has been modified and adapted to meet the needs of adolescents within forensic settings. Mentalization-based treatment for adolescents (MBT-A) is a psychodynamic psychotherapy programme with roots in attachment theory, aimed at enhancing the young person's capacity to represent their own and other's feelings accurately in emotionally challenging situations. MBT-A has been influential in the development of a more systemic approach called adolescent mentalization-based integrative therapy (AMBIT), specifically designed for 'hard-to-reach' adolescents with mental health problems who may be or are at risk of offending [48].

The National Institute for Health and Care Excellence (NICE) [49] recommends multimodal interventions for the treatment of conduct disorder in children and young people aged between 11 and 17 years. A meta-analysis of eight family-based treatment studies of adolescent conduct disorder found better outcomes for three family-based treatments: functional family therapy (FFT), multi-systemic therapy (MST), and multi-dimensional treatment foster care (MTFC), compared to routine treatment [50]. The most well-evaluated is MST.

MST is a multimodal intervention where interventions are targeted at not only the young person, but also their family, school, and peers. Evaluation studies of MST have been promising [51]. In particular, it has also been shown to be effective for young people with substance misuse disorders. However, criticisms of MST include the requirement for a high level of therapeutic expertise, as well as the cost of implementation.

McGuire [52] identified six principles for effective programmes:

1. The intensity should match the extent of the risk posed by the offender.
2. A focus on active collaboration, which is not too didactic or unstructured.
3. Close integration with the community.
4. Emphasis on behavioural or cognitive approaches.
5. Delivered with high quality with training and monitoring of staff.
6. Focus on the proximal causes of offending behaviour (peer groups, promoting current family communication, and enhancing self-management and problem-solving skills), rather than the distal causes (early childhood).

Serious crimes

Homicide

Longitudinal studies are invaluable in mapping out the range of factors and processes that contribute to the development of aggressive behaviour and in showing how they are causally related [2]. Research suggests that risk factors that increase violent offending overlap with those increasing the risk for homicides as well, for example repeat offending, substance abuse problems, and exposure to early risk factors such as family dysfunction and educational difficulties [53, 54]. The Pittsburgh study found that the strongest predictors of becoming a homicide offender were environmental, rather than individual, factors [54]. The study found that there was no single factor explaining homicide offending, but instead a cumulative effect, with the greater the number of risk factors, the more likely it was that the individual would become involved in a homicidal incident.

Murder and manslaughter are more often committed alone, and on average, the perpetrators start their criminal activities at a later age and are much less likely to have previous convictions than other minors taken into judicial youth institutions. However, there is a great variety in terms of motives and victims, etc. Studies show that children and adolescents who murder share a constellation of psychological, educational, and family system disturbance [53]. The majority of young persons who have killed initially dissociate themselves from the reality of their act but gradually experience a progression of reactions and feelings akin to a grief reaction. The young person, while facing a still adversarial and public pre-trial and trial process, has to move safely through the process of disbelief, denial, loss, grief, and anger/blame. PTSD arising from the participation in the sadistic act (either directly or observing the actions of co-defendants) has to be treated, as does trauma arising from their own past personal emotional, physical, and/or sexual abuse. A combination of verbal and non-verbal therapies are effective, but factors such as a history of severe aggression, low intelligence, and a poor capacity for insight are associated with poorer outcomes [53].

In understanding the role of violence and sadism in a young person's life, one has to understand their reaction to perceived threat and their past maladaptive behaviours aimed at allowing them to feel in control of their lives.

Harmful sexual behaviour

Harmful sexual behaviours by children and young people is a considerable problem that impacts on victims and their perpetrators, as well as their families. The sexual behaviours of children and young people are on a continuum, which ranges, on the one hand, from normal and developmentally appropriate to highly abnormal and violent on the other. It is important to place any assessment of a child's sexual behaviour within a developmental context, as such behaviours may have substantially different motivations and different developmental significance across these two developmental stages. Models have been developed to describe children and young people's sexual behaviours at various levels of seriousness or concern, including age-appropriate and inappropriate [55].

Most, but not all, abusers are male, often come from disadvantaged backgrounds, with a history of victimization and sexual and physical abuse, and show high rates of psychopathology [55]. Females with harmful sexual behaviour were found to have higher rates of PTSD and a history of family dysfunction and have been victims of sexual abuse, in comparison to male offenders [56]. People with learning disability (LD) and ASD are overrepresented in services for sexual offenders, which may relate to a number of factors, including a lack of socio-sexual knowledge, difficulties understanding the nature of relationships and the feelings of others, and more limited opportunities for intimate relationships [30, 55].

A core part of any assessment of an adolescent sex offender should include a holistic assessment of needs and risks, including an assessment of mental health [55]. These young people often have a history of other offending behaviours, experienced trauma and loss, and are likely to suffer from a range of mental health disorders. Assessment and treatment of these disorders should be an integral part of the process, including the awareness that addressing harmful sexual behaviours may have an adverse impact on the young person's emotional well-being and behaviour.

The AIM assessment model [57] identifies mental health concerns as risk factors, distinguishing between those with strong empirical support (high levels of trauma, for example own victimization and witnessing domestic violence; a formal diagnosis of conduct disorder; poor social and intimacy skills; and highly compulsive/impulsive behaviours) and others based on practice consensus (diagnoses of ADHD, depression, or other significant mental health problems).

New approaches to CBT with sexually abusing youths have recently been described within the context of relapse prevention, and a more complex CBT intervention—mode deactivation therapy (MDT)—has been suggested for disturbed, sexually abusive young people with reactive conduct disorders or personality disorders [58]. CBT group work with sexually abusing children and young people is widely practised in the UK [59].

More recently, there has been an increased emphasis on strength-based models of intervention for young people with harmful sexual behaviours. Treatment is therefore seen as an activity that should add to the young person's skills and personal functioning [55].

For some young people with significantly risky sexually harmful behaviour, treatment needs to be undertaken within a close

supervised, intensive, community-based foster placement with specially trained foster carers. Approaches include MTFC and forensic foster care. However, there continues to be a lack of longitudinal studies to measure the effectiveness of existing programmes.

Fire-setting and arson

Arson can have a devastating impact on the victim and the wider society. Juvenile arsonists are not a homogenous group, with a wide range of familial, social, and developmental needs [60]. High-frequency fire-setters (three or more episodes in the past year) were more likely to have started their fire involvement before the age of 10 years and had cumulative risk factors and other problem behaviours, including antisocial behaviour, aggression, impulsivity, and alcohol and drug misuse [61]. Other factors identified include lower IQ, poor social judgement, lack of empathy, and poor super-ego development. Environmental factors such as parenting practices (low monitoring or absence of a parent) and experiences of physical and sexual abuse have also been reported. Epidemiological studies showed that males are more common perpetrators than females and more likely to fire-set on multiple occasions [61].

Kolko and Kazdin [62] used a bio-psychosocial framework to specify the individual, social, and environmental risk factors related to the onset, severity, and maintenance of fire-setting behaviour and highlighted the importance of attraction to fire, heightened arousal, impulsivity, and limited social competence. A review of different fire-specific assessment tools is available [60]. Assessing factors, such as caregiver supervision, behavioural modelling, and access to fire-setting materials, are included in fire risk assessment protocols [62] and as treatment targets in intervention programmes [60].

The first component of a multi-disciplinary intervention should include a home safety visit, as most fatal fires occur in the home. Other interventions include fire safety educational sessions (to promote the understanding of cause and effect), motivational interviewing (to assess capacity for change), and CBT (to increase the understanding of the behaviour, including antecedents and establishing the behavioural reinforcers) [60]. Parent management training for caregivers has been shown to be effective for young people with a range of antisocial behaviour. Caregivers working with young people provide opportunities to address environmental risk factors, including parenting approaches.

Gangs and violence

The definition of a gang includes a relatively durable group of young people who seem themselves as a group, engage in criminal activity, and have some form of structure. Longitudinal studies have identified many risk factors for poor outcomes in later life such as poverty, a lack of positive parenting, family conflict, maltreatment, and school failure, as well as individual factors [2]. There is an association between the number of risk factors experienced by young people and gang membership [63]. Qualitative research also highlights a range of other drivers for gang involvement, including the need to feel protected and feel safe, the need to build and maintain status or to boost young people's reputation, and using gangs as a substitute family unit [63]. The literature on young women in gangs includes family histories characterized by exposure to violence, maltreatment, and abuse [64]. The gang offers an opportunity to feel safe and protected within a substitute family unit.

There is evidence that young people in gangs, and particularly young women, have higher levels of mental health needs [63, 64]. Many of these needs are long-standing and unmet, with few young people accessing early support [64].

The evidence base for interventions to reduce gang involvement is still evolving, with many interventions focusing on multiple risk factors affecting the young person or on the systems around the young person. Primarily developed in the US for males, rather than females, few of these interventions help to address young people's mental health problems. MAC-UK's Integrate approach is delivered as an adaptive, flexible intervention for young people who do not otherwise easily access support from professionals [65]. Integrate projects are intensive and use a multi-agency approach, reconfiguring staff from other agencies to work in partnership with excluded young people within their local community.

Legal framework

A 'child' is defined by the Children Act [66] and the United Nations Convention on the Rights of the Child [67] as 'any person under the age of 18'. In England, Wales, and Northern Ireland, criminal responsibility is set at the age of 10. However, there is evidence that brain development continues into the early 20s, with the frontal lobes developing later [1]. These areas are involved in consequential thinking, inhibition of impulses, empathy, and planning. These normal developmental stages are important to consider when assessing and passing comment on a child's criminal responsibility [68]. Developmental level is important in the context of criminal liability (so-called 'mens rea', the ability to form a guilty mind).

Fitness to plead and effective participation

Mental health professionals are frequently asked to assess a young person in relation to their 'fitness to plead', which is a standard set in caselaw (Pritchard criteria). 'Fitness to plead' in this context requires that the individual (whether adult or child):

1. Has the ability to understand the charge(s).
2. Has the ability to decide whether to plead guilty or not guilty.
3. Has the ability to follow the course of proceedings.
4. Has the ability to instruct a solicitor.
5. Has the ability to challenge a juror.
6. Has the ability to give evidence in his/her own defence.

Important for children and young people is the principle of 'effective participation'—which examines the ability of the young person to engage with the trial. A child's age, level of maturity, and intellectual and emotional capacities must be taken into account when they are charged with a criminal offence, and appropriate steps should be taken in order to promote their ability to understand and participate in the court proceedings. The responsibility therefore falls on the defence lawyer to be aware of the possibility that a young person may not be able to participate effectively in the trial process, particularly if they are under 14 years old or have learning problems or a history of absence from school.

Capacity

One fundamental distinction in criminal law is between conditions that negate criminal liability and those that might mitigate the

punishment deserved under particular circumstances. Very young children and the profoundly mentally ill may lack the minimum capacity necessary to justify punishment [68]. Those exhibiting less profound impairments of the same kind may qualify for a lesser level of deserved punishment, even though they may meet the minimum conditions for some punishment. Immaturity, like mental disorder, can serve both as an excuse and as mitigation in the determination of just punishment. Capacity is a feature that is both situation-specific and open to influence.

Capacity is multi-faceted, with four key elements:

1. The capacity to understand information relevant to the specific decision at issue (understanding).
2. The capacity to appreciate one's situation as the defendant is confronted with a specific legal decision (appreciation).
3. The capacity to think rationally about an alternative course of action (reasoning).
4. The capacity to express a choice among alternatives.

Any evaluation of competence should include an assessment of psychopathology and emotional understanding, as well the cognitive level, the child's experiences, and appreciation of situations comparable to the one relevant to the crime and to the trial, and any particular features that may be pertinent in this individual and this set of circumstances [68].

Conclusions

Politicians and professionals have begun to acknowledge the importance of meeting the needs of offenders, as long-term costs to society become increasingly apparent. The major challenge of altering the trajectories of persistent young offenders has to be met in the context of satisfying public demands for retribution, together with welfare and civil liberties considerations. Over the last 30 years, there has been increasing research studies evidencing the risk factors and developmental pathways to antisocial behaviour.

This chapter has evidenced the high prevalence of mental health needs and neurodisability in young people who offend and outlined the implications for policy and practice, including recent developments. It demonstrates the increasing importance of providing a standardized and evidence-based approach to screening and intervention for a variety of health needs. Provision of appropriately designed programmes can reduce recidivism among persistent offenders. Initiatives within the community include the development of liaison and diversion teams within police and court interfaces to screen and divert young people away from the criminal justice system where possible. Opportunities also exist through multi-agency partnerships. Early co-ordinated care is essential in meeting the complex needs of this group of young people, highlighting the important role of a multi-agency public health strategy.

Child molesters and other sexual offenders

Stephen J. Hucker

Introduction

Though widely condemned, and often severely punished, throughout the world, only a relatively small proportion of all reported offences involve sexual behaviour. Nonetheless, research has repeatedly shown that, even if taken only as minimal figures, large numbers of people, both children and adults, report having been subject to some form of sexually unwelcome behaviour [1]. The legal term 'sexual assault' is now widely used in most Western countries to embrace any type of non-voluntary sexual act in which the victim is coerced or physically forced to engage against their will, or any non-consensual sexual touching of another person [2]. It includes forced vaginal, anal, or oral penetration (rape), drug-facilitated sexual assault, groping, forced kissing, child sexual abuse, or sexual torture.

The long-term effects of victimization have been extensively studied, and individuals with a history of childhood sexual abuse, for example, report a wide range of long-term psychological consequences [3]. And those who have been sexually assaulted as adults similarly and uniformly report extensive psychological, if not physical, repercussions [4].

Although often perceived as the purview of specialized forensic services, nearly all psychiatrists will at some time meet victims of sex offenders, if not offenders themselves. The general psychiatrist, for example, is almost certain on occasions to encounter a 'flasher' (exhibitionist) or a 'peeping Tom' (voyeur), as these are usually viewed by authorities as minor sex offenders not needing specialist attention. It is therefore important for the generalist to have at least some knowledge of sex offenders and their treatment, as they may be called upon to provide a report for court purposes, especially in places where availability of expert forensic services is limited.

Some definitions

A 'sex offender' is simply an individual whose sexual behaviour contravenes the law in a particular jurisdiction. However, criminological preoccupations with particular kinds of sexual offences have often varied considerably over time. The types of activities that may be proscribed will also vary considerably. Thus, in the last century, incest, homosexuality, and bigamy seem to have been the main

concerns, and child molestation and sexual assault much less so. Though some are more tolerant than others, most societies provide sanctions for sexual activity involving children below the age of consent, non-consensual sexual acts, sexual relations with close family members, and sexual interference with animals or corpses. Typically also there are legal and other interventions available in cases where a person fears sexual harassment or assault, where abuse of a child is suspected, and where there has been abuse, or likelihood of abuse, in certain professional relationships. As well there is commonly regulation of pornography and other obscene material.

'Sexual deviance' refers to those sexual behaviours that go beyond societal norms. They may be subject to legal sanctions as well, though in many cases not. It involves consistent, rather than occasional, sexual interests and behaviours. Common perceptions of what is 'normal' will also be influenced by whether the acts are committed in public or private. As with sex offending, the concept of sexual deviance will vary greatly across jurisdictions and at differing times.

Finally, 'paraphilia' is a diagnostic term popularized by Money [5] and currently used in official classification systems such as the World Health Organization's *International Classification of Diseases* (ICD) and the American Psychiatric Association's *Diagnostic and Statistical Manual* (DSM) to identify the experience of intense sexual arousal to atypical objects, situations, or individuals. The current edition DSM-5 introduced the term 'paraphilic disorder' which causes the individual distress or interferes with their personal functioning, whereas a 'paraphilia' in itself does not. The ICD prefers the term 'disorders of sexual preference', but both systems require the characteristic sexual behaviours or preferences to be persistent or recurrent and to cause subjective distress or interference with their social, occupational, or other important areas of their lives.

Although Money and others list numerous unconventional sexual interests and behaviours [6], in the two dominant classifications, worldwide only a few of the most common are listed individually and others relegated to a miscellaneous category such as 'unspecified paraphilia' [7]. Not all sex offenders are paraphilic or have a paraphilic disorder, and not all those diagnosed with a paraphilia or paraphilic disorder are sexual offenders. The psychiatric categories of paraphilia and paraphilic disorders and their characteristics are outlined in Chapter 115 of this textbook.

Types of sex offender

General psychiatrists will be concerned with sexual behaviours such as indecent exposure, obscene telephone calling, voyeurism, bestiality, incest, child molestation, and pornography collecting. Specialists will also be interested in sexually motivated homicide, the more serious forms of sexual assault, and necrophilia. Most sexual offenders are male, though a small number of women may commit similar crimes [8].

Child molesters

Sexual abuse of children has been reported and generally condemned throughout history [9], and the reportedly more permissive attitude in ancient Greece seems more or less an exception [10].

Thus, for example, a recent meta-analysis of 217 studies based on self-report data [11] estimated a global prevalence of 12.7–18% for girls and 7.6% for boys. A World Health Organization study [12] earlier reviewed estimates of childhood sexual abuse from 39 countries and found that the prevalence of non-contact, contact, and intercourse in female children was approximately 6%, 11%, and 4%, respectively; corresponding figures for males was about 2% for all categories. It is well known that many victims do not report such experiences, and when guaranteed confidentiality, individual sex offenders admit to many more offences than they were charged with or convicted of [13]. Similarly, sex offending against adults has also been underreported, though it is estimated that about 13% of women and 3% of men have been sexually assaulted at some time during their lives [14].

An early typology [15] for this group was based on the degree of apparent paraphilic attraction (sexual deviancy). The ‘fixated’ subtype identifies those paedophiles with an enduring attraction to children, typically dating from adolescence, and thereby conforming to the definitions of paedophilia in DSM-5 and ICD-10. Paedophiles attracted to male children are more likely to repeat their offences with recidivism at least twice as high as those attracted to girls. Homosexual paedophiles tend to victimize boys aged 11–15 years of age, whereas heterosexual paedophiles prefer girls of 8–10 years. ‘Fixated’ paedophiles tend to commit premeditated offences that often involve considerable planning, manipulation, and ‘grooming’ behaviour to lure, and even abduct, children into sexual activity, and they may gain the trust of the parents or other caregivers. Often they appear to have an excellent rapport with the child victims and treat them kindly, but the motive is primarily for the child to meet their sexual needs, rather than the reverse. It is for this reason that ‘needy’ children are often selected as victims. Such offenders will typically profess their ‘love’ for children and convince themselves that their behaviour is not harmful. Other rationalizations, such as that they were educating the child or introducing the child to sexual love in a caring way, are also common.

‘Regressed’ or ‘situational’ child molesters are, according to this typology, attracted primarily to adult females and may be in a marital relationship at the time of their offence. They will often report feelings of personal inadequacy or low self-esteem, and their offences are typically spontaneous and occur in the context of a stressful life circumstance.

In contrast to the ‘fixated’ type, the ‘regressed’ child molester is less inclined to ‘groom’ victims and their caregivers. Victims of this

type may be older than those involved with the ‘fixated’ type of molester. However, molestations may begin before and continue beyond puberty.

Critical of earlier typologies such as this, as well as of the definition in DSM, in their attempts to delineate paedophiles from other types of child molester, Knight *et al.* [16] developed a different model incorporating two axes that assess psychological issues, abuse behaviours, and the degree of sexual fixation. Though empirically validated, others have doubted its clinical usefulness because of its complexity [17]. It is worth noting that, in the literature, the terms ‘child molester’ and ‘paedophile’ are often used interchangeably, tacitly acknowledging that it is often difficult to differentiate the two. Moreover, the treatment may be determined by actuarial estimates and are also very similar.

Despite dire parental warnings to their children to be aware of strangers as potential sexual predators, the majority of individuals who molest children are either already acquainted or are related to them. The term ‘incest’ is used to identify situations in which a close blood relative is subjected to sexual abuse. Some researchers, based on statistical reoffence data, have suggested that the phenomenon is primarily a symptom of family dysfunction distinct from paedophilia, and that the perpetrator represents a low risk of extending their behaviour outside the family [18]. However, other authorities have found that as many as half of self-reported father or stepfather incest offenders had also abused children outside their families and 18% had raped adult women [13]. Some men pursue and subsequently marry or cohabit with single mothers with the intent to gain access to their children.

At one time, it was believed that paedophiles were inadequate, unaggressive men unable to form relationships with adult women. It is now well recognized that gratuitous violence is used by a substantial minority of paedophiles [19].

A further aspect of paedophilia that needs to be mentioned because of its increasing identification in the age of the Internet is the use of computers to view, manufacture, and distribute pornographic images of children [20]. Such imagery is widely used by such men to generate sexual fantasies, and the behaviour will then be reinforced by masturbation. Some have argued that this sequence essentially normalizes the fantasy and further disinhibits the user. This combination of disinhibition and cognitive distortions regarding the impact of the behaviour may stimulate the urge to seek more intense experiences from ‘hands-on’ experiences, rather than simply on a computer screen. However, the risk of this progression is likely exaggerated, as only a minority of Internet child pornography offenders, in fact, progress to molest a child [20]. Those with previous or concurrent contact sexual offences are more likely to have more than one reconviction, whether general or sexual, than those with child pornography offences who are only rarely reconvicted [21]. Nevertheless, research has shown that there are psychological and other similarities between men who use child pornography and those who actually do commit such offences. Child pornography offenders more often show evidence of arousal to children on phallometric laboratory testing than those who committed ‘hands-on’ offences against children.

Sexual assault of adult women

As with those who molest children, men who perpetrate sexual assault on adult women (rapists) do not necessarily justify a

diagnosis of a paraphilia [22]. Indeed attempts by some sexologists to have individuals who appear to prefer sexual relations with non-consenting partners identified by a paraphilia label (terms such as biastophilia, rape preference, or paraphilia-not otherwise specified—non-consenting) have been repeatedly rejected, often based on feminist arguments that to do so would thereby ‘medicalize’ inappropriately a predisposition in males generally to dominate women [23].

The typology proposed by Knight [24], though not extensively used and rather complicated for routine clinical use, does have the merit of highlighting the fact that several different motivations appear to underlie sexual assault of adult women. Thus, ‘anger-motivated’ rapists act out deviant fantasies of retaliation towards the victim, using violence as a means of expressing generalized anger, typically towards women specifically, but sometimes towards people in general. The motive of the attack is to humiliate and debase the victim who will typically have been picked randomly. The ‘power-motivated’ rapist is further divided into the ‘power-reassurance’ and ‘power-assertive’ subtypes. The former is afflicted by doubts and insecurities about their own masculinity and sexual adequacy, often uses minimal force, and may apologize to the victim or even seek a relationship afterwards. However, the victims may have been stalked and the attacks on them premeditated. The ‘power-assertive’ subtype is motivated by the desire to dominate women, and such men have no doubts about their masculinity. However, unlike the previous subtype, they typically do not use gratuitous violence to subdue the victim. On the other hand, ‘sadistic’ rapists, the least common but, in many ways, most worrisome subtype, derive sexual pleasure from inflicting pain and suffering on the victim. However, this is often difficult to differentiate from other rapist types where pain, suffering, and humiliation are also the consequences, but not the primary motivation for the attack [25].

Other types of sexual assault may not involve any kind of penetration but represent related behaviours, including toucheurism and frotteurism. These involve, respectively, touching or grabbing strangers, typically females, in a way that provides the perpetrator with sexual gratification. The former, in particular, may pass unnoticed by the victim, as attackers will typically touch or grab sexual areas such as breasts, buttocks, or crotch, in crowds and similar situations and the incident may be discounted as ‘accidental’.

Non-contact sexual offences

There are several common types of sexual offence that do not involve any physical contact with the victim [26]. The group includes ‘peeping Toms’, ‘flashers’, and indecent phone callers, with their corresponding psychiatric diagnoses of the paraphilias voyeurism, exhibitionism, and telephone scatologia, respectively.

‘Peepers’ or voyeurs like to observe an unsuspecting female stranger undressing, or couples in the act of copulation. They may masturbate at the scene or later in private, while recalling what they saw. Most voyeurs, like most sex offenders generally who are paraphilic, are aware of their deviant impulses while still adolescent, but the behaviour may become chronic. Many men will admit to enjoying watching adult women in this situation or attend striptease shows, making these difficult to differentiate from those who prefer this activity.

‘Flashers’ or indecent expositors will often justify a psychiatric diagnosis of exhibitionism. These men become sexually excited

while exposing their genitals, sometimes erect and sometimes not, to unsuspecting female strangers. The preferred reaction is one of shock or outrage. Complete indifference is a useful response if the victim has the presence of mind. The perpetrator may masturbate at the time or later in private. It is unusual to see an exhibitionist still active past the age of 40, but many are nevertheless for a time quite intractable and will expose themselves in situations where they may well be apprehended or reported. This suggests a degree of risk-taking that enhances the excitement.

Obscene telephone callers, corresponding to the paraphilic diagnosis of telephone scatologia, call unsuspecting female victims and proceed to bombard them with explicit and sometimes frightening sexual comments, such that the victim may be very distressed by them. However, they often do not report them unless they are particularly persistent or if their voice or something they say reveals their identity. Often the individual masturbates while doing this. If apprehended, which is uncommon, it may be difficult to distinguish them from a simple prankster. However, a repetitive pattern will usually point to the appropriate diagnosis.

Though typically seen as ‘nuisance offences’, they are, in fact, much more common and more psychologically disturbing than is generally appreciated, and recent research [27] has indicated that large numbers of young women have directly experienced the behaviour of frotteurs and exhibitionists and experience considerable subsequent emotional distress.

As well, these non-contact offences are not generally regarded as a danger. However, in some cases, estimates place them somewhere around 10%, and the individual may engage in related paraphilic behaviours or progress to more serious sexual assault [28]. Attempts to approach or speak to the victim may well be warning signs of this. The behaviour therefore should not be taken lightly, and all available information about the perpetrators’ actual behaviour in the index offence, as well as previous incidents, needs to be scrutinized with this possibility in mind.

Assessment of sex offenders

As was noted at the beginning of this chapter, more serious sex offences are likely to require the expertise of specialized forensic services. The less serious or less intrusive offences may well fall into the hands of a general psychiatrist, and it is useful therefore to have a sense of what is involved if the matter requires a report or even an actual testimony in court.

Pre-trial situations usually require assessment of fitness (competence) to stand trial, though sometimes criminal responsibility will also need to be addressed. Only a small number of sex offenders show symptoms of a psychotic mental disorder such as schizophrenia or depression [29]. However, when such disorders are present, it will be necessary to explore whether and how the symptoms bear specifically on the sexual behaviour [30]. For example, the patient may report that they were acting in response to auditory hallucinations or specific delusional ideas about the victim or type of victim.

It is more likely, however, that other psychiatric disorders will be found among sex offenders. A diagnosis of mental retardation or personality disorder or, more particularly, paraphilia will be more relevant with respect to the offending behaviour [31].

Especially in more serious cases, the court may be interested in sentencing considerations, specifically the risk the offender presents to others and whether and what medical and/or other professional treatment or interventions might be ordered or recommended by the court to reduce that risk.

Few sex offenders will have presented to a psychiatrist or psychologist voluntarily. It is therefore helpful for the interviewer to assume that the subject will be at best guarded or possibly frankly hostile in their response to the assessment. It may be difficult to achieve the level of rapport more commonly experienced with non-psychotic general psychiatric patients. A non-judgemental approach is therefore desirable, regardless of the examiner's personal emotional reaction to the offences that are alleged. For example, an offender who has molested a child, or exposed to a group of children, will often arouse very strong feelings in the examiner, particularly when they have children of their own, and it is necessary to hold such reactions in check. Judging the alleged offender, especially when his guilt has not been determined by the court, is not an appropriate professional attitude.

Denials, rationalizations, distortions, and minimization are the kinds of cognitive distortions that are the norm with sex offenders. There is a frequent tendency to prevaricate or frankly lie. It is therefore essential for the examiner to have detailed information from police reports and elsewhere about the act or acts that are alleged to have occurred. Direct, interrogation-style confrontation is usually not particularly productive, and an oblique approach may obtain more information that will be useful in identifying a diagnosis and determining rational treatment possibilities.

Particularly unhelpful in gaining rapport or obtaining information is to accuse the individual of dishonesty or dissembling. A sympathetic approach, suggesting that sometimes people have difficulty accepting unpleasant aspects of themselves, may be more helpful. Alternatively, one can invite the subject to explore why the victim might have made the accusations if they are untrue and whether they can accept, if not the whole, then some parts of the accusations against them. Also important to remember is that while the individual may have been accused of one type of deviant sexual behaviour, other types of paraphilic behaviour may also have occurred and been undetected. Paraphilic disorders tend not to occur alone, but rather in association with other paraphilias [32], typically at least two or three. Thus, for example, an exhibitionist may have been reported for exposing specifically to children, rather than adults, and this will suggest an additional diagnosis of paedophilia. Similarly, an individual who is being convicted of rubbing himself against women in public places may also have made obscene phone calls and harbour fantasies of rape.

In the case of child molesters, it is important to consider how the perpetrator gained access to his victims. Exploration of the methods of 'grooming' is important in understanding ways to assist the offender to avoid risky situations in the future.

In terms of the overall assessment, identification of psychopathology outside the domain of sexual deviation is important. The presence of psychotic illness will have implications for the type of treatment to be recommended, even if it is not common among sex offenders [30]. It seems likely that, in some such offenders, the sexual behaviour is dismissed as a function of their mental illness and the underlying paraphilic disorder may easily be discounted

or not be considered at all. More commonly, it will be personality disorders or traits, alcohol or substance abuse, mild to moderate depression, and anxiety disorders [31, 33], rather than major mental illness that will be noted. Attention to these will nevertheless be an important part of any subsequent treatment or management recommendations [33].

Psychometric testing may contribute additional information to the overall assessment of a sex offender, in particular where the subject is not forthcoming in a personal interview. There are a number of general personality assessment instruments available. These include the well-known and widely used *Minnesota Multiphasic Personality Inventory* (MMPI), the *Millon Clinical Multiaxial Inventory-III* (MCMI-III), and the *Personality Assessment Inventory* (PAI). All have been, and are being, extensively used in offender populations, including sex offenders, and common profiles have been identified. Although none can specifically identify a sex offender, the information gained concerning impulsivity, denial, judgement, and general psychopathology may be very useful.

In addition, there are a number of psychological tests that have been developed specifically for the assessment of sex offenders. These include the *Multiphasic Sex Inventory-2* (MSI-2) [34] and the revised version of the *Clarke Sex History Questionnaire* (SHQ) for Males [35]. The MSI-2 is designed to measure the sexual characteristics of an adult male (there is a female version as well) alleged to have committed a sexual offence or sexual misconduct, including those who deny the allegations. Though standardized in the United States on a large sample of sex offenders, it is used very widely. It consists of 560 true/false questions, and the completed questionnaire must be sent to the developers for computerized scoring and interpretation. The SHQ consists of 508 questions, and the completed questionnaire may again be sent away for scoring and an interpretive report returned.

Phallometric testing (penile plethysmography)

Because sex offenders commonly lie and distort their self-report of deviant interests and behaviours, a more objective method of assessment has long been sought. One of the earliest to be developed was penile plethysmography (PPG)—phallometry—to measure changes in response to erotic stimulation [36]. This method involves measuring changes in the size of the penis, either in circumference or volume, while presenting the subject with carefully selected images, both still and moving, of both sexes and different age groups, and audiotaped descriptions of various sexual activities. There are certainly problems with PPG testing [37, 38], including the standardization of stimulus materials used [39, 40]. Some offenders are able to either learn to suppress their physiological response or masturbate before the testing in order to render themselves unresponsive. Nonetheless, PPG, most commonly using a circumferential device or the volumetric method, is extensively used in the assessment of sex offenders.

In the United States in particular, PPG has come under attack [41, 42] as, in addition to standardization and reliability issues, it has used pictures of children whose consent or that of their parents had never been obtained. Computer-generated images have been developed in an attempt to obviate this concern [43].

Other less intrusive methods of assessment are also widely adopted, including the Abel screen [44, 45] which measures time the subject spends viewing non-nude images.

Mention must also be made of the polygraph, or 'lie detector', with sex offenders which is being used extensively in many parts of the United States and in the United Kingdom [46, 47]. The subject is asked questions relating to the sexual interests and activities, while their pulse, respiration, and skin conductance are measured. Research in the area is generally weak, and despite its widespread use and perception of usefulness, particularly for monitoring sex offenders in the community, the method is controversial [48, 49].

Assessment of risk in sex offenders

An assessment of the future risk of sex offending is often requested by the court, so it is important for any psychiatrist being asked to provide this to have an understanding of the factors that contribute to this (Boxes 141.1 and 141.2).

Box 141.1 Established risk factors for sexual recidivism

- Sexual criminal history:
 - Prior sexual offence
 - Victim characteristics (unrelated, strangers, males)
 - Early onset of sex offending
 - Diverse sexual crimes
 - Non-contact sexual offences.
- Sexual deviance:
 - Any deviant sexual preference:
 - Sexual preference for children
 - Sexualized violence
 - Multiple paraphilias
 - Sexual preoccupation.
- Attitudes tolerant of sexual assault.
- Lifestyle instability/criminality:
 - Childhood behaviour problems (for example, running away, grade failure)
 - Juvenile delinquency
 - Any prior offences
 - Lifestyle instability (reckless behaviour, employment instability)
 - Personality disorder (especially psychopathy)
 - Grievance/hostility.
- Social problems/intimacy deficits:
 - Single (never married)
 - Conflicts with intimate partners
 - Hostility towards women
 - Emotional congruence with children
 - Negative social influences.
- Response to treatment/supervision:
 - Treatment dropout
 - Non-compliance with supervision
 - Violation of conditional release.
- Poor cognitive problem-solving.
- Age (young).

Source: data from *J Consult Clin Psychol.*, 66(2), Hanson RK, Bussiere MT, Predicting relapse: a meta-analysis of sexual offender recidivism studies, pp. 348–62, Copyright (1998), American Psychological Association; *Sex Abuse*, 22(2), Mann RE, Hanson RK, Thornton D, Assessing risk for sexual recidivism: Some proposals on the nature of psychologically meaningful risk factors, pp. 191–217, Copyright (2010), SAGE Publications.

Box 141.2 Characteristics with little or no relationship with sexual recidivism

- Victim empathy.
- Denial/minimization of sexual offence.
- Lack of motivation for treatment.
- Clinical impressions of 'benefit' from treatment.
- Internalizing psychological problems (anxiety, depression, low self-esteem).
- History of being sexually abused as a child.
- Sexual intrusiveness of sexual offences (for example, intercourse).
- Low social class.

Source: data from *J Consult Clin Psychol.*, 66(2), Hanson RK, Bussiere MT, Predicting relapse: a meta-analysis of sexual offender recidivism studies, pp. 348–62, Copyright (1998), American Psychological Association; Hanson RK, Morton-Bourgon K, Predictors of sexual recidivism: An updated meta-analysis 2004–02, Copyright (2004), Public Works and Government Services Canada; *J Consult Clin Psychol.*, 73(6), Hanson RK, Morton-Bourgon KE, The characteristics of persistent sexual offenders: a meta-analysis of recidivism studies, pp. 1154–63, Copyright (2005), American Psychological Association.

Risk factors have been divided into:

1. Static risk, that is, involving those factors which cannot change, such as the offender's age, sex, or number of previous criminal convictions; and
2. Dynamic risk, that is, involving those factors which potentially could change, either as a result of treatment or some other intervention or simply the passage of time. This can be further subdivided into: relatively stable, but nonetheless potentially changeable; factors such as sexual preferences or negative attitudes; and acute factors such as access to victims, reversion to substance use, and active mental illness.

Static factors have received the most scientific study, and it is chiefly these that have been incorporated into various actuarial or statistical instruments that have been developed, based on follow-up studies of samples of sex offenders [50]. Among these instruments, the Static-99 and its recent modifications [51] and the Sex Offender Risk Appraisal Guide (SORAG), now replaced by the Violence Risk Appraisal Guide-Revised (VRAG-R) [52], are the most widely used. Though the assessment instruments have been published or are available online, a professional intending to use any of these instruments needs to be thoroughly familiar with the literature on the topic of risk assessment and to have participated in training workshops that are given at conferences and elsewhere from time to time [53]. Useful though these tools can be, too heavy reliance upon them is no substitute for a full understanding of how they were constructed and their limitations [54].

Treatment issues

It is rare for a paraphilic individual to present for treatment in order to prevent themselves from becoming a sex offender (though see [55]). While some paraphilias are usually not associated with criminal behaviour (for example, transvestic disorder or fetishistic disorder), others, such as paedophilia or sexual sadism, are much more likely to be referred from the court or subsequently by probation and parole services.

It is important to realize that, though some dissent from this view [56], sexual preferences are highly resistant, if not impossible, to change (see [57]). The most that can usually be expected with sex offenders who have deviant sexual preferences (paraphilic disorders) is to help them learn to control their behaviour and to recognize that their propensity will always remain in the background, much as alcoholics are advised to consider themselves always vulnerable to relapse.

Psychological treatments have often been attempted with sex offenders [58]. Psychodynamically based individual and group treatments have been the most commonly used in the past. It has become clear more recently, however, that cognitive-based therapies are the preferable strategy to employ, although techniques involving classical behaviour therapy, for example covert sensitization, are also sometimes used for specific purposes such as creating aversion to deviant arousing images and replacement of these with non-deviant ones. Cognitive-based therapy itself involves helping the subject to develop strategies to alter their thought processes in order to avert their deviant behaviour, to improve their social skills, and to remedy their distorted beliefs and attitudes.

There is little or no evidence for the efficacy of psychological treatments prior to the introduction of cognitive-based therapy. Based on a meta-analysis of 43 published studies, it has been shown that treatment programmes using this approach are associated with a reduction in overall recidivism rate from about 17% to 10% [59]. Similar findings have been reported by others [60], though, as Hanson and Yates pointed out, there have been very few high-quality treatment studies [55]. The most effective programmes are those that adhere to risk/need/responsivity principles (see [61]). Thus, the highest intensity of treatment should be given to those of highest risk; treatment must address factors known to be associated with a risk of recidivism, and the therapy needs to be presented in a language and format such that the culture and learning styles of the offenders are addressed adequately.

Psychological treatments of all types have, until recently, focused on offenders' deficits and difficulties, rather than their strengths and other assets. The development of the 'Good Lives Model' [62] marked a turning point, and this approach has been integrated in to many of the programmes currently in use. The aim of this treatment is to help the sex offender meet his needs more appropriately and achieve pro-social life goals, thereby reducing the attractiveness of his offending behaviour [63].

Another approach that has yielded some very positive results has been the Circles of Support and Accountability (CoSA) [64]. Originating with leaders of the Mennonite Church in Canada, it has been adopted in a way that does not require religious affiliation. It is designed to provide intensive support for offenders upon release from prison and develop realistic risk management strategies to achieve successful community reintegration.

Despite some apparent progress, there is still controversy over the effectiveness of sex offender treatment programmes, and there remains a continuing need for better designed research.

Medications

A number of different medications have been used to treat sex offenders [65–70]. Based on empirical observations of animals, which

become less sexually active following neutering, hormonal treatments that reduce testosterone levels have been extensively employed. All require careful discussion with the potential patient concerning side effects, and it is important to obtain written, informed consent [71].

Oestrogens proved to be problematic because of the serious risk of thromboembolic complications, and a safer alternative was found in cyproterone acetate (Androcur[®]) [72], an anti-androgen which is available in Europe, including the United Kingdom, and in Canada, but not in the United States. Medroxyprogesterone acetate (Provera[®]) [73, 74] was introduced as an alternative. Both drugs may be responsible for minor side effects such as weight gain, tiredness, and gynaecomastia (especially with cyproterone), as well as more serious problems, including thromboembolism and increased blood sugar.

More recently, luteinizing hormone-releasing hormone (LHRH) agonists [75–77], such as leuprolide acetate (Lupron[®]), goserelin (Zoladex[®]), and others, have been found useful as they produce almost total suppression of testosterone production, such as would be seen following surgical castration [78]. However, they tend to be used mainly in very high-risk offenders or those who have failed with other drugs [79].

Reduction of oestrogen or androgen removes restraining effects on osteoblastogenesis and osteoclastogenesis, and causes an imbalance between resorption and formation of bone by prolonging the lifespan of osteoclasts and shortening the lifespan of osteoblasts. Thus, all of these hormone-reducing substances, though especially the LHRH agonists, have a tendency to increase the rate of bone remodelling and weaken its structure; it is necessary to monitor carefully for this side effect through annual bone density scanning and to administer antidotes, including calcium supplements, vitamin D, and possibly bisphosphonates [80].

However, the main problem with hormonal treatments is their lack of acceptance by those who might potentially benefit. An alternative approach using serotonin reuptake inhibitors has therefore been better received, though the necessary double-blind trials are still lacking [81]. They depress libido in only about 50–60% of cases. Higher doses, such as those used in obsessive-compulsive disorder, are sometimes necessary. The risk of prolonging the QT interval on the electrocardiogram is then one of the few reasons for which to choose one selective serotonin reuptake inhibitor (SSRI) over another, besides patient tolerance of different subjective side effects like nausea and sleep disturbance.

Ethical problems

Several ethical issues have so far been mentioned in passing. However, it is worth re-emphasizing in conclusion that a disinterested professional demeanour is important when assessing sex offenders. No matter what his or her own private views, it is not the place of the clinician to decide on guilt or innocence or in any other way to pass judgement on the offender or alleged offender. Moreover, alienating the offender will present a further impediment to gaining information and to providing treatment when indicated and necessary.

It is important, at the assessment stage, to identify for the subject the nature of the evaluation, the role of the assessor, and the person or agency for whom they are acting, for example a child protection

service, a defence lawyer, or a crown prosecutor. This may limit the degree of co-operation. However, when the purpose of the evaluation is solely to provide a risk assessment, not to explain this fully (and simply to present oneself as a 'doctor' in a helping role) would be unethical.

Certain assessment procedures, such as PPG or polygraphy (when used in a clinical setting), are particularly contentious. Though both may provide useful information, written and fully informed consent should always be obtained beforehand.

Finally, when the drugs that have been developed and marketed for other purposes are used to suppress sexual drive (so-called 'off-label' use), the patient needs to be fully informed of the potential benefits, as well as the risks involved, and should not be denied complementary or alternative treatments should they decide not to expose themselves to potential side effects. They also need to be aware that, though the clinician is not in a position to insist on such treatment, their refusal to participate may well have repercussions with probation and parole officers or the court itself, and these issues need to be fully discussed with the patient to avoid misunderstandings.

Stalking and querulous behaviour

Rosemary Purcell and Paul E. Mullen

Stalking

Stalking occurs when a person repeatedly intrudes upon another in such a manner that the recipient fears for his or her safety or experiences significant distress [1]. The intrusions can involve following, loitering nearby, maintaining surveillance, approaching the victim, and communicating via telephone, letters, email, social media, or notes attached to property. Associated behaviours include ordering or cancelling goods and services on the victim's behalf (for example, pizzas or taxis in the former, and utilities such as gas or electricity in the latter), spreading malicious rumours, vexatious complaints, threats, property damage, and assault.

Stalking is motivated by a range of intentions. Some stalk in hope, some in anger, some in lust, some in ignorance, and some in mixtures of these motives [1]. Research suggests that the overarching term 'stalking' encompasses two basic patterns [3]. The first involves incursions that are largely confined to following or unwanted approaches perpetrated usually by a stranger, which last only a day or so before ending, usually without the need for intervention. The second is characterized by a broader range of intrusions, perpetrated most commonly by someone known to the victim (for example, an ex-partner, acquaintance, colleague, or neighbour), that lasts for months or even years. The first type of stalking is often distressing but rarely culminates in threats or physical violence or inflicts psychosocial damage. The second type is far more likely to be associated with longer-term psychological disturbance and lifestyle alterations, as well as threats and assault. The watershed between these two forms of stalking is the continuation of the behaviours for more than 2 weeks [3], which is important to recognize from an early intervention perspective.

Stalking is proscribed as a criminal offence in most English-speaking countries, as well as a number of European countries (Austria, Belgium, Denmark, Germany, Italy, Malta, and the Netherlands), although to date only Japan and India have enacted laws in the Asian region. The drafting of stalking legislation has not been without controversy [4, 5], particularly since stalking behaviours can overlap with interactions that, however unwelcome or inappropriate, are nonetheless part of many people's everyday experience (such as being pursued for a relationship) or regarded as culturally acceptable.

Epidemiology of stalking

Estimates of the prevalence of stalking, as with any other phenomenon, will vary according to definition, sampling, method of enquiry, and the willingness of subjects to respond and disclose their experience. Reported lifetime rates of victimization suggest that stalking is a prevalent social problem, affecting an estimated 10–15% of adults [6–10]. Stalking also occurs among juveniles [11, 12], with an estimated 12-month incidence of 16.5% for victimization and 5.3% for perpetration [13]. Irrespective of age, the majority of victims are female (70–80%), while stalkers are male (80–85%). Victims are typically pursued by someone known to them (80%), though strangers account for a significant minority.

Cyberstalking has attracted considerable media interest, but few systematic studies. Broadly defined as repeated, unwanted contacts via the Internet, social media, and other communication technologies, 'pure' cyberstalking is relatively uncommon, affecting an estimated 6% of Internet users [14] or 7% of stalking victims [15]. Cyberstalking appears to be one more technique in a perpetrator's arsenal, rather than a distinct type of activity. The level of concern about cyberstalking appears to be driven more so by the *potential*, rather than the actual, size of the problem. Well over half a billion people share personal information every day on Facebook alone, let alone other platforms such as Twitter or Instagram. The scope for cyberstalking, particularly gathering information about a victim, is undoubtedly immense.

The impacts of stalking

Stalking is an act of violence in itself that causes psychological distress and social disruption (and, in many cases, occupational impairment), as well as a harbinger of assault. Being stalked can produce a corrosive state of fear, arousal, and helplessness. As with intimate partner violence, for most victims, it is not the blows which are the most destructive, but living in a chronic state of intimidation or looming vulnerability. Clinical and epidemiological studies have indicated that the majority of stalking victims report psychiatric morbidity, most commonly disruptive levels of anxiety (including hyperarousal), sleep disturbance, and lowered mood [16–18]. A significant minority also report considering suicide to escape the situation [16] and/or admit to homicidal fantasies toward the stalker [1].

Psychiatric morbidity appears to be mediated not only by stalking-related factors, particularly threats and ongoing harassment, but also by individual vulnerability factors, especially the use of avoidance as a coping strategy [19], the latter being amenable to treatment.

Stalkers: classifications and typologies

Stalking, like most forms of complex human behaviour, can emerge from a wide range of psychological, social, and cultural influences. In the absence of any comprehensive explanatory theory of stalking, over 20 typologies have flourished [20], most of which categorize according to the stalker's prior relationship with the victim, an underlying mental disorder, and/or the primary motivation for the stalking.

Classifying stalkers by the nature of their prior relationship with the victim has the advantages of simplicity and utility. Mohandie and colleagues [21] used this approach in their classification, which divides stalkers into those with a prior relationship and those without. This classification's greatest utility is in predicting the risks of assault, with those targeting ex-intimate partners constituting the highest-risk group and those targeting public figures/strangers the lowest. The nature of the prior relationship is recognized as a critical aspect of any classification but, in isolation, is insufficient, as it is unlikely to adequately guide clinical or legal interventions.

The typology developed by Mullen and colleagues [1, 2] is multi-axial, depending primarily on the context in which the stalking emerges and the motivations which initiated and sustain the behaviour, along with the nature of the prior relationship and any underlying mental disorder in the perpetrator. Its appeal has been primarily to clinicians managing stalkers and stalking victims [22]. The typology enables predictions to be made about the duration of the stalking, the nature of the stalking behaviours, the risks of threatening and violent behaviour, and, to some extent, the response to management strategies [1, 23]. There are five main stalker types:

1. *The rejected* whose stalking begins in the context of the breakdown of a close (usually sexually intimate) relationship. The stalking is initially motivated either by the desire for reconciliation or to express rage at rejection, with a mixture of both being common. The stalking is often sustained by the pursuit becoming a substitute for the lost relationship, with the satisfactions from intrusion and control replacing those of intimacy.
2. *The intimacy seeker* who is pursuing love. The stalking begins in the context of a life lacking intimacy and is motivated by the hope, or firm expectation, of obtaining a loving relationship with a person on whom they have fixed their amorous attentions. The pursuit is sustained in the face of indifference or outright rejection, because better a love based on fantasy or delusion than no love at all.
3. *The incompetent suitor* who is pursuing a sexual encounter or friendship. This usually begins in the context of loneliness and is motivated by a desire to start some form of relationship with someone who has attracted their interest. This group often pursues intensely but rarely persists for prolonged periods, presumably because multiple rebuffs bring few rewards.
4. *The resentful*, whose stalking starts in the context of a grievance at being unjustly treated or humiliated. The initial motivation is revenge, but this gives way to the satisfactions obtained from the sense of power over someone who has previously been experienced as an oppressor.
5. *The predatory*, which begins in the context of the desire to act out violent or sexual fantasies often of a sadistic or paedophilic nature. The initial motivation is to gain information about the movements of a potential victim (usually a stranger or acquaintance). The stalking continues because of the satisfactions accruing not just from voyeurism, but from the excitement and sense of power which comes from rehearsing the planned attack in fantasy while watching the future victim.

Each of the stalker types (hopefully with the exception of the predatory) has correlates in normal behaviour [24]. When relationships break down, one partner is often confused or distressed by the separation and seeks to understand, reconcile, or express anger. The incompetent suitor is akin to the awkward adolescent or socially inept adult who fails to traverse the social minefields of dating or simply making acquaintance. The intimacy seeker is the adolescent crush and the enthusiastic fan writ large. Even the resentful is not far removed from some seekers after justice and those asserting their rights. In theory, the boundary between persistent approaches as part of socially acceptable behaviour and the crime of stalking is difficult to isolate. In practice, the distinction is rarely a problem. Stalkers are those who repeatedly impose themselves on another person in a manner that creates obvious distress. It is the disregard of, or blindness to, the disturbance that their behaviour creates that distinguishes the stalker from their more normal counterparts.

Psychopathology of stalkers

Stalkers are rarely drawn from the psychologically adequate or socially able of the world. The proportion of stalkers whose behaviour is directly related to mental illness varies according to where the researchers derived their sample (for example, clinical settings vs law enforcement) and the proportion of strangers or acquaintances in the sample, with the rates of mental illness, particularly psychosis, highest in these groups [25, 26].

In broad terms, psychotic disorders are relatively frequent in the intimacy-seeking group. In the resentful type, paranoid disorders unsurprisingly predominate, though most are not associated with frank delusion. The rejected most often have problems around dependency, entitlement, rigidity, and control, with substance abuse and depressive states occasionally complicating the picture. The incompetent suitors are socially disabled by shyness, narcissism, intellectual limitations, or autism spectrum disorders, but always with interpersonal insensitivity or indifference. The predatory are sexually perverse and not infrequently have marked psychopathic traits, but they are rarely psychotic [1].

Attachment theory has unsurprisingly been evoked to explain stalking [27]. That stalkers as a group do not manage interpersonal relationships very well is obvious. Attachment style has been shown to differ according to stalker type [28], which may be useful in the formulation process, but what connection it may have with any theory of early development is speculative. A deficit in verbal, relative to performance, intelligence quotient (IQ) has also been found [29], which should be considered in relation to an individual's ability to engage in particular psychological treatments.

Stalking of health professionals

Health professionals have a heightened vulnerability to being stalked by their clients [30–32]. The risk stems both from resentful, disappointed, or disgruntled patients, and lonely and disordered people who misconstrue empathy and attention for romantic interest [33, 34]. While some stalking behaviours constitute little more than minor irritations, they may also ruin a clinician's career.

Rates differ according to the setting and professional groups surveyed. For example, 53% of clinical staff in an inpatient psychiatric service reported being stalked by a patient [35], compared to 21% of psychiatrists in a large mental health organization [36]. General practitioners report high rates of intrusiveness by patients (70%), with 20% having been stalked and a further 20% subjected to a short burst of harassment [37]. Almost one in five psychologists report stalking by a client [38], 30% of whom were subjected to vexatious complaints to professional boards, which left many considering whether they wanted to continue with their profession.

Clinicians who fall victim to stalking by patients may bear the additional burden of implied or overt criticism from colleagues to the effect that, had they more adroitly managed the therapeutic encounter, they would not now find themselves in this predicament. There should be no tolerance with blaming the victim, even if it comes in the guise of collegial advice or supervision. Being stalked is an occupational hazard for the health professions. Affected colleagues should be accorded support and help, if for no other reason than we do not know when it may be our turn to face the pursuit of the vengeful or lustful patient.

Risk assessment and risk management

Assessing and managing the stalker requires a primary focus on the risks they present to the victim, in terms of physical violence, as well as psychosocial damage. The risk that stalkers incur from their *own* behaviour also needs to be considered. The conflict between the stalker's desires and the victim's interests is obvious, but they are at one in being at risk of damage from the stalking situation. There can be a tragic symmetry between the victim becoming preoccupied with the stalking and forced to live an increasingly restricted life in a state of apprehension and the stalker devoting all his/her time and resources to a damaging and ultimately self-defeating pursuit. The victim's and the perpetrator's lives can be laid waste. This is not to argue for equivalence between victim and perpetrator, but merely to note that they share the chance of disaster. A perspective which encompasses the risks to stalkers and victims has the advantage for health professionals of reducing the ethical dilemma when treating stalkers around whose interests one is serving, the patient's or their victim's. Both are assisted to the extent that treatment stops the stalking or reduces its damaging impacts.

The empirical basis for evaluating risk in the stalking situation

Risk assessment in stalking situations is hampered by a paucity of retrospective or prospective studies of representative samples. Clinicians do not have the luxury of deferring action until such evidence emerges, and so must instead depend on integrating knowledge from stalking research or systematic studies of risk in other areas and drawing on clinical experience [1].

The risk of continued or recurrent stalking

Once stalking has continued for more than 2 weeks, the chances are high that it will continue for months [3]. The duration is longest for intimacy seekers and rejected stalkers pursuing ex-intimates, with the incompetents usually pursuing only briefly [1, 2]. Stalking recidivism (of the same victim) is associated with mental status, personality disorder, and prior criminal offending [39, 40].

The risks of psychosocial damage to victims

There is some indication that female stalking victims report a greater psychological impact than males [6, 16]. Male victims are less inclined, however, to report fear (a requirement in most legal definitions) when they are stalked by a female; this likely explains the preponderance of same-gender stalking among men in community samples [6, 8]. Psychological distress is higher among victims subjected to prolonged and repeated following and the experience of property theft or destruction [17, 41, 42]. The relationship between psychological impact and the experience of physical violence is less clear, despite its intuitive appeal [42, 43].

The risks of physical violence

Prior relationship

Victims who have shared a prior intimate relationship with their stalker are at high risk of assault [44–47]. In a random community sample, ex-intimates were the most likely to be attacked (56%), followed by estranged relatives or friends (36%), casual acquaintances (16%), work-related contacts (9%), and strangers (8%) [8]. Such findings should not be interpreted as suggesting that victims of stalkers who are not ex-intimates are in little danger of physical violence. A chance of between 8% and 36% of being assaulted is no small risk.

Threats

Between 30% and 60% of stalking victims are threatened [2, 26, 44]. In a community-based study, 44% of those threatened were subsequently assaulted and 73% of victims assaulted by their stalker had previously been threatened [8]. In short, threats are highly associated with violence and should be taken seriously.

Mental disorder

Research has generally concluded that psychotic stalkers are less likely to be physically violent than their non-psychotic counterparts, but the relationship to personality disorder remains unclear [46, 48, 49].

Substance abuse

Substance abuse is associated with violence in the stalking situation [2, 50–52].

Prior offending and antisocial behaviour

Empirical data on the association between past criminal or violent behaviour and stalking violence are inconsistent [43]. However, the balance of the evidence favours such a relationship [44, 50].

Demographic variables

The gender of stalkers has no impact on the rates of threats or assault [53–55]. Preliminary research indicates that the prevalence of

threats and assault is higher among juvenile stalkers, compared to their adult counterparts [12], suggesting that younger perpetrators prefer more direct forms of harassment, as opposed to some of the more surreptitious pursuit employed by adults.

The nature of the stalking

Violence is predicted by escalating intrusiveness and the intensity of the stalking behaviour [56]. The strongest association is with physical intrusions into the victim's house or place of work [49].

Assessment and management

Initial assessments of stalkers often occur in the context of presentence or parole board evaluations. Victims may be encountered in a wider range of contexts, many seeking help from general, rather than forensic, mental health professionals. Stalkers usually lack insight into their behaviour and tend to deny, minimize, and rationalize their actions. Victims often minimize the experience of stalking and over-emphasize their own responsibility for the harassment, which should be of no surprise to anybody experienced in working with victims in other contexts. Conversely, the problem of false claims of stalking victimization cannot be entirely ignored [57] and indeed can be guaranteed to be encountered among practitioners who specialize in the treatment of stalking victims. This group, particularly if delusional, are often obvious, given implausible and exuberant accounts of victimization. Care should be taken in dismissing claims of being stalked, however, as there are some calculating stalkers who leave few, if any, objective signs. False victims require help and treatment, not rejection, but they require quite different treatment from actual victims [57].

In all cases, it is essential to assess collateral information from such sources as witness statements, victim impact reports, judges' sentencing remarks, and professional-to-professional contacts, confidentiality allowing. Attempts to contact the victim when assessing the stalker, or the stalker when assessing the victim, are not advised. However, skilfully managed, such contacts tend to be experienced by the victim as the professional acting as an agent of the stalker, and by the stalker as support for their beliefs that this is a misunderstanding within a mutual relationship.

A comprehensive assessment of the stalker should answer at least the following questions, to enable a preliminary formulation:

1. What motivated the stalking, what sustains it, and what is the nature of the prior relationship with the victim (if any)?
2. What, if any, is the nature of the stalker's current mental disorder (including salient personality characteristics)? How has this been managed previously?
3. What is the nature and extent of the stalker's substance use/misuse?
4. Into which stalking type does the stalker best fit, based on these previous questions?
5. What are the stalker's current social circumstances/supports?
6. What role could treatment have in ameliorating the stalking?
7. What is the probability of continued stalking and/or physical violence?

The management of stalkers remains very much the province of forensic mental health professionals, and even among them, it is a specialist area. Basic approaches to identifying potentially

remediable risks and their management, along with more specific interventions for particular stalker types, have been explored by Mullen and colleagues [1].

Stalking victims rarely present for mental health care after the fact; most will be exposed to ongoing intrusions, such that their safety needs have to be prioritized, along with their mental health. Some victims of prolonged, intense stalking can manifest symptoms of complex post-traumatic stress disorder (PTSD) [58] and may have a poorer response due to the sense of having been permanently changed or damaged by their victimization. Like many victims of crime, stalking victims may be reluctant to disclose the details or even the existence of traumatic experiences. As noted earlier, self-blame (or indeed explicit blame by those around them) is not infrequently part of the picture.

Stalking victims need good psychiatric care. Strategies to manage stress reactions are required, along with methods to ameliorate hyperarousal and/or depressed mood. The following is a brief account of key interventions to combat stalking that should be canvassed in the treatment of victims:

1. *Inform others.* It is essential that victims inform those they love or with whom they work or socialize. This performs three functions:
 - i. It enables others to support the victim and to avoid inadvertently assisting the stalker.
 - ii. It prevents those around the victim from being put at risk by ignorance or by provoking the stalker and exacerbating the situation.
 - iii. It allows victims a 'reality check' on their fears that the stalking is occurring or about the seriousness of their situation.
2. *Avoid contact and/or confrontation.* All contacts or direct communications with a stalker risks reinforcing their behaviour and must be actively avoided. Once stalking is established, it is usually too late to resolve matters by meeting 'one last time'. Threats of suicide if the victim refuses to meet or otherwise engage with the stalker should not be rewarded or reinforced, despite an elevated risk of suicide among perpetrators [59].
3. *Documentation.* The best protection for stalking victims often lies in criminal law. The police are more likely to respond appropriately if victims can demonstrate that the behaviour is repeatedly occurring and make it relatively easy for them to pursue the allegations. Retain phone or text messages, emails, letters, and unwanted 'gifts', and keep a diary noting approaches, threats, or property damage, and, where possible, witnesses to (or photographic evidence of) such events. This will be invaluable for any prosecution and further assist the victim to take back control over their lives.
4. *Restraining/intervention/apprehended violence (and other such) orders.* The effectiveness of these orders to combat stalking is debatable, with 35–80% breached in stalking situations [60–62]. Nonetheless, these civil orders can be used to demonstrate for subsequent criminal proceedings that the stalker's behaviour was intentional, which may often be a legislative requirement. Reservations have to be expressed, however, not only about their utility (being totally ineffective, for example, for delusional intimacy seekers), but also about the level of insecurity and distress consequent on their breach. These orders are also often

provocative, particularly for the rejected, and victims should be advised about the potential for an escalation in violence after obtaining an order against a former intimate (particularly if the relationship was characterized by violence).

5. *Increased security.* Inexpensive measures, such as good locks, movement-triggered outdoor lighting, secure mailboxes (or post office boxes), and ensuring high-privacy settings on social media accounts, may provide a degree of reassurance and a modicum of security.

Querulous behaviour: abnormally persistent complaining and vexatious litigation

In response to a perceived or real personal grievance, querulous individuals relentlessly pursue their notion of justice in a manner that is seriously damaging to the person's economic, social, and personal interests and disruptive to the functioning of courts and/or other agencies involved in attempts to resolve the claims [63]. A minority may engage in stalking as part of their campaign, but most pursue their quest via relentless complaining and litigation.

Psychiatry's interest in the querulous (from Latin, to mutter and to mumble) thrived in the late nineteenth and early twentieth centuries. Classical psychiatry viewed querulousness as a form of paranoia, with the term *Querulantenwahn* ('litigants' delusion') coined in 1857 by Johann Ludwig Casper to describe:

'A form of so called paranoia in which there exists in a patient an insuppressible and fanatic craving for going to law in order to get redress for some wrong which he believes done to him. Individuals who fall victim to this disorder are always strongly predisposed ... extremely egotistical ... know everything better ... differs from other forms of paranoia in so far as the wrong may not be quite imaginary ... the more he fails the more he becomes convinced that enormous wrong is being done to him ... neglects his family and his business ... going down the road to ruin' [64].

The accuracy of this description aside, the classical view of querulousness as a form of paranoia was problematic, given that the behaviour was usually based on a genuine grievance and frequently regarded as developing on the basis of vulnerabilities in the individual's personality [65–67]. The diagnosis of querulous paranoia was appealed to less and less, and by the latter half of the twentieth century, the literature largely fell silent [68]. Unreasonable complainants ultimately came to be considered as a purely legal, rather than a medical, issue [69]. The disappearance of querulousness from the realms of psychiatry paralleled the decline of paranoia as a diagnostic entity, but also reflected psychiatry's increasing reluctance to play the role of social regulator. Perhaps most significant in the diminishing interest in the querulous was the coinciding emergence of the culture of blame [70], which drew more and more vulnerable people into the systems of complaint management [1].

Cultural factors have been little explored in the querulous, but individuals who have migrated from Eastern bloc countries appear overrepresented in our clinical experience, likely reflecting the historical absence of avenues to complaint or redress from injustice under oppressive regimes. We speculate that these individuals are susceptible to becoming overwhelmed with the myriad of

opportunities afforded to them with a Western 'culture of complaint' and blame.

Agencies of accountability, including courts and tribunals, Ombudsmen's offices, registration boards, and complaints departments, are those now primarily charged with navigating the problems created by a tiny fraction of people pursuing grievances with a persistence and insistence disproportionate to the substantive nature of their claim. In the civil, administrative, and family courts, the number of intractable cases being pursued—usually by self-represented litigants—increases each year. By pursuing what they regard as their rights through repeated petitions and intrusive approaches to politicians and heads of state, querulants are also distracting protection services from more substantial threats [63, 71–74].

The querulous pursue their vision of justice through litigation in courts and tribunals, through petitions to the powerful, and through the various agencies of accountability. In practice, all three avenues are exploited simultaneously. Courts and agencies of accountability are designed to deliver conciliation, mediation, reparation, and compensation, but rarely retribution, except in the exceptional case of punitive damages, and never personal vindication. As the querulous seek, above all, personal vindication and retribution, from the outset, they are doomed to fail.

Clinical features

It is not easy to distinguish the querulant from the difficult complainant, or even from social reformers and victims of gross injustice. The following simple typology may assist [63]:

1. *Normal complainants* are aggrieved and seek reasonable compensation, reparation, or simply an apology. They can engage in, and will accept, mediation and conciliation, though they may become persistent and insistent if provoked by inefficiency or injustice.
2. *Difficult complainants* also seek compensation and reparation for their grievance but, in addition, can pursue retribution. They tend from the outset to manifest victimization and anger, and resist all solutions but their own. Eventually, they will settle for the best deal they can obtain, albeit still complaining of injustice.
3. *Altruistic reformers* pursue goals of social progress via the courts, petitions, and complaints. They sacrifice their personal interests in pursuit of better outcomes for others. Though they may have a political agenda that is sectarian (for example, genetically modified foods, fathers' rights), they do not have idiosyncratic and personalized objectives.
4. *Fraudsters* who knowingly pursue false or grossly exaggerated claims.
5. *The mentally ill* whose claims are driven by delusional pre-occupations that are frequently bizarre in nature, which reflect underlying disorders often of a psychotic type.
6. *The querulous* who seek personal vindication, in addition to compensation, reparation, and retribution. They are on a quest for justice that becomes their preoccupation (and often substitutes any occupation). Unlike reformers, and most of the difficult complainants, there is an obvious discrepancy between the provoking event and the salience attached to it by the querulous. They appear to seek not resolution, but continuation of the

conflict. Their loss of perspective lays waste to their social and economic functioning.

The querulous are predominantly males, who first become embroiled in complaining and claiming later in life, usually in their fourth or fifth decade [69, 75]. Premorbidly, most function reasonably well [69] and may well be above average in intelligence or functioning. They rarely have criminal records or prior psychiatric contact, and substance abuse is not prominent. Many have close relationships, but by the time they reach mental health professionals, they have usually alienated their family and friends. Querulants are often disappointed people who feel their effort (indeed striving) and qualities have been ignored and left unrewarded. Their pursuit of justice offers an opportunity to vindicate their lives and obtain the public recognition so long denied. Their personalities tend to have the traits of self-absorption, suspiciousness, and obsessionality, combined with an enviable capacity for persistence.

Clinically, querulants typically present as energized individuals eager to convince of the merits of their case. There is an enthusiasm that can seem almost manic, but unlike the manic, they are totally focused and almost impossible to distract from their narrative of injustice. They may attend appointments with reams of documents testifying to their misplaced scholarship. If challenged, they usually become patronizing as they pedantically refute all objections, to their complete satisfaction. Alternatively, they may become menacing and overtly threatening.

Communications from querulants [75] and vexatious litigants have been observed to be often characterized by:

- Multiple methods of emphasis, including underlining, highlighting, capitalization, or italics.
- The generous use of exclamation marks and question marks.
- Numerous footnotes and marginal notes.
- The use of attachments, some potentially pertinent (for example, letters received, copies of legislation), others of less obvious relevance (for example, Magna Carta, United Nations Declaration of Human Rights).
- And many, many pages.

The content of communications may also be unusual [75], sometimes containing:

- Legal, medical, and other terms used frequently, but often incorrectly;
- Repeated rhetorical questions;
- Reference to the self in the third person;
- Veiled threats to harm themselves or others if their wishes are not granted; or
- Exaggerated politeness and attempts to ingratiate.

Clinical assessment

The querulous can only be adequately assessed by considering the development over time of their behaviour, as well as their state of mind. In an interview, they may present as merely overenthusiastic or overly hopeful, pursuing their legitimate rights with, at worst, a degree of fanaticism. It is the unfolding of their story which reveals the damage they are suffering and that they have inflicted on those around them.

Case example

An academic in her mid forties, whose fixed-term contract was not renewed, complained to the University that this was a result of bullying by her supervisor, who she claimed was seeking to appropriate her intellectual property for his own career advancement. The University investigated but ultimately rejected her complaint, noting that the contract non-renewal was due to a lack of ongoing funding and role redundancy. She initiated civil action in the state administrative tribunal and submitted dozens of Freedom of Information (FoI) applications pertaining to the University, her former supervisor, and numerous other departmental colleagues. Only a handful of the FoI applications were granted, and the civil action was dismissed. She unsuccessfully appealed the latter over the next 12 years (as a self-represented litigant), including eventually to the full bench of the national administrative court. She repeatedly sought stays and postponements of court hearings that had been scheduled to determine (that is, finalize) her case, the delays causing tremendous inconvenience both to the University staff named as respondents in the claims and the court staff. A frequent tactic was to 'reserve the right' to terminate proceedings due to 'health issues', which she typically employed at the end of lengthy proceedings when an adverse decision (in her opinion) was about to be adjudicated. Her administrative court claims were joined by complaints to the privacy commissioner, the human rights commissioner, and numerous members of parliament. She also contacted the registries of each state administrative tribunal, inundating staff with emails and phone calls and revelling in any inconsistent advice provided (which she regarded as confirmation of the tribunals' gross incompetence, rather than regional procedural differences). She was ultimately instructed by the Principal Registrar to deal only with the registry manager of the tribunal in which her original claim was lodged, whom she came to believe was responsible for the failure of her various claims. She finally made death threats against the registry manager, for which she was charged and subsequently convicted. On the day of sentencing, she abused and threatened the Magistrate ('No one has the right to stop me! ... Just try and you'll pay, bitch!') and assaulted a court attendant who intervened. She was imprisoned for a brief period, after which she resumed her complaining and litigation with a vengeance. She continues to pursue various actions in the courts, with her identity (obvious to all who encounter her) inexorably linked to her dogged self-righteousness.

Traditionally, psychiatry has attempted to distinguish between deluded querulants, who are in the business of mental health services, and the non-deluded who are not. Unfortunately, the querulous present a formidable phenomenological challenge in this regard. They advance their ideas plausibly, making apparently rational connections between the underlying grievance (which is almost always based on some actual event or injustice) and their current claims and complaints. The querulous offer a detailed and apparently logical account of the emergence of their grievances and the progress of their quest for justice—logical that is, if taken in cross-section, but not when considered over time, when gross discrepancies between the supposed initiating cause and subsequent behaviour become apparent. Their persuasive presentation can obscure the essential futility of the quest and distract attention from the chaos they have created for themselves and those around them. The temptation is to normalize the clinical presentation, but this is to ignore both the peculiarity of their behaviour and beliefs, as well as the devastation

they have wrought on their own lives. Sometimes the querulous are obviously deluded, and sometimes they appear to inhibit the borderline between overvalued ideas and delusion-like ideas. Debates over the phenomenological niceties should not, however, distract from recognizing the pathological nature of such querulousness.

Management

Psychiatrists currently only tend to be involved in the management of querulants after the situation has reached the stage of the person either becoming seriously depressed or being charged with threats, violence, or contempt. The literature on the therapeutic management of the querulous is meagre. Ungvari [76] reported successful treatment using pimozide, which is consistent with our clinical experience that relatively low doses of a dopamine antagonist are helpful, though the response is slow in coming. The critical hurdle in treatment, however, is attaining some semblance of a therapeutic alliance with the patient. This requires avoiding being caught up in discussions of the rights and wrongs of their quest. The focus should be on the price they and their loved ones are paying for the pursuit [63]. Interestingly, some of those who come on orders from the court that mandate treatment will accept medication and other therapeutic interventions, as they wish to make clear they abide by the law. Paradoxically, a number have continued voluntarily in treatment after the end of the order, though they never acknowledge either that they were in error or in need of treatment because of their querulousness. What change are the involvement in the querulous ideas, the degree of preoccupations, and the behaviour, but the core belief that they were right never wavers. Querulous behaviour appears to be sustained by a range of cognitive distortions, including:

- Those who do not fully support their cause are enemies.
- Any lack of progress is the product of malevolent interference from someone.
- Any compromise is humiliating defeat.
- The grievance is the defining moment of their lives.
- That because they are in the right, the outcomes they seek must be not only possible, but also necessary.

These distortions are open to challenge and amelioration, and the cognitive therapy approaches advocated for delusions [77, 78] should, in theory, also be of value. The problem with the therapeutic management of querulous behaviour is that there are no adequate clinical trials of treatment, or indeed much beyond case reports. This reflects the prevailing zeitgeist that the querulous are not the concern of mental health, and even if they are, they are largely untreatable. Hopefully, if this neglect is overcome and querulous behaviour is once more recognized as a legitimate concern for mental health professionals, then systematic studies of therapy will follow.

Conclusions

Not a few psychiatrists have difficulties with the notion of problem behaviours like stalking and querulousness being a proper subject for mental health concern. Psychiatry has traditionally been wary of concerning itself directly with criminal and antisocial behaviours [79, 80]. The approach taken in this chapter was to define patterns of behaviour destructive to the interests of the perpetrator

and the victim, and then to examine the origins, effects, and potential therapeutic management. By recognizing that psychiatry can have a role in assessing and managing problem behaviours, without first performing obfuscating transformations into supposed mental disorders (such as impulse-control disorders), allows a more clear-sighted and effective approach to areas of human activity where our intervention can benefit both the actor and the wider community.

Domestic violence and abuse and mental health

Louise M. Howard and Deirdre MacManus

Introduction

Violence and abuse is a pervasive problem in our society. It includes physical, sexual, and psychological abuse, coercive behaviour, and deprivation. Violence can be perpetrated by family members, intimate partners, and ex-partners (domestic violence) or by strangers and acquaintances (non-domestic or community violence, including violence by care providers) [1] (Fig. 143.1). Domestic violence, the focus of this chapter, is a global public health problem [2]. Worldwide, intimate partner violence (IPV) (one form of domestic violence) has been estimated to account for up to 7% of the overall burden of disease among women, mostly due to its impact on mental ill health [3, 4]. Annual direct and indirect costs of domestic violence and abuse (DVA) in the UK have been estimated to amount to £16 billion per annum [5]. In the UK, DVA is defined as: ‘controlling, coercive or threatening behaviour, violence or abuse between people aged 16 or over, who are or have been intimate partners or family members, regardless of gender or sexuality. It includes psychological, physical, sexual, financial and emotional abuse’ [6]. This definition applies to adult family members (>15 years of age). Emotional and psychological abuse, including coercive control, are therefore recognized as part of DVA [7, 8]. (DVA also encompasses traditional practices, including forced marriage, so-called ‘honour crimes’, and female genital mutilation, in addition to partner violence, but these are beyond the scope of this chapter.) The World Health Organization (WHO) focuses on IPV, defining it as: ‘behaviour by an intimate partner or ex-partner that causes physical, sexual, or psychological harm, including physical aggression, sexual coercion, psychological abuse or controlling behaviours’. In this chapter, we will use the term DVA, unless a study refers specifically to IPV only, and will specify where studies are referring to non-partner violence. It is important to note that victims of DVA are rarely subjected to just one form of abuse—around half of women suffering from DVA experience more than one type of partner violence [9, 10].

DVA is sometimes classified into typologies, for example ‘situational couple violence’ and ‘intimate terrorism’ [11–13], and there is some preliminary evidence for the existence of IPV typologies, though further research empirically validating typologies is needed

[14]. Situational couple violence is generally considered much more common than intimate terrorism and includes abuse, but without a context of control. Individuals who engage in situational couple violence are characterized as poor communicators who respond to frustrations with verbal or physical aggression. Although situational couple violence is harmful, intimate terrorism is the type of DVA that accounts for most serious injury and death. It is also more gendered than situational couple violence, with women more likely to be the victims of repeated and severe DVA by men, although intimate terrorism also occurs in same-sex relationships. Perpetrators may display emotionally unstable personality traits, develop strong disordered attachment to their victims, and engage in violence in order to prevent abandonment. Other intimate terrorists may have sociopathic traits and seek to dominate and control many aspects of their lives, including their relationships [14].

Prevalence of domestic violence and abuse

DVA is common. A systematic review of international studies of physical violence in intimate relationships found that more than one in four women (28.3%) and one in five men (21.6%) reported perpetrating physical violence in an intimate relationship [15]. The British Crime Survey estimates of DVA (using the broad definition given) showed that some 8.2% of women and 4% of men were estimated to have experienced domestic abuse in 2014/15 [16], while 27.1% of women and 13.2% of men, between the ages of 16 and 59, had experienced any domestic abuse since the age of 16. In the United States, the National Intimate Partner and Sexual Violence Survey (2011) found that severe physical violence by an intimate partner (including acts such as being hit with something hard, being kicked or beaten, or being burnt on purpose) was experienced by an estimated 22.3% of women and 14.0% of men during their lifetime and by an estimated 2.3% of women and 2.1% of men in the 12 months before taking the survey [17]. DVA has the highest rate of repeated victimization of any violent crime [18–20]. There is substantial variation globally; the WHO multi-country study of female DVA victims reported that the lifetime prevalence of physical or

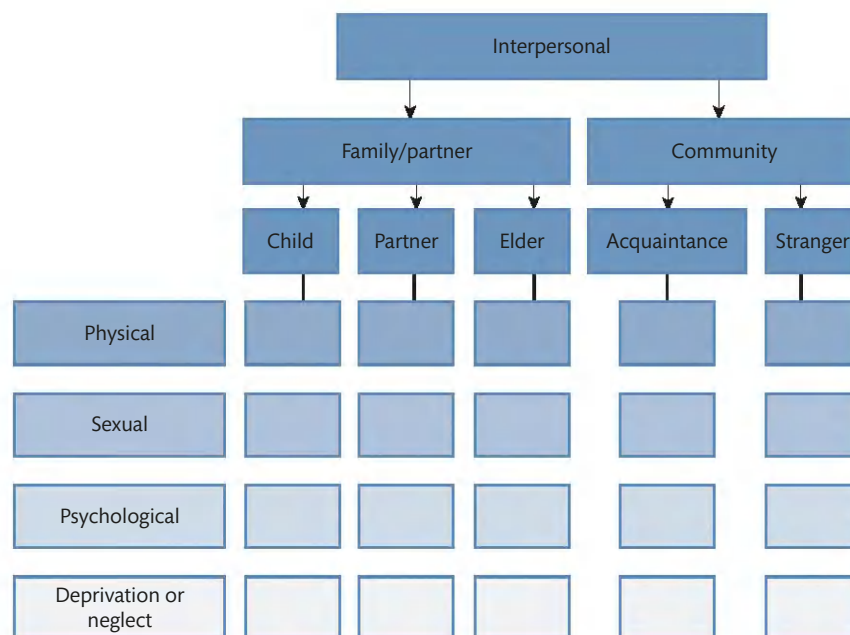

Fig. 143.1 World Health Organization's typology of violence.

Adapted from Krug EG, Dahlberg LL, Mercy JA, et al. [Eds.], *World Report on Violence and Health*, Copyright (2002), with permission from World Health Organization. Available at http://www.who.int/violence_injury_prevention/violence/world_report/en/

sexual partner violence, or both, varied from 15% to 71%, and past-year violence between 4% and 54%, among the countries studied [21, 22]. Prevalence is higher in some clinical populations; for example, a systematic review found the highest prevalences of physical violence (30–50%) and sexual violence (30–35%) in studies conducted in psychiatric clinics and obstetrics and gynaecology clinics, and the highest mean lifetime prevalence of psychological violence in psychiatric clinics and emergency departments (65–87%) [23]. Adolescent and young women face a substantially higher risk of experiencing IPV than older women [24]. Lower rates of physical and sexual IPV are reported in older women, but the prevalence of emotional and economic abuse and controlling behaviours are similar to those experienced by younger women [25].

Gender differences

While studies that have investigated the prevalence of DVA in both men and women have often found that the prevalence of victimization is similar in both genders, this masks the frequent finding that women are at greatest risk of serious and sexual assaults. A study in the United States using a representative general population sample found the lifetime prevalence of isolated domestic violence incidents to be comparable for men and women, but that nearly 25% of surveyed women, compared to 7.6% of surveyed men, reported that they were raped and/or physically assaulted by a current or former partner at some time in their lifetime [26]. Gender differences in the type of violence experienced were also found in the National Violence Against Women Survey (NVAWS), a telephone survey of over 6000 women and 7000 men across the United States. While they also found similar proportions of women and men reporting that they had experienced physical, sexual, or psychological IPV during their lifetime (28.9% and 22.9%, respectively), it was found that women were significantly more likely than men to experience physical or sexual IPV and abuse of power and control, but less likely

than men to report verbal abuse alone [27]. A systematic review of international studies of homicide revealed that one in seven of global homicides were committed by an intimate partner, and this proportion was six times higher for female homicides than for male homicides (38.6% vs 6.3%) [28]. Sexual violence against men by women partners has been found to be rare; in contrast, at least one in four women report sexual violence by a male intimate partner [29, 30].

Reports of comparable lifetime occurrence of 'all-type' DVA among men and women also mask the gender differences with regard to the number and type of specific assaults. For example, Tiaden and Thoennes [26] found that women in the United States were at greater risk of repeated coercive, sexual, or severe physical violence. British Crime Survey for England and Wales findings also suggested differences in repeat victimization; male victims may experience, on average, up to seven instances of repeat victimization, and women an average of 20 incidents [31]. Women are also more likely to report more severe injuries and to be more likely to be frightened as a result of domestic violence [29, 31].

However, there may also be gender differences in reporting. Brown [32] noted gender discrepancies in the rates of arrest and prosecution for IPV. Male victims were reluctant to report the incident, and the police were unwilling to arrest women accused of perpetrating violence, resulting in only 2% of suspected female perpetrators being arrested, which raises the concern that national prevalence rates based on surveys may not accurately reflect prevalence rates, particularly for men. A number of researchers also have challenged the assumption that IPV has a greater impact on women than men [33, 34], with studies increasingly examining the psychological impact of IPV on men [35] (see also later discussion of DVA and mental disorder).

Less is known about gender differences in male, compared with female, homosexual relationships, but a survey from the United States found that rates of emotional and physical violence victimization

among urban men who have sex with men were substantially higher than previously reported among heterosexual men—34% reported psychological violence, 22% physical violence, and 5% sexual violence [36]. Studies from the United States increasingly suggest that the prevalence of DVA may be similar across same-sex and heterosexual relationships and what differs are help-seeking behaviours [37]. In a UK survey of 800 homosexual men and women, Hester (2009) reported that more than a third of respondents (38%) said that they had experienced DVA at some time in a same-sex relationship, with similar proportions in women (40%) and men (35%) [38]. However, the main prevalence data on DVA worldwide are derived from surveys that do not identify individuals in same-sex relationships, so current knowledge on violence occurring in homosexual relationships in epidemiologically representative populations is limited.

While this chapter includes more studies of women as victims and men as perpetrators of DVA, the authors acknowledge that this reflects the smaller research literature on women as perpetrators and men as victims (irrespective of whether in heterosexual or homosexual relationships).

Risk factors for domestic violence and abuse: an ecological model

The WHO uses an ecological model when considering risk factors for DVA to provide a theoretical framework to help explain the multi-faceted nature of violence (Fig. 143.2) [1]. Risk factors operating at the level of the individual include being female, young age [39, 40], disability [41], poverty [40, 42], witnessing DVA as a child, childhood abuse [40, 43], and substance abuse [44]. Many of these factors are also risk factors for mental disorders, which emphasizes the social determinants of both mental disorders and DVA and the complex pathways involved in being a victim of violence through the lifespan. Aetiological factors also occur at the level of the relationship (for example, partner with substance misuse), community characteristics (for example, high population density, unemployment, and social isolation), and larger societal factors, including health, educational, economic, and social policies, cultural norms, gender disadvantage, and social inequalities [1, 45].

Victimization

Being a victim of DVA is associated with mental disorders across the diagnostic spectrum, including anxiety, depression, post-traumatic stress disorder (PTSD), eating disorders, and psychosis, though there are limited data on this relationship for men [46–52]. Prospective studies have shown that psychiatric disorder can increase domestic violence perpetration and victimization, and that domestic violence is associated with both risk and chronicity of mental disorder [53, 54].

The prevalence of DVA victimization is particularly high among people in contact with secondary mental health services; a recent survey of mental health care service users in London reported that 70% of women and 50% of men had been DVA victims as adults, with many (27% of women, 10% of men) experiencing recent and current DVA, that is, significantly higher than the general population [odds ratio (OR) adjusted for sociodemographics (aOR) 2.7, 95% confidence interval (CI) 1.7–4.0 for women; aOR 1.6, 95% CI 1.0–2.8 for men] [55]. In addition, of note, family (non-partner) violence comprised a greater proportion of overall DVA among SMI than control victims (63% vs 35%; $P < 0.01$), and adulthood serious sexual assault led to attempted suicide significantly more often among SMI than control female victims. Witnessing DVA also impacts on the health and mental health of children of adults who engage in IPV [56–58]. Mental health problems and violence can thus be transmitted through the generations [59].

The association between DVA and mental disorder is likely to be complex. Pre-existing mental health problems influence vulnerability to domestic violence. Indeed, there is evidence that a bi-directional causal relationship exists between some mental disorders and DVA. Prospective studies have shown that DVA contributes to both the emergence and the exacerbation of mental health symptoms [54, 60]. A systematic review of longitudinal studies of IPV and depressive symptoms reported both an association between depression and subsequent DVA and that DVA increases the risk of depression among women with no previous history of symptoms [61]. Moreover, data from an earlier systematic review [48] found that rates of depression declined over time once the abuse had ceased and that the severity or duration of violence was associated with the prevalence or severity of depression. Serious mental illness increases the likelihood of being in unsafe environments and relationships, and vulnerability to violent victimization [62]. There has,

Fig. 143.2 The ecological model for understanding violence.

Adapted from Krug EG, Dahlberg LL, Mercy JA, *et al.* [Eds.], *World Report on Violence and Health*, Copyright (2002), with permission from World Health Organization. Available at http://www.who.int/violence_injury_prevention/violence/world_report/en/

however, been limited longitudinal research into the relationship between DVA and other mental disorders, and more work is needed to disentangle the role of childhood abuse, which is associated with both mental disorder and DVA [63].

It has been suggested that DVA is more psychologically damaging than stranger violence or other forms of trauma [64]. The psychological effects of domestic violence can be conceptualized within a trauma framework, but the complex presentation of victims who have often been exposed to extensive control and repeated assaults, particularly if abuse was also experienced in childhood and escape was not possible due to physical, psychological, family, or societal factors, may be more adequately captured with the concept of 'complex PTSD' [65]. Although not a category in DSM-5 (but will be included in ICD-11), complex PTSD is considered a useful concept by many working with chronically traumatized victims [66]. Complex PTSD extends beyond the classic cluster of intrusive, avoidance, and arousal symptoms to incorporate changes in victims' attitudes about self, the perpetrator, relationships, and beliefs. Symptoms include those of PTSD, with additional disturbance in affect regulation and interpersonal relationships (see associated features of post-traumatic stress disorder in DSM-5 [67], including: feelings of ineffectiveness, shame, despair, or hopelessness; feeling permanently damaged; loss of previously sustained beliefs; hostility; social withdrawal; feeling constantly threatened; impaired relationships with others; or a change from the individual's previous personality characteristics).

Perpetration

Although there is a wealth of research literature supporting the link between mental disorder and increased risk of perpetrating violence in general [68–70], fewer studies have examined DVA perpetration specifically. A recent systematic review found only 17 studies reporting the risk of DVA perpetration among men and women with mental disorders [71]—three reported on past-year violence, and these three studies did not consistently report increased risk for any diagnosis. Most studies examined lifetime risk of physical violence towards a partner and reported increased risk among samples with mental disorder of any diagnosis. However, most studies were cross-sectional, and importantly, alcohol and substance misuse were not examined as potential confounding or mediating factors. Further research is needed to investigate whether psychiatric disorders are associated with a current risk of violence to partners.

Recent studies of general violence and mental disorder have advanced our understanding of the link between mental disorder and violence perpetration. Some have identified the important mediating role of alcohol and substance misuse [72], and some have unpicked the mediating role of certain symptoms, such as psychotic delusions, negative affect, or anger [73, 74] in those with severe mental disorder. These pathways have not been investigated in relation to DVA perpetrated by people with mental disorders. Similarly, although treatment (for example, with antipsychotics and mood stabilizers for those with severe mental disorder) is associated with reduced violent crime [75], the impact of treatment for mental disorder has not been investigated in relation to DVA. It seems possible, however, that similar mechanisms may be important in any relationship between DVA perpetration and mental disorders.

The general premise in the literature, historically, was that even if women and men engage in equivalent rates of IPV in heterosexual

relationships, male-perpetrated violence has more negative consequences for its victims than does female-perpetrated violence. Supportive evidence for this view comes from studies suggesting that women are more likely than men to sustain serious physical injury and negative psychological consequences [27, 76, 77]. However, recent cultural shifts have led to the acknowledgement that men can also be victimized in their relationships and research has shown that men can sustain similar levels of psychological injury. The NVAWS of women and men aged 18–65 found that, for both men and women, physical IPV victimization was associated with an increased risk of current poor health, depressive symptoms, substance use, and developing a chronic disease, chronic mental illness, and injury [27]. In general, psychological IPV was more strongly associated with these health outcomes than physical IPV. The proportion of IPV survivors meeting criteria for moderate to severe PTSD did not differ by gender (20% male, 24% female) [78], and psychological abuse was just as strongly associated with PTSD as physical abuse. This raises questions about the assumed lesser impact of IPV by women towards men, given findings that women are more likely to perpetrate psychological than physical aggression towards male partners. However, it is also clear that at the population level, being a victim of DVA is more prevalent in women and the psychiatric burden (estimated as population-attributable fractions, assuming causality) of DVA is higher in women [79].

Identification of domestic violence and abuse by mental health services

Identification of victims

Women are more likely to disclose domestic violence to a health care professional than to the police [80]. However, despite the high prevalence of DVA among mental health service users, a review in 2010 found that only 10–30% of DVA victims were identified by mental health professionals internationally [19]. Qualitative research in primary and secondary care has found that women may not disclose unless they are asked [81–83]. Barriers to disclosure for psychiatric patients include fear of consequences such as social services involvement and consequent child protection proceedings, fear that disclosure would not be believed, and fear that disclosure would lead to further violence. Other barriers included the actions of the perpetrator (such as always being present when the victim is seen by health professionals) and feelings of shame. A review of qualitative studies involving mental health service users found that DVA victims want mental health professionals to acknowledge and/or validate their disclosures of domestic violence in a non-judgemental and compassionate manner [81]. Patients reported limited opportunities to discuss DVA during clinical consultations, which were focused on diagnosing and treating psychiatric symptoms which prevented discussion of abuse or the extent of abuse. When disclosures were not taken seriously or minimized or there is the sense of being blamed by professionals, this was considered unhelpful and was associated with persistent symptoms. Concerns for future safety were prominent, with some responders expressing fear that mental health professionals' responses to the violence could place (and had placed) them at risk of further harm (for example, if the perpetrator hears about the DVA disclosure). There can be an expectation that

they leave their partner, but mental health professionals may fail to understand that choosing to remain in an abusive relationship may be based on a strategic risk—benefit analysis which balances the risk of ongoing harm with the potential negative consequences of leaving their partner (financial concerns, social stigma, custody of children) and the hope that their partner may change [82, 84]. Some women fear more severe violence if they leave their partner. Indeed, it has been identified that women are at greatest risk of homicide in the months immediately following separation [85, 86].

There is some evidence that when routine enquiry about DVA is introduced across mental health services, detection rates improve. But even then, formulations and management plans rarely include issues around domestic violence and often do not include safety planning or trauma-focused therapy [87]. Therefore, it is now health policy in England, and in some parts of the United States, Australia, and New Zealand, to routinely enquire about DVA in all mental health assessments in psychiatric care [88]. Routine enquiry refers to ‘asking all people within certain parameters about the experience of DVA, regardless of whether or not there are signs of abuse, or whether DVA is suspected’. Enquiry and disclosure in mental health settings have been found to be facilitated by a supportive and trusting relationship between patient and professional [82], with similar findings in other health care settings [83]. However, barriers to routine enquiry by professionals have also been identified, such as a lack of understanding of different types of DVA and a lack of confidence in facilitating and managing disclosures [82, 89]. Mental health professionals may be unsure of their role in the identification and management of DVA, and surveys have identified knowledge gaps [90]. International guidelines, including from the WHO and the National Institute for Health and Care Excellence (NICE), recommend that appropriately trained mental health professionals should facilitate DVA disclosure as part of comprehensive clinical assessments [30, 91].

Trials of systemic interventions to improve identification and response to DVA victims [92] in primary care (that is, integrated training, support, and advice from DVA advocates) have been shown to significantly improve health professionals’ facilitation of disclosure and their subsequent response [92, 93]. As yet, there have been no trials in mental health settings, but a pilot has suggested that there are similar increases in identification rates of DVA victim with improvements in health and quality of life outcomes [94].

All mental health professionals need comprehensive training in how to enquire safely, with clarity on subsequent referral and care pathways [30]. The World Psychiatric Association (WPA) has just published an international competency-based curriculum for mental health care providers on IPV and sexual violence against women [95]. In England, the Department of Health has recommended that a question about any past or current violence and abuse should be asked during assessments and care programme approach meetings [96]. However, disclosure is more likely if more than one specific behaviour-based questions are used. Open questions can be asked initially about relationships, and normalization of the area of enquiry can also be helpful, but more specific questions about each type of abuse should also be asked (Boxes 143.1–143.4). Such questions can only be asked if a patient is alone or with a professional interpreter (rather than a family member).

However, there is evidence internationally that guideline dissemination and training in isolation do not necessarily create consistent,

Box 143.1 Introductory open questions

- Are you having any problems with your husband/partner?
- We know that one in four women (and one in five men) experience domestic violence at some time in their life, so I ask everyone if that has ever happened to them. Has that happened to you?
- Some women have these symptoms when they are experiencing abuse. Are you afraid of anyone at home?
- Sometimes partners use physical force. Is this happening to you?
- Have you felt humiliated or emotionally abused by your partner (or ex-partner)?
- Has your partner ever physically threatened or hurt you? Or have you been kicked, hit, slapped, or otherwise physically hurt by your partner (or ex-partner)?
- In the past year, have you been forced to have any kind of sexual activity by your partner (or ex-partner)?

sustainable improvements in identification and response to DVA [92, 97], and research into strategies to improve the integration of DVA into the scope of mental health services is needed. Integration of DVA advocates within mental health teams, with additional dedicated time for training, may improve rates of identification of DVA and outcomes for individuals [89], but training in identification may not lead to improved patient outcomes if they do not lead to increased engagement in interventions [98].

Identification of perpetrators

A recent UK qualitative study with mental health professionals revealed that while they routinely ask about violence in general, they often fail to ask about current or ex-partner DVA (even though it has been shown that the risk of lethal violence increases after separation [99] due to inadequacy of current risk assessments, which often do not specifically refer to different types of DVA; and lack of clarity on information sharing when DVA was also a concern is disclosed [100]. In England, the National Confidential Inquiry into Homicides and the Home Office reported a failure of mental health

Box 143.2 Questions about psychological abuse

- Does anyone insult you, call you names, or swear at you?
- Does anyone make it difficult for you to see friends/family or leave the house?
- Does anyone act in a jealous way or keep track of where you go?
- Does anyone put you down, embarrass you, or criticize you?
- Does anyone undermine your independence or try to make you feel small?
- Does anyone make you feel as if you have to walk on eggshells or as if you do nothing right?
- Does anyone order you around like a servant?
- Does anyone blame you for things that are not your fault?
- Does anyone control the money, make you ask for it, or stop you earning?

Box 143.3 Questions about sexual abuse

- Do you ever feel that you have to have sex, even though you don't want to?
- Have you felt forced into sex because of what your partner might do?
- Has your partner made you have sex or carried on when it was painful?
- Has your partner made you have oral or anal sex when you didn't want to?
- Has your partner used an object in a sexual way that you didn't like?
- Has your partner made you do things or perform sexual acts that you didn't like?
- Has your partner refused safe sex or to use birth control?
- Has your partner made you have sex with another person?
- Has your partner talked about sex or done things in a way you didn't like?

professionals to assess for DVA perpetration risk [101], despite a clear responsibility of mental health services to identify potential perpetrators of all forms of violence within current risk assessment frameworks. Recent studies using data from statutory domestic homicide reviews in England and confidential enquiries into homicides by people with mental illness have highlighted that a significant proportion of domestic homicides are perpetrated by male mental health service users; 14% of intimate partner homicides and 23% of adult family homicides were perpetrated by men who had been in contact with mental health services in the preceding year (men made up 80% of both types of homicide perpetrators) [72]. A study of homicide–suicides in England and Wales similarly found that current or former partners were the victims in two-thirds of cases and that 12% of perpetrators had been in contact with mental health services in the year before the offence [102].

Although there has been less research on how to respond to mental health service users who disclose DVA perpetration, there is extensive guidance on how to manage risk of violence, which includes consideration of the safety of the victim and appropriate

disclosure, if necessary, even if in breach of patient confidentiality. Homicide–suicides, 88% of which are perpetrated by men, with 77% of victims being female, are commonly preceded by relationship breakdown and separation [102]. With such a high proportion identified as having mental health problems, more research and guidance are needed on management risk of DVA perpetration among mental health professionals.

How should mental health professionals respond to domestic violence and abuse experienced by psychiatric patients?

International guidelines, including from the WHO and NICE, recommend that, following the facilitation of DVA disclosure during a comprehensive clinical assessment, mental health professionals should provide support, ensure safety, and treat physical and mental disorders arising in the context of any DVA [30, 88]. There is debate about the role of universal screening for DVA in the health care system in generic services such as primary care or emergency departments [83]. However, the prevalence of violent victimization is so high in mental health service users [55, 103], and clinical guidelines recommend that mental health professionals routinely ask about DVA experienced in childhood and adulthood as part of clinical assessment and ongoing care [30, 88, 104].

As highlighted, however, routine enquiry may not improve outcomes if the enquirer is not appropriately trained in how to respond [88]. Guidelines recommend appropriate training, in combination with the establishment of protocols for inter-agency communication and information sharing, referrals to specialist DVA services, and referrals for interventions, including to specialist trauma services, if necessary. In some jurisdictions, there are specific multi-agency risk assessment conferences (MARACs) [105] which enable all services, including the DVA sector, to share information and reduce risk, and there is evidence to suggest that these can reduce risk of subsequent DVA.

Although there is limited research evidence in this area, good clinical practice includes making accurate notes, carrying out a risk assessment (particularly regarding immediate safety and considering the need for emergency action and/or child protection procedures), prioritizing safety planning, avoiding victim-blaming, and discussing available options [106]. Information about domestic violence services should be given, but professionals need to check whether it is safe for the patient to take information home with them—there may be an escalation of violence if such information is seen by the perpetrator. Potential interventions are discussed later in this chapter, but local health care trust policies (on domestic violence and on safeguarding of children and vulnerable adults), care pathways, and training should include information on what to do after disclosure [96].

When working with survivors of DVA, mental health professionals should ensure women have opportunities to be seen without partners, family members, or acquaintances present; provide access to independent interpreters; respond sensitively, compassionately, and non-judgementally to disclosure; reassure women that they are believed and not to blame for their experiences; and offer information and practical support that responds to women's concerns and

Box 143.4 Questions about physical abuse

- Has your partner shaken you or grabbed you roughly?
- Has your partner shoved you or made you fall?
- Has your partner slapped you or smacked you?
- Has your partner tried to hit you with something or used an object as a weapon?
- Has your partner punched you?
- Has your partner tried to choke you or put his hands round your throat?
- Has your partner pushed you against the wall or thrown you down?
- Has your partner pulled your hair?
- Has your partner burnt you or scalded you with something?
- Has your partner threatened you with a knife or gun?
- Has your partner hurt you while you were pregnant?

respects their autonomy [30, 107]. It is also crucial for health professionals to recognize children as direct victims of domestic violence and abuse through witnessing or being aware of DVA in the family. Such experiences are associated with an increased risk of health problems and DVA in adulthood. There is also an increased risk of them being abused directly themselves by the abusive parent [91]. Professionals should recognize children's experience of the impact of DVA and strengthen professional responses to them as direct victims, not as passive witnesses to violence [108].

There is a need for greater focus on the interaction of the wider health infrastructure, including mental health services, in order to improve the management and reduction of DVA. This interdisciplinary and inter-agency approach was highlighted in the 2014 *Lancet* series on violence against women [109] and can be extrapolated beyond violence against women to DVA in general. Although additional research is needed, strengthening of health systems can enable providers to address DVA, including protocols, capacity building, effective co-ordination between agencies, and referral networks.

What interventions are effective for psychiatric patients experiencing domestic violence?

Interventions for victims

There is now a wealth of evidence for the effectiveness of a variety of pharmacological and psychological interventions for victims of trauma. NICE recommends cognitive behavioural therapy (CBT) and eye movement desensitization and reprocessing (EMDR) for PTSD [110], but until recently, there was a lack of research into the efficacy of these treatments for survivors of DVA who often present with more comorbidity or complex PTSD (as described). There is a growing evidence base for the treatment of complex PTSD, though this is currently under critical review [111]. However, while evidence-based interventions are already well established for victims of trauma, without identification and an understanding of the interpersonal dynamics of coercive, controlling DVA, it is likely that treatment may be less effective; indeed, some have hypothesized that DVA may be a moderator of treatment response if not identified or addressed [112].

Systematic reviews of treatment for DVA-related trauma have reported that CBT-based interventions may be associated with improved PTSD and depressive symptoms in survivors no longer in abusive relationships [84, 85]. Advocacy and CBT interventions may also be effective in reducing physical and psychological DVA [113]. However, these findings cannot be extrapolated to women with more severe psychiatric illnesses. Studies are emerging which have shown the effectiveness of NICE-recommended trauma-focused therapies in treating PTSD comorbid with psychosis [114, 115], but none have specifically focused on trauma in the context of domestic violence. Few studies have examined whether interventions are helpful in reducing psychological symptoms among women still subject to abuse.

Interventions for perpetrators

Evidence is lacking on the effectiveness and appropriateness of DVA perpetrator programmes for people with mental disorders, and these programmes receive few referrals from mental health services [116].

However, interventions for modifiable risk factors (such as medication for persecutory delusions, psychological interventions, and treatment of comorbid alcohol and substance misuse), while ensuring the safety of the potential victim, may be expected to improve health and reduce violence for DVA perpetrators in contact with mental health services whose DVA perpetration appears linked to these factors.

Future research

As this chapter has highlighted, there is still limited understanding of pathways to DVA and mental disorders, particularly in relation to DVA perpetration. It is also not clear how treatments need to be modified for DVA victims and perpetrators, nor how to prevent recurrent DVA. Future research needs to investigate the underlying mechanisms between DVA and mental disorders in both victims and perpetrators, develop and evaluate interventions to address these potential targets, and examine systemic interventions to improve responses of mental health services as a whole.

Conclusions

DVA is an endemic problem in our society, but even more of an issue in psychiatric patients. Traditional training of psychiatrists has not included knowledge about DVA, and in view of the high rates of both DVA perpetrators and victims in psychiatric patients and the potential impact, this clearly needs to change. Current guidance is based on limited evidence, and further research is needed to improve the evidence base on identification and treatment of both victims and perpetrators.

Assessing and managing the risk of violence to others

Alec Buchanan

Introduction

Assessing the risk of patient violence has always been integral to the practice of psychiatry. There are several reasons. Violence risk assessment is a necessary part of providing safe and effective outpatient psychiatric care. It is an essential element of proper decision-making around hospital admission and discharge and of providing a safe environment to patients and those who care for them. Finally, like many other aspects of psychiatric practice, when things go wrong, an inadequate assessment of violence risk is a potential source of legal liability for clinicians and mental health services.

While its importance is long-standing, the prominence of violence risk assessment has risen over the past 40 years. The most commonly identified causes for this increased prominence include the closure of many large psychiatric hospitals and discharge of patients to community settings, although empirical evidence linking this to an increase in violence is lacking. On both sides of the Atlantic, community care is widely regarded as inadequately resourced to manage the challenge of increased caseloads and challenging patient behaviour. Individuals and groups seeking to improve community care sometimes highlight violence rates in an attempt to highlight the need for increased resources.

These public, press, and political pressures are external. It is also the case, however, that over the past 40 years the focus of medicine itself has shifted. Public health indices, of which violence is one, have replaced the relationship between patient and doctor as the primary object of medical attention [1]. The value of screening clinics, vaccination, and antenatal care is now commonly assessed by reference to the health of the general population, not to the health of patients in care. Prevention of all types is now more than ever the province of medicine. As a recognized, if unusual, consequence of mental disorder, patient violence has become a recognized 'outcome measure'.

In some respects, psychiatry has been unprepared for this increased focus on the infrequent, but sometimes serious, violence of its clients. Throughout the developed world, bed closures have reduced the availability of psychiatry's principal tool in managing violence risk—admission to hospital. In the UK, proposals aimed at

detaining people with personality disorders were justified by reference to doctors using 'loopholes' in existing legislation to discharge dangerous patients. In the United States, psychiatry has struggled to find a single path through the conflicting demands that patient confidentiality be respected and that potential victims and others be warned about risk. The primacy of the doctor–patient relationship, once unchallenged, is now seen as out of place in a world where a shrinking proportion of those in care see a doctor at each visit.

This chapter reviews the principles governing the assessment of violence risk in psychiatry. It discusses the practice of conducting such assessments and examines the limits of psychiatric violence risk assessment. In doing so, it draws on material published in previous reviews of risk assessment and management [2–4]. While not all psychiatric patient violence can be prevented, good practice in assessing violence risk is both a necessary element in ensuring the safety of patients and others and a vital aspect in the care of people with mental disorders.

The principles of violence risk assessment

Overview

Much violence risk assessment in psychiatry is invisible, carried out routinely by clinicians in the course of their work. Violence risk is one of many considerations that inform decisions that range from admitting a patient to hospital to deciding on the most appropriate form of outpatient care. Even when risk of harm to others becomes the principal focus of the doctor's interaction with his or her patient, the principles underlying its assessment are the same as those underlying psychiatric practice more generally. A good evaluation will usually be based on the results of obtaining a history and examining a patient's mental state.

Accurate assessment depends on the availability of accurate information. In violence risk assessment, this will usually include information obtained from collateral sources including medical records, informants, and, where the police have been involved, police reports. Assessments carried out at the point of admission to hospital are often brief and unresolved issues of risk require continued

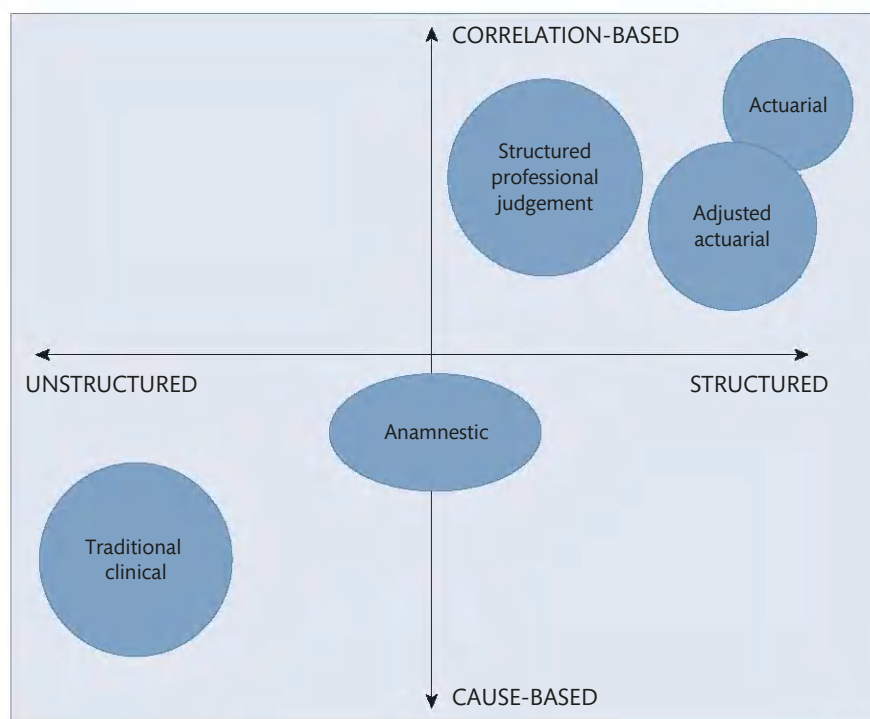

Fig. 144.1 Approaches to violence risk assessment in psychiatry.

attention in the course of an admission. Additional investigation, including psychological testing, may be required. Particularly with regard to specialist areas of practice, such as assessing the risk of sexual offending, it may be appropriate to ask specialist services, such as forensic psychiatry, to become involved.

The literature contains descriptions of numerous approaches to risk assessment. These approaches can usefully be described by virtue of where they fall on two dimensions. These dimensions are presented as the axes in Fig. 144.1.

The first dimension reflects whether a risk assessment method helps clinicians to assess risk by attending to known statistical correlations (sometimes referred to as a ‘nomothetic’ approach) or through a cause-based analysis of a client’s behaviour (also known as an ‘ideographic’ method). The second dimension reflects the degree to which the approach provides a structure for the assessor to follow. Some risk assessment methods, including actuarial schemes, require the scoring of a prescribed list of items and the combining of a subject’s scores on those items in a particular way. Other methods, particularly traditional clinical ones, permit the assessor greater discretion and, to this extent, provide less structure.

Correlation and cause in risk assessment

Research findings from the past several decades have identified numerous factors associated with psychiatric patient violence. Psychiatric patients are, in some ways, like the general population in terms of what increases the risk for violent offending, and in other ways different. Among the psychiatric population, being male is less strongly associated with violence, first offences tend to occur later, risk reduces less with advancing age [5], and stable relationships

are not as protective, especially when individuals experience poor overall function [6–8].

There are also many similarities, in terms of risk factors, between psychiatric patients and the general population. Substance abuse is a significant risk factor, as are unemployment, living in a high-crime neighbourhood, and having antisocial peers. Violent crimes tend to be committed by young males. Recidivism is lower for violent and more serious crime than for non-violent crime. Criminal history is a particularly strong predictor [9–12].

A second way in which psychiatrists assess risk, in addition to looking for risk factors, is by comparing their understanding of the patient’s personality, symptoms, and environment with their understanding of the likely causes of violence. Where someone suffers from persecutory delusions that concern their spouse, for instance, there will usually be available no empirical data from research conducted on samples of similar patients demonstrating a correlation between continued cohabitation and violence. Yet the clinician’s understanding of the likely causes of violence may still allow him or her to conclude that continued cohabitation presents a risk [13].

Pollock described the processes involved:

‘The skillful clinician assessing dangerous behavior formulates and tests a series of clinical hypotheses to define patterns of violence in the individual’s history. Once defined, these patterns can be applied to the explanation and prediction of violence in that individual.’ [14, p. 105]

Approaches to risk assessment based on explanations of this type seem to rely heavily on induction. They require the clinician to draw conclusions about the future from past observations. Future conditions will never exactly mimic the conditions in which behaviour

has occurred in the past, yet the circumstances of other episodes of violence, whether in the patient's case or more generally, will usually be relevant and sometimes critical. Notwithstanding the uncertainty inherent in this process, one task of risk assessment is to determine the relevance of past patterns.

Clinicians trying to work out what might cause future violence are guided also by the understanding of patterns of behaviour that they develop in their training and through clinical practice [15, 16]. Claims that 'causal' ways of thinking are better than correlation-based ones at predicting rare events [17] have not been confirmed by empirical research. Instead, the persistence of causal approaches when clinicians think about risk may relate to the fact that many of the other judgements required in medicine are causation-based also—establishing why someone has symptoms, for instance, or deciding which further investigations are needed to complete an evaluation. Because clinical practice requires each of these judgements to be integrated into a single plan, it may be that clinicians find it helpful to use the same causal heuristic in assessing risk that they use in other aspects of their work.

Structure in risk assessment

Although not frequently discussed in the literature on risk assessment, it is important to recognize that the cause-based analyses of many clinicians are structured. The structures are derived from their professional training. They include accepted practices and guidelines concerning taking a clinical history and examining the patient. Structure offers the same advantages to risk assessment that it offers to other areas of clinical practice. It is a means of integrating and communicating information [18]. It can be a useful aide-memoire, particularly when the clinical question being addressed is unusual (some risk factors apply particularly to sex offences, for instance). Learning how to structure the clinical approach is a key aspect of clinical training.

The correlation-based approach is most commonly structured using structured risk assessment instruments (SRAs). Actuarial instruments, such as the Violence Risk Appraisal Guide (VRAG), formalize the process by which the simultaneous presence of more than one correlate of violence increases the perception of risk. They do this by rating variables, such as poor school adjustment and alcohol problems, and combining these mathematically to generate an overall score or category. A different type of instrument relies on 'structured professional judgement'. The Historical, Clinical Risk Management-20 (HCR-20), for instance, encourages the clinician to assess the relevance of a list of pre-identified variables, but also to take into account other information, including factors he or she considers unique to the case, before allocating a case to a risk category.

There are now a large number of such instruments [19]. Some of the most widely used are listed in Table 144.1. Using some of these instruments requires specialist training and experience, which are described in the references in Table 144.1.

Structured approaches to violence risk assessment have been shown to have greater predictive validity than unstructured ones when the follow-up period is measured in years [20, 21]. In the shorter term, unstructured predictions made by emergency room clinicians have been shown to have levels of accuracy comparable to that of structured instruments [22, 23].

The proven predictive validity of structured correlational approaches has not led to their unqualified clinical acceptance [24]. One person's structure is another's straitjacket. Clinicians complain

Table 144.1 Structured risk assessment instruments

Type, name, and reference	Target population
Actuarial	
VRAG [53]	General psychiatry, forensic
SORAG [53]	Sexual offenders
Static 99 [57]	Sexual offenders
COVR [58]	General psychiatry
PCL-R [59]	General psychiatry, forensic
PCL-SV [60]	General psychiatry, forensic
Structured professional judgement	
HCR-20 [61]	General and forensic
SARA [62]	Spousal assault
SVR-20 [63]	Sexual offenders
RSVP [64]	Sexual offenders

Source: data from Buchanan A, Norko M, Violence risk assessment. In: Buchanan A, Norko M [Eds.], *The Psychiatric Report*, pp.224–239, Copyright (2011), Cambridge University Press; Buchanan A, Norko M, Violence risk in community settings. that they have to respond both to risky circumstances not listed in an instrument and to mitigating factors such as the incapacitation through hospitalization or imprisonment of someone with a high actuarial score [25, 26]. One alternative would be to outline permissible exceptions, when the results of using a scale could be ignored, but this course has been opposed by the authors of some of the most accurate instruments [27]. A related clinicians' complaint is that it is difficult to use the score on a rating scale to guide treatment when research has yet to show whether treatment will change the score or whether the risk will then be less.

On the other hand, unstructured approaches to risk assessment may not integrate straightforwardly with other aspects of treatment, either. In addition, unstructured approaches are more vulnerable to cognitive biases, such as attending disproportionately to recent events, that afflict many of the judgements that people make [28], risk assessment included [29]. Finally, if the central task of risk assessment lies in establishing and quantifying statistical correlations, the arithmetic techniques contained in some structured approaches may be best suited to this task [30].

Criteria have been developed in other areas of medicine to establish whether a validated rating scale will be useful in an individual case [31]. Three are statistical: whether the confidence limits are acceptable; whether the scale works for all subgroups of subjects ('goodness of fit'); and whether its predictions are accurate. While the predictive accuracy of many instruments is uncontroversial, confidence intervals remain contentious [32, 33]. Non-statistical criteria are the degree to which the patient resembles patients in the validation study, the similarity between the outcome in the study and the outcome of interest to the clinician, and the availability to the clinician of data similar to those that were used in the study.

Integration

Correlation-based approaches can indicate whether someone shares some characteristics with a high-risk group, but not whether they can properly be seen as representative of the group and what intervention

is the most appropriate. Causation-based approaches can incorporate more kinds of information but offer no obvious mechanism whereby the psychiatrist can use data to compare the risk to that posed by other people. Because they offer different things, a risk assessment that makes use of both approaches is, at least in principle, in a better position to be helpful than one that chooses between them [34].

There is little agreement, however, as to how such integration might be achieved. One possibility is that the psychiatrist should proceed sequentially, first reviewing the established correlates of violence that are present and then using this review as a starting point for a cause-based analysis that makes use of the psychiatrist's understanding of the subject and his or her circumstances. Correlation-based approaches, after all, generate information that courts and others can usually obtain by other means, for instance from pre-sentence reports prepared by the probation service. In theory at least, causation-based approaches have the potential to provide something extra.

Three factors are likely to govern the extent to which they can do this in practice. The first is the degree to which the psychiatrist has had access to the patient's mental state. Only if someone is willing to discuss their feelings, intentions, and beliefs, can a clinician incorporate this information.

The second is whether circumstances may change. Where consideration is being given to treating in the community a patient who has recently acted violently, for instance, an evaluation that concentrates on identifying the population correlates of violence, such as past violence and age, is unlikely to be helpful. A more useful assessment may employ data concerning past behaviour and include a cause-based conclusion that focuses on the origins of recent violence and examines what has, and what has not, changed. Where the circumstances are dynamic, for instance when it is not known whether the subject of the evaluation will return to live with the partner he has abused, a cause-based approach that incorporates different plausible scenarios may be particularly helpful.

The third factor affecting the usefulness of a causation-based approach is the period over which the risk assessment will apply. In emergency settings, where an assessment is often required to cover days or weeks, there are few correlates to guide clinicians [35], although anger [36] and substance use [37] both seem to be important. Instead, a sound risk assessment is more likely to be based on an understanding of the likely effect on a patient of the circumstances to which they are being discharged. Assessments designed to apply over longer periods, on the other hand, are less able to rely on this kind of understanding because mental states, circumstances, and the sources of risk change. Unless they know what these changes will be, clinicians who wish to offer an estimate of risk designed to cover months or years have little choice but to concentrate on recognized risk factors, using either an unstructured approach or a recognized instrument.

The practice of violence risk assessment

Obtaining the background information

A number of factors that are identified in the course of taking a psychiatric history have been shown to be associated with future violence [38–42].

Table 144.2 lists those variables identified most frequently in psychiatric reviews. Because past violence is the strongest correlate of

future violence, and because the risk of future violence increases with each subsequent offence [43], risk assessments should include details of the client's history of acting violently. The dates and types of violent act are important, because criminological variables, such as age of onset of violent behaviour and the number of violent convictions, are themselves correlates of future violence.

A cause-based analysis, however, will usually require more information. The circumstances of each act should be described in sufficient detail to allow the identification of patterns, if these exist. These circumstances include the individual's living situation, their relationship to the victim, what they intended to achieve, their mental state (and whether they were in treatment), and their use of drugs and alcohol. The nature of the victim's injury should be described; hospital treatment is often an indicator of severity. Collateral sources that can be of assistance in gathering this information include arrest records, police reports, trial transcripts, pre-sentence reports, and treatment records.

The association between substance use and violence is one of the most widely reported empirical findings in risk assessment. Moving beyond the statistical correlation to include a cause-based analysis requires that the assessor addresses the details of an individual's behaviour in relation to substances. Violence may be the result of intoxication, and past instances of violence when using substances should be noted. It may follow an exacerbation of mental illness precipitated by drug use, in which case the history may indicate previous instances of drug-induced relapse. Finally, violence may be a consequence of involvement in a drug market where territorial conflicts are common and where weapons are carried, although this is less of an issue for alcohol. The response of the subject to treatment for substance abuse problems will usually be important, especially in criminal sentencing.

The description of the past psychiatric history should make clear the relationship, if any, between an individual's history of violence and his mental disorder. The nature of any treatment, the individual's compliance with treatment, and his or her response to treatment will usually be important. The psychiatric history may also suggest what psychiatric measures have been helpful previously in reducing risk. The subject's social circumstances should be described for past episodes of violence (see earlier), for the present, and with reference to the period over which the risk assessment is required. Attention should be paid to the presence or absence of potentially protective factors such as stable relationships, employment, and housing. The availability of likely victims, including the victims of past violence, should be noted.

Examining the mental state

The implications for violence risk of mental state abnormalities depend on the context. Where someone harbours delusions regarding an individual, for instance, the likelihood of their coming into contact with that individual and the likely nature of that contact are important. Pathological jealousy is likely to be managed differently if the jealous man plans to live with the wife he believes is being unfaithful. The mental state findings and circumstances most commonly listed by reviewers as associated with risk of harm to others [44–48] are listed in Table 144.3.

The weight that can be appropriately attached to mental state abnormalities depends also on the period over which the risk assessment is intended to apply. Some features listed in Table 144.3, such

Table 144.2 Correlates I. Background factors and social circumstances linked to violence

	Substantial correlate	Correlate	Protective
Sociodemographics		Youth	
		Male sex	
Past behaviour	History of violence if no change in person or circumstance		
	Recent violence		
		History of threats not acted upon	
Psychiatric and substance abuse	Substance use, especially if rising		
		Conduct disorder	
Social circumstances	Availability of weapons, familiarity with their use		
			Good social networks
		Domestic conflict, especially if escalating	
	Future circumstances likely to resemble those in which violence has previously occurred		
Traits	Hare psychopathy (Table 144.3)		
		Impulsiveness	
		Fleckless disregard for consequences in schizophrenia	
			Fear of own potential for violence
			Has demonstrated internal resources to cope with conflict

as threats, carry particular short-term significance. Others, such as those related to personality, will usually be more relevant when the assessment is intended to cover months or years.

The description of thought content should include reference to thoughts of violence and their quality. Obsessional thoughts concerning violence in the absence of psychotic symptoms are not unusual, and empirical research has not linked them to future violence. Command hallucinations have been described in association with violence, but the association is inconsistent, the empirical base limited and conflicting, and the implications at the population level uncertain [49]. As with other symptoms, a detailed analysis of past violence may nevertheless reveal their importance in an individual case. Violent thoughts that are pleasurable warrant particular concern and, when the pleasure has a sexual component, particular attention to the sexual history.

In describing a subject's insight into his or her past behaviour, a detailed description or verbatim account will usually be more helpful than a summary statement. 'Lack of remorse', in particular, can cover a range of phenomena, of which a general unwillingness to take responsibility probably carries fewer implications for future dangerousness than a sense of self-justification, the persistence of a grudge, or a reference to unfinished business [50]. A subject's willingness to address the causes of violence should be assessed in the light of their response to previous interventions. Ambivalence may not always have prevented successful treatment.

Psychological testing

Psychological testing contributes to the assessment of violence risk in community settings in several respects. Firstly, the testing of personality and cognitive function can contribute to an understanding of the reasons behind an act of violence, for instance when neuropsychological testing demonstrates impaired executive function secondary to a head injury.

Secondly, some tests of personality and general psychological functioning serve as risk assessments in their own right. Of these, the best known is the Hare Psychopathy Checklist [51], which has been shown consistently to predict acts of physical violence with a level of accuracy comparable with that of the other structured instruments listed in Table 144.1 [52]. The personality traits identified include a number of negative markers encompassing inflated senses of self-worth, devious and manipulative attitudes towards others, behavioural problems, and lifestyle characteristics.

Thirdly, the understanding of someone's personality structure that testing can sometimes offer can be a valuable aid to community management, particularly when it helps the clinician to understand what aspects of their family and social environment people find most threatening, and why. Fourthly, a patient's history may indicate a need for specialized assessments such as assessments of sex-offending risk. These may need to be repeated at regular intervals, either for clinical reasons or because a court imposes such evaluations as a condition of someone remaining in the community.

Finally, a range of other investigations may be made necessary by particular aspects of a patient's case. Occupational assessments offer particular insights into the stresses that may affect a patient moving from institutional care to the community, and into possible ways of addressing these. Neurological investigation and treatment will be an enduring component of the care of some patients. One of

the tasks of the team providing care, whether they carry the label of forensic or general psychiatry, is to ensure that physical health needs are adequately met. Some of those health needs are generated by the same medications that allow some patients to remain in the community.

The limits to risk assessment

In conducting any assessment of violence risk, it is important to bear in mind the levels of accuracy that can be expected. Those levels of accuracy are not simple to describe. One approach is to ask: if a particular structured instrument was used as a screening test and those identified as likely to be violent were not discharged, over any given period, how many patients would need to be detained to prevent one unwanted act? This statistic—the number needed to detain (NND) [51]—is the inverse of the positive predictive value (PPV) and analogous to the 'number needed to treat'. Used as a screening test where the base rate of violence is 10% and where, as a result, an unselective approach would lead to the detention of ten people in order to prevent one from acting violently, the VRAG (Table 144.1) would require the detention of five people to achieve the same end [52].

Other structured instruments could be expected to perform similarly. Unstructured approaches have been less studied, but what research does exist does not suggest that they fare better. More importantly, for risk assessments conducted in everyday clinical settings the NND rises as the prevalence falls [53]. One consequence is that the number of mistakes rises when unusual acts, such as serious acts of violence, are sought to be prevented. At the base rate recorded in the Epidemiologic Catchment Area (ECA) study, where 17% of the sample self-reported violence in the previous 12 months, the NND to prevent an act of violence is 3.5 [54]. The outcome measure in the ECA study did not require injury. When injury is required, the base rate falls. In the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, the 6-month prevalence of assault with a weapon or causing serious injury was 3.6% [55]. Here, the NND at a sensitivity of 0.73 and a specificity of 0.63 is 15.

Data such as these have been used in the past to support statements to the effect that psychiatrists 'can' or 'cannot' distinguish which of their patients will act violently. This is to miss the point. There is no threshold of accuracy at which psychiatric risk assessment becomes possible or not possible. Instead, assessments of violence risk are just some of the numerous pieces of information that clinicians use to manage a case. Good assessments are more helpful in this regard than poor ones, and good assessments do not simply seek to be accurate, but also seek to inform clinical management.

Conclusions

The limits to the accuracy of what can be achieved represent one reason why violence risk assessment will usually be one factor, among many, that clinicians consider in the course of managing a case. Particularly where a patient has a history of violence or has stated a desire to harm, however, violence risk assessments will remain an essential part of clinical practice. Specialist advice will sometimes be necessary.

It is likely that the most helpful psychiatric violence risk assessments make use of both known statistical correlations and causal explanations. As one author put it:

'By supplementing a knowledge of relevant risk factors with a detailed examination of an individual's mental state, it may be possible to build up some picture of the calculus of reasons on which that individual's future actions may be based and in this way to give a more precise prediction . . . ' [56, p. 70].

The author went on to point out that the more an action is dominated by some overriding preoccupation or delusion, the more precise will be a prediction. He also pointed out, however, that however detailed our understanding of someone's calculus of reasons, we usually cannot predict with any certainty what they will do, or when.

While the ability to inform clinical decisions is not the same as predictive accuracy, the accuracy of violence predictions is important in helping clinicians decide which approach to risk assessment they should use. Research over the past 40 years has demonstrated a modest improvement in the level of accuracy that can be achieved using structured risk assessment instruments. As those instruments are further refined and developed, further research may show that they are capable of levels of accuracy beyond those that can currently be achieved. This work should be complemented by research on the cause-based approaches to risk assessment that remain widespread in clinical practice. Finally, research should examine the ways in which correlational and causal approaches can most helpfully be combined.

The expert witness in the criminal and civil courts

John O'Grady

Introduction

As an expert witness in court, the psychiatrist ceases to be simply a doctor, as a psychiatrist's report and testimony address issues on the boundary between law and psychiatry. The law is not primarily concerned with the welfare of the defendant. Criminal law is concerned with justice, fact-finding, and the attribution of guilt, while psychiatry concerns itself with the welfare of the individual, their mental disorder, and its treatment. This chapter will explore the legal framework for expert reports and testimony, expert witness standards, and an ethical framework for practice and will provide practical guidance on the preparation of reports and testimony.

Expert witness reports and testimony can only be usefully discussed within the legal framework of a particular jurisdiction. This chapter will discuss expert witness evidence in the context of jurisdictions based on common law (UK, Ireland, United States, Canada, and New Zealand). The legal framework for expert witness evidence in England and Wales is used as the primary jurisdiction, but the discussion will be applicable to other common law areas. While civil law jurisdictions (most of Europe) manage expert evidence differently from common law jurisdictions, both share concerns about admissibility, reliability, and impartiality of expert witness evidence. The focus of this chapter is on expert testimony in criminal courts, but the chapter will also discuss how expert evidence is handled in civil courts.

Expert psychiatric evidence

Witnesses in court can only give evidence of facts they personally perceived, and not evidence of their opinion. The opinion of an expert witness is an exclusion to this general rule, because the court needs the assistance of experts to consider issues beyond their knowledge. The judge, whether sitting alone or in a jury trial, acts as gatekeeper on whether expert evidence is admissible. In criminal courts, it is for the jury to draw inferences from, and adduce weight to, the evidence. In the absence of a jury, the judge decides both on admissibility of, and weight accorded to, expert evidence [1–4].

Miscarriages of justice and development of rules governing expert evidence

All jurisdictions have had miscarriages of justice attributed, at least in part, to poor-quality expert evidence. Two cases in the English jurisdiction—*R v Clark* and *R v Cannings*—concerned miscarriages of justice where medical evidence influenced the court's decision. Both cases concerned two infant deaths in the same family due to sudden infant death syndrome. An expert paediatrician gave evidence that there was only a 1:73 million chance of such deaths in the same family in the absence of a genetic or an environmental cause, thereby implying that the alternative proposition, that of deliberate killing, was more likely (see The prosecutor's fallacy, p. 1472). Both the statistical methodology and assumptions proved faulty, and both mothers were acquitted on appeal. The appeal court was critical of the expert medical evidence. The expert was not a trained statistician and had not consulted a trained statistical colleague before giving his opinion, thereby straying beyond his area of expertise. The opinion was dogmatic, that is, was a view based on a hypothesis not sufficiently scrutinized or supported by empirical evidence and did not give sufficient weight to conflicting views. The appeal court was concerned that the criminal court had been swayed by the aura of expertise and infallibility of the expert and had not critically appraised the reliability of the expert's evidence. These themes will be picked up in the rest of this section.

Case law and expert witnesses

Two landmark cases from the United States—*Frye* and *Daubert*—have become highly influential in developing case law on expert testimony across jurisdictions. The English courts have cited and amended a judgement in the Australian courts (in turn, citing *Frye* and *Daubert*) *Bonython* and decided upon four criteria to be considered by the court in deciding the admissibility and reliability of expert evidence:

1. Whether the subject matter of expert evidence is beyond the 'common knowledge' of judge and jury, making such evidence necessary to the court to be able to form a sound judgement on that subject matter.

2. Whether the expert's evidence forms 'part of a body of knowledge that is sufficiently organized or recognized to be acceptable as a reliable body of knowledge or experience', thereby making the expert evidence of special assistance to the court.
3. Whether the expert has 'acquired by study or experience sufficient knowledge of the subject' to render his or her opinion of value to the court.
4. Whether the expert can demonstrate that they provide an impartial opinion, recognizing the expert's duty is to the court.

By rigorously applying these four criteria to expert evidence, courts strive to ensure scientific evidence does not contribute to miscarriages of justice.

Common knowledge

Lawton L. J. in *R v Turner* established a 'common knowledge' rule governing expert evidence, specifically psychiatric evidence in this case, as follows:

'An expert opinion is admissible to furnish the Courts with scientific information which is likely to be outside the experience and knowledge of a Judge or a jury. If on the proven fact, a Judge or jury can form their own conclusions without help, then the opinion of an expert is unnecessary. In such a case if it given dressed up in scientific jargon it may make judgement more difficult. The facts that an expert witness has impressive scientific qualifications does not by that fact alone make his opinion on matters of human nature and behaviour within the limits of normality any more helpful than that of the jurors themselves; but there is a danger that they may think it does ... jurors do not need psychiatrists to tell them how ordinary folk who are not suffering from any mental illness are likely to react to the stresses and strains of life.'

This seems to limit psychiatric evidence to recognized mental disorder [as in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) and the *International Classification of Diseases*, tenth revision (ICD-10)]. However, expert advice is allowed which is 'outside the experience and knowledge of a judge or jury'. The abnormal/normal dichotomy is not a rule of law, but guidance. Courts have allowed evidence on a variety of conditions which would not normally be thought of as an established mental disorder, for example 'battered women's syndrome'.

Particular problems arise for the court in respect of borderline conditions falling short of a recognized mental disorder. Here admissibility will be determined by the court's judgement as to whether the expert evidence addresses matters outside the experience or knowledge of a judge or jury. The psychiatrist will have other knowledge of assistance to the court such as assessing the risk associated with a mental disorder or providing an opinion on professional standards to be applied in cases of medical negligence. Such evidence will be deemed admissible.

Even if the evidence meets this test, the court has discretion to render it inadmissible, for example if the court deems it prejudicial or misleading.

Body of knowledge

The second limb concerns itself with the reliability of expert testimony. Given that the court will have decided that the evidence is

'outside the experience and knowledge', it faces an inevitable dilemma in reaching a judgement as to its reliability when, by definition, it lacks the scientific knowledge to do so. Recognizing this dilemma, courts have sought tests that can be applied to determine this issue.

The most stringent is the test arrived at by the court in the United States in *Daubert v Merrell Dow Pharmaceuticals*, namely that 'the technique, body of knowledge, or theory can be tested; has been subjected to peer review and publication; has a known rate of error; is subject to maintenance of standards and controls and is generally accepted by the scientific community'. English courts have been reluctant to adopt this test, as its stringent criteria could rule out consideration of expert evidence, based on novel or developing science for which there may be no definitive peer review and which may not be accepted fully by the wider scientific community. Psychiatric evidence derives from scientific evidence, but also from expert consensus and experience—based on knowledge, and thereby not likely to meet the Daubert test. The Law Commission [5] considers expert evidence to be a continuum between experience-based evidence and narrowly scientific evidence and recommended that the criteria applied to expert evidence be flexible enough to be able to encompass this continuum. A phrase that recurs often in addressing reliability is that the evidence should be 'soundly based', such that simply stating 'in my clinical experience ...' would not be sufficient to be classed as soundly based, and courts should be mindful of the trap of accepting dubious scientific evidence on the basis of prestige and professional standing of the witness.

The Law Commission [5] considered the problem, concluded that the common law approach to the admissibility of expert witness evidence is one of *laissez-faire*, and recommended instead that a test of reliability be placed on a statutory basis. The Commission [5] was particularly concerned that without such a statutory test, there would be a 'danger that juries will abdicate their duty to ascertain and weigh the facts and simply accept the expert's own opinion evidence, particularly if the evidence is complex and difficult for a non-specialist to understand and evaluate'. The government was reluctant to limit the discretion of the court in admitting evidence and instead issued a practice direction [6] to the courts, with detailed guidance on criteria to be applied to expert scientific evidence to decide upon its reliability. This practice direction is reproduced in [Box 145.1](#). Rule 702 of Federal Rules of Evidence (United States) [7] likewise provides judges with guidance.

The leading textbook on expert evidence in the UK [1] concludes 'English judges now have the benefit of the most comprehensive guidance in the common law world as to how the reliability of expert evidence should be assessed'. This guidance ([Box 145.1](#)) should be understood and applied by psychiatric experts to their reports and could form the structured criteria by which reports are subjected to peer review case conferencing.

Acquired by study or experience

In English law, there is no statutory definition of what constitutes an expert. In *R v Bunnis*, the court stated that an expert is 'one who has by dint of training or practice acquired a good knowledge of the science concerning which his opinion is sought'. Rule 702 of the Federal Rules of Evidence (United States) [7] defines an expert as 'a witness qualified as an expert by knowledge, skill, expertise or training'. As psychiatry is a recognized specialty within medicine, which, in

Box 145.1 Criminal Practice Directions 2015 [6]

19A Factors which the court may take into account when determining the reliability of expert opinion, and especially of expert scientific opinion, include:

1. Extent and quality of the data on which the expert's opinion is based and the validity of the methods by which they were obtained.
2. If the expert opinion relies on an inference from any findings, whether the opinion properly explains how safe or unsafe the inference is (whether by reference to statistical significance or other appropriate terms).
3. If the expert's opinion relies on the results of any method (for instance, a test, measurement, or survey), whether the opinion takes proper account of matters such as the degree of precision or margin of uncertainty affecting the accuracy or reliability of those results.
4. The extent to which any material upon which the expert opinion is based has been reviewed by others with relevant expertise (for instance, in peer-reviewed publications) and the views of those others on that material.
5. The extent to which the expert opinion is based on material falling outside the expert's own field of expertise.
6. The completeness of the information which was available to the expert and whether the expert took account of all relevant information in arriving at the opinion (including information as to the context of any facts to which the opinion relates).
7. If there is a range of expert opinion on the matter in question, where in the range the expert's opinion lies and whether the expert's preference has been properly explained.
8. Whether the expert's methods followed established practice in the field and, if they did not, whether the reason for the divergence has been properly explained.

In addition, the court should be astute to identify potential flaws in such opinion which detract from its reliability such as:

1. Being based on a hypothesis which has not been subjected to sufficient scrutiny or which has failed to stand up to scrutiny;
2. Being based on an unjustifiable assumption;
3. Being based on flawed data;
4. Relying on an examination, technique, method, or process which has not been properly carried out or applied, or was not appropriate for use in the particular case; or
5. Relying on an inference or conclusion which has not been properly reached.

turn, is accepted as a scientific discipline, psychiatrists who have completed recognized training, are members of their professional body, adhere to standards of professional practice laid down by their regulatory body, and hold registration in the area of psychiatry they practise should have no difficulty in being accepted as an expert by the court.

When giving evidence based on novel or developing science or practice or where the opinion is experience-based, the expert should be in a position to demonstrate practical knowledge or have conducted research in the relevant science or practice and be careful not to give evidence outside their professional knowledge or practice. The UK regulatory body the General Medical Council (GMC) provides the following guidance: *'You must only give expert testimony and opinions about issues that are within your professional competence or about which you have relevant knowledge including, for example, knowledge of the standards and nature of practice at the time of the incident or events that are the subject of the proceedings. If a particular question or issue falls outside your area of expertise, you should*

either refuse to answer or answer to the best of your ability but make it clear that you consider the matter to be outside your competence' [8].

Impartial evidence

Courts have, over time, defined what is expected of an expert witness. The landmark case is that of the *Ikarian Reefer*. In *Field v Leeds City Council*, the judge stated that the expert witness 'should provide independent assessment to the court by way of objective unbiased opinion'. These and other judgements have led to the overriding principle governing expert evidence being that the expert's obligation is to the court, and not to whoever has instructed them. All other standards flow from that overriding obligation.

Case law judgements on expert evidence have been drawn together into sets of Rules governing expert witnesses in court. In England and Wales, three sets of Rules have emerged:

1. Civil Procedure Rules (CPR), Rule 35 [9].
2. Criminal Procedure Rules (CrPR), Part 19 [10].
3. Family Procedure Rules (FPR) [11].

In the United States, expert evidence is governed by Federal Rules of Evidence [7] and in Australia by the Australian Evidence Act [12].

Psychiatrists are, in addition, subject to standards set out by their professional and licensing bodies [8, 13, 14].

Box 145.2 draws together common standards from court rules and professional standards.

Bias

Bias is a shadow to impartiality [15].

Cognitive bias

Psychiatric experts come to the court with their own particular way of looking at the world underpinned by their values, cultural and ethnic background, professional experience, and theoretical framework and training. Experts should, through supervision and peer review, recognize their own preconceptions with resultant due weight given to contrary views. The psychiatric expert may have particular views within their field, for example particular views on the biological vs familial/interpersonal understanding of attention-deficit/hyperactivity disorder (ADHD). Particular training, for example in psychoanalysis, may shape the expert's opinion. To counter this, regulatory frameworks emphasize the expert's obligation to give due weight to the range of opinion on particular issues (see listed item 7 in **Box 145.1** and listed item 4 in **Box 145.2**). Rix [3] recommends, as a framework, addressing the range of opinion that might be expressed in a peer review case conference by respected consultant colleagues who may hold legitimate contrary views on psychiatric issues to the expert's own. He adds that there may be times when the expert has to address unreasonable opinions by colleagues lacking respect.

Adversarial bias

Adversarial bias can arise through selection bias and unconscious or deliberate partisanship. Legal firms may choose particular experts because they are known to support their client's particular viewpoint (Hired Guns). Experts are human and do not like to disappoint their instructing party. Deliberate partisanship can arise from the expert subtly or otherwise moulds their opinion to whoever hires them.

Box 145.2 Regulatory rules for expert witnesses: common across jurisdictions [7–14]

Overarching duty: the paramount duty of the expert is to assist the court on matters within his or her own expertise, and this overrides any obligation to the person from whom the expert has received instructions or receives payment.

Expert reports must contain:

1. Details of academic and professional qualifications, together with experience and accreditation relevant to the opinions expressed in the report (usually as a summary in the introduction, with more detail within an appendix);
2. A statement of the range and extent of expertise, together with limitations upon that expertise, particularly declaring when a particular issue is outside his/her expertise;
3. A statement setting out the substance of all instructions received, together with a listing of all materials provided and considered, upon which the opinion is based;
4. Where there is a range of opinion on matters dealt with in the report, a summary range of opinion, together with reasons for the expert's preferred opinion;
5. A declaration of any facts, materials, or investigations which might bear upon, or be made against, the expert opinion;
6. Extracts of the literature or any other material upon which the scientific evidence is based;
7. A statement of which facts are within the expert's own knowledge and which are assumed;*
8. Where an opinion is qualified, a statement to that effect;
9. A statement that the expert will inform all parties, including the court, in the event that his or her opinion changes on any material issue; and
10. A declaration of truth.

* Courts distinguish true and assumed facts. The only facts the psychiatric expert will routinely know to be true are the results of examination and results of tests or investigations. All other facts will be assumed to be true.

Confirmation bias

Confirmation bias can arise where the expert starts with a particular preconception on issues to be addressed to the report. Evidence is then sought and funnelled through that preconception (opinion-based evidence).

The prosecutor's fallacy

In the cases of *R v Clark* and *R v Cannings*, two conflicting propositions to explain two unexplained infant deaths in the same family were proposed: (1) the two deaths occurred due to sudden infant death syndrome; and (2) the two deaths were due to double murder by the parent. The first was presented in court where the likelihood was judged to be one in 73 million, with the inference being that the second proposition was therefore more likely. The fact that two sudden infant deaths are unlikely by itself is misleading, as the other proposition may be even more unlikely, that is, two deaths by murder by the same parent. The presentation of only one of the competing hypotheses in these cases has been dubbed the prosecutor's fallacy, as it usually favours the prosecution case. Rules on expert evidence therefore stipulate that the expert must consider and assign due weight to alternate views on any scientific issue before expressing their own opinion (see listed item 7 in [Box 145.1](#) and listed item 4 in [Box 145.2](#)).

Strict adherence to Court Rules ([Box 145.2](#)) and ensuring reports meet tests of reliability ([Box 145.1](#)) mitigate against bias.

Other forms of bias are recognized, which are more applicable to forensic science practice (for a full review, see [15]).

Legal governance

Should any party in court proceedings have reason for concern regarding an expert witness's adherence to standards of practice, there are a range of remedies available (UK case law, but similar remedies apply in other jurisdictions):

1. A judge in court can refer an expert to their regulatory body (the GMC for psychiatrists) to consider their fitness to practise.
2. The court can make an expert witness subject to a wasted costs penalty if they have seriously delayed or obstructed the progress of the case through poor adherence to the standards expected of an expert witness.
3. An expert witness can be held in contempt of court through wilful disregard or disrespect for the authority of the court.
4. In *Jones v Kaney*, the Supreme Court overturned a 400-year-old convention that an expert in court should enjoy immunity from suit. This means that the expert psychiatric witness can be sued for damages, but that is limited to parties to whom the expert owes a duty of care, as when the expert is instructed by one party in a civil dispute. The implications of this judgement continue to be worked out, but it appears a professional witness to fact, court-appointed experts, or experts instructed by the presiding judge do not owe a duty of care to a particular party in an adversarial system and therefore retain immunity from suit.
5. The expert witness can be charged with perjury where they are held to be wilfully telling an untruth or making a misrepresentation in their evidence.

The practical implication for the psychiatric expert witness is that they must have their own personal indemnity insurance for court work.

Ethical practice (with special reference to risk assessment)

Stone [16] used the term 'dual role' to describe the psychiatrist in the legal context. In Stone's view, the roles of the clinician and expert are ethically irreconcilable. The dual role arises from the conflicting expectations and responsibilities between their duty to the evaluatee to maximize their welfare (medical ethics) and the duty to put their clinical knowledge and experience at the disposal of the court (justice ethics).

Evidence on the risk associated with mental disorder is an exemplar for the dual role dilemma. Judges when considering an indeterminate (life) sentence or a longer-than-usual sentence, will, for offenders who may be mentally disordered, routinely require a psychiatric opinion on mental disorder, risk, and treatability. That assessment may result in welfare disposal in the form of a hospital order for treatment, instead of a custodial sentence, or where a mental disorder (for example, personality disorder) is identified and linked to future risk, but no treatment disposal recommended, the judge may justifiably conclude that the protection of the public would be best protected by imposing an indeterminate or longer-than-usual sentence.

One solution is to separate the clinical and legal roles [16], such that the expert does not have a clinical role to play in respect of the evaluatee. Adshead [17] argues that this is not viable in the UK. For any one offender, the psychiatrist may have multiple roles. In a public health system, the psychiatrist will have obligations to the state to fairly distribute health resources and thereby act as gatekeeper to psychiatric health care. At trial, the psychiatrist may give evidence on legal matters (for example, diminished responsibility) and, at the point of sentencing, provide an opinion impacting upon disposal (welfare or custodial). The psychiatrist's opinion may, at a later time, for the same offender, be central to legal decisions—the Mental Health Review Tribunal or parole hearing on release. Considering these overlapping and contradictory roles, Martinez and Candilis (United States perspective) [18] and Adshead (UK perspective) [17] reject the strict view of experts as being answerable to either the law (justice ethics) or their profession (medical ethics). Professional responsibilities cannot be divided along any absolute or clear lines.

The narrow domain of medical ethics does not remove from doctors the duty to consider the interests and the rights of other people and to consider the distribution of benefits and risks [19]. To work ethically within this framework presupposes a just state. Adshead [17] argues that the psychiatrist has duties as a citizen to participate in processes that could protect others from risk arising from individuals with mental disorder. The psychiatrist must, if acting as an expert witness, continuously negotiate a struggle between the welfare of the individual defendant, the legitimate need to the court for expert testimony, and duties to the wider society to address the risk to others associated with mental disorder. Very high standards are required of the expert in presenting findings on risk and their reliability. While probabilistic risk assessments may be accurate at a group level, at an individual level, the confidence intervals for any risk instrument are so wide as to make individual predictions highly problematic [20]. This has led Mullen [21] to conclude that 'the margin of error in every actual or conceivable risk assessment instrument is so wide at the individual level that their use for sentencing or any formal detention, is unethical'. While the court will recognize the limitations of risk assessment, nevertheless, risk assessment for the mentally disordered will fall outside the 'common knowledge' of the judge and jury. If the state has a legitimate claim on the psychiatrist's expertise in passing sentence or when considering parole, the psychiatrist would appear to have little option but to report their assessment of risk despite its clear limitations. This places grave responsibility on the psychiatric expert to report the findings on risk in a way that informs the court on the limitations of the risk assessment, particularly the problem of extracting an individual risk assessment from probabilistic group risk. Furthermore, when obtaining informed consent for reports, the psychiatrist should provide information to the evaluatee on the use the court or tribunal may make of the psychiatrist's risk assessment.

Common to approaches to developing an ethical framework for the psychiatric expert witness is the necessity to draw upon multiple ethical perspectives and values when undertaking evaluations and recognizing that there may be conflict between those ethical perspectives. These approaches combine ethics derived from traditional medical ethics, but also incorporate ethics derived from the perspective of justice (for a full theoretical account of this approach,

see [19]). Martinez and Candilis [18] proposed the following principles to guide practice:

- *Respect for persons*: everyone subject to a psychiatric evaluation for the court should be regarded with respect and professional fairness.
- *Respect for privacy and confidentiality*: while acknowledging that there are inherent limitations to this value in the legal context, nevertheless, care must be exercised in dealing with sensitive information. Balance and perspective are critical to the presentation of clinical findings, avoiding the provision of gratuitous information and avoiding bias through selective use of information.
- *Respect for consent*: psychiatric experts must ensure that those they evaluate understand the purpose of the evaluation, the limitations of confidentiality, and the potential use of the expert's opinion by the court (dual-role obligations).
- *Commitment to honesty and striving for objectivity*: this is reflected in the formulation of procedure rules across jurisdictions (Box 145.2), which must be adhered to by the psychiatric expert witness. The expert must resist the hired gun bias and exhibit thoroughness and transparency in respect of their personal values.

To this list, the author would add:

- *Respect for the human rights of others*: balancing the distribution of benefits and risks for the person being evaluated and society, including fair distribution of health resources [17, 19].

Individual psychiatrists and their professional bodies have a duty to ensure that psychiatric experts are properly trained and understand their dual obligations as a doctor and as a witness in court. This can be achieved through professional development, appraisal, and revalidation. The psychiatric expert must be willing to submit their medicolegal work to peer scrutiny and, through peer review and training, gain knowledge of the values and prejudices they bring to evaluations. Professional obligations include a willingness to tackle poor practice by colleagues, including referral to professional regulatory bodies.

The psychiatric report

Rix [22] and Buchanan and Norko [23] provide detailed guidance on the preparation of reports for courts and tribunals. The main points are summarized in Box 145.3. The court or tribunal has little time to read lengthy reports and are primarily concerned with the expert's findings and opinion. However, if detailed facts or narrative are necessary for whatever purpose, then the details can be confined to appendices. The aspiring expert should seek out formal training in medicolegal report writing and be thoroughly familiar with the subtle, but important, differences between reports for criminal, civil, and family courts (see [3]).

If there is no evidence of mental disorder, then the privileged exception accorded to psychiatric experts may no longer apply (see Common knowledge, p. 1470). However, the court may use psychiatric evidence where the boundary between disorder and normality is blurred. As in all aspects of interaction with the court, transparency is key to acting as a responsible expert. Psychiatric expertise derives from established scientific evidence, but also from expert consensus

Box 145.3 Report structure

The report should be typed using numbered paragraphs and headings and subheadings, and should make use of short sentences and paragraphs.

The psychiatric report should contain the following sections:

(a) Instructions, documentation, and methodology

The report should include details of instructions received, the methodology, documents received, assumptions adopted, and interviews conducted. The overriding principle is transparency. Full disclosure of all documents and information upon which the opinion is based is essential, along with disclosure of limitations and assumptions employed. In a psychiatric report, assumptions might include that the subject has been truthful and that medical records are accurate.

(b) The facts

The report should record briefly the facts upon which the opinion is based and should avoid interpretation which is the proper function of the opinion section. In psychiatric reports, the only facts that are within the psychiatrist's own knowledge are likely to be those based on findings of the mental state examination. All other facts are assumed. If structured tests are utilized, they may also constitute facts within the psychiatrist's own knowledge. Sufficient detail, recognizing that the court will have full knowledge of the case, for the court or another expert to understand the basis for opinion is what is required of the report. Further detail can be relegated to appendices.

(c) Opinion

The role of the psychiatric expert in the criminal court is to provide an opinion on mental disorder and its implications for the matters before the court. The features that lead to a diagnosis of mental disorder should be described, avoiding jargon and including mental state findings, so that others can understand how the opinion is reached. The diagnosis or differential diagnosis should be clearly stated, using a recognized classification (ICD-10, DSM-5). Where a condition is described which is not part of such recognized classification systems or where 'leading-edge' scientific findings or opinion based on experience or special knowledge are used to support the opinion, that should be justified by disclosure (as an appendix to the report) of the relevant literature to support the expert's opinion, together with, if applicable, the expert's own experience and knowledge of the field. In the civil court, opinion in clinical negligence should be anchored to established codes of practice, clinical practice guidelines, or service protocols and should be backed by providing relevant citations (which may form the basis for cross-examination).

The second stage of the opinion is to apply the psychiatric findings to the issues to be addressed in the report. Each issue should have its own section. The content should show how the opinion derives from the facts. The opinion should highlight the strength of the opinion, giving due weight to matters that might undermine the opinion or could fairly be made against it. The opinion should highlight any unusual or contradictory findings, must be balanced, and must give due weight to the range of reasonable opinion on the issue to be addressed (the psychiatric case conference model).

(d) Declarations and statement of truth

Court rules require the report writer to provide a declaration that the expert understands and has complied with their duty to the court (Box 145.2). Court Rules require a statement of truth to the effect that the content of the report is true and that the report writer is aware of their liability to be prosecuted for untruth in court.

(e) Qualifications and experience

Usually as an appendix.

(f) Appendices

Included here are recorded lists of documents, publications cited, and definitions of any technical terms.

Source: data from Rix K, The structure, organisation and content of the generic report, In: Rix K, *Expert Psychiatric Evidence*, pp 35–51, Copyright (2011), The Royal College of Psychiatrists.

and experience-based knowledge. In broad terms, the court needs to be informed of the level of evidence underpinning opinion.

Particularly in the civil court, the expert may be given reports of other experts in the case and due weight should be accorded to their opinion before commenting on their opinion and setting out the basis for agreement or disagreement (see listed item 7 in [Box 145.1](#) and listed item 4 in [Box 145.2](#)).

There may be conflict in the factual evidence, and the report should avoid preference for one side or the other but instead give alternative opinion, based on differing judgements on the evidence.

Terms such as 'diminished responsibility', 'insanity', or 'automatism' have precise legal definitions, and the report should address how the psychiatric findings translate to the legal definitions employed by the court.

Where recommendations for a mental health disposal under specific Acts are included, the precise wording of the relevant section of those Acts should be employed.

Opinion on the ultimate issue

There is long-standing prohibition in common law jurisdictions against the expert providing an opinion on the ultimate issue before the court. The judge will decide if a hospital is negligent in a civil negligence claim. The jury will decide in a criminal court whether a defendant is guilty. In deciding upon the ultimate issue, the court may require knowledge outside their common knowledge, for example interpreting the M'Naughton rules for insanity or applying the criteria for a finding of diminished responsibility. In such cases, the court has allowed opinion on the ultimate issue. The court in the United States generally allows opinion that embraces the ultimate issue, but this is limited by Rule 704 of the Federal Rules of Evidence [7], which states that the expert 'must not state an opinion about whether the defendant did or did not have a mental state or condition that constitutes an element of the crime charged or of a defence. Those matters are for the trier of fact alone.' The psychiatric expert should be careful when expressing an opinion on the ultimate issue that their opinion is necessary to assist the court on matters outside the common knowledge of the court.

Confidentiality

Medicolegal work undertaken by psychiatrists is governed by the same rule of confidentiality as applied to other clinical work. Reports cannot be disclosed to a third party without the consent of the body commissioning the report. Psychiatric reports do not form part of a person's medical record, except by the express consent of the individual or their legal representative. Defence solicitors can exercise a right not to disclose a report to court. Failure to comply with the rules of confidentiality can lead to civil action or reporting to a professional regulatory body. Breaching confidentiality may be justified in particular cases.

While the psychiatric expert owes an overriding obligation to the court, nevertheless, the expert remains a doctor with consequent medical responsibilities. If the report writer concludes that the evaluatee requires treatment, then the expert must consider whether their medical practitioner should be alerted to that treatment need.

This is usually done with the agreement of the evaluatee or their legal representative. Where, for whatever reason, that recommendation is not passed on to the evaluatee's medical practitioner, consideration must be given to disclosure in the person's best interests.

A psychiatrist who believes that the evaluatee is not co-operating with the preparation of a report because of mental illness has a duty to consider whether the evaluatee's mental illness could interfere with a fair trial (for example, fitness to plead or lack of consideration of a mental health disposal). The psychiatrist must then make a judgement whether it is in the best interests of the evaluatee for sufficient information to be provided to the court to alert them of the doctor's concerns. Such disclosure will almost certainly be justified in the interests of a fair trial and justice.

The other situation where a breach of confidentiality may be justified is where a report is not disclosed, but the report writer believes that the court ought to consider the report findings on potential risk to the public or where the court is unaware of information that might have a crucial bearing on outcome. In *BW v Edgell*, the court held that the doctor's duty of confidence did not prevent a psychiatrist from taking steps to communicate the grounds of concern to the court. The strong public interest in disclosure to prevent a court from making decisions based upon inadequate information was held to override the psychiatrist's duty of confidentiality. Where a doctor is considering disclosure in these circumstances, advice should be sought from an experienced colleague and the case law consulted, and the psychiatrist should thoroughly understand their regulatory bodies' guidance on disclosure, as well as consult their indemnity insurer.

In all cases, disclosure should be limited to providing sufficient information to the receiving body (court or medical practitioner) to make a decision. In *Cornelius v DeTaranto*, a psychiatrist who wished to arrange treatment for a claimant in a civil case disclosed the full report to the claimant's medical practitioner without the claimant's consent and was held to be negligent in doing so. Limited disclosure would have been sufficient to alert the medical practitioner to the treatment need, rather than full disclosure of the report.

It is the responsibility of the expert to ensure the security of clinical records and court documents, and the expert must adhere to relevant data protection legislation. The three Rs should be followed:

- **Retain:** all documentation until the statutory time limits for retention of documents has passed and to at least the time of any potential appeal, civil suit, or referral to regulatory bodies.
- **Record:** keep structured, clear, legible, and comprehensive records in a format suitable for other instructed experts to consult.
- **Reveal:** all sources of information in the report.

The interview

At the beginning of the interview, the examining psychiatrist should explain carefully to the defendant the nature of the doctor's dual role, the limits of confidentiality in producing a medicolegal report, and that the court will have full disclosure of all material known to the report writer (no off-record material). It is prudent to obtain a signed record of this discussion and to include it as part of the introduction to the report. Whenever possible, an informant should be interviewed—by telephone, if necessary.

Appearing in court

Experts are allowed, unlike witnesses of fact, to sit in court and hear the evidence of other witnesses before they, themselves, give evidence. An expert can be called by any interested party in proceedings. The cardinal rule when giving oral evidence in court is that, although called by one party, the expert witness is not giving evidence for that party's side but is under duty to provide fair and impartial evidence to the court, even where this conflicts with the interests of the party calling them [1, 3].

In the criminal court, the report will have been pre-read by the judge, and it is usual for the examiner to refer to relevant sections of the report. A report with numbered paragraphs is easier for the court to follow. The jury will not have read the report and will not usually be given sight of the report. Their knowledge of the expert's report will come from submissions made by either side and through the judge's questioning and summing up.

When calling an expert witness, the advocate must elicit the following:

1. The expert's qualifications: the report should have been prepared according to court procedure rules and therefore contain a biography setting out the qualifications and experience of the witness. It will then be usual for the advocate to lead this part of the evidence by reference to the biography supplied in the report. It will be perfectly permissible for the other side to call into question the expert's qualifications. This should be met politely by outlining the reasons why the expert believes they have the requisite qualifications and experience to answer the questions posed in instructions and have not strayed beyond their area of expertise.
2. Advocates are under duty to challenge disputed evidence. Thus, where more than one expert opinion is provided and they differ, the expert must expect their opinion to be disputed. The expert must resist pressure from one party to deviate from, or express greater certainty about, an opinion they have reached in the written report. The use of joint expert statements helps this process.
3. An expert witness may be cross-examined as a hostile witness if there is good reason to suppose that they are not telling the truth. Thankfully, this is extremely rare. The possibility of deliberate or inadvertent bias must, however, always be considered.

Civil courts

(See [1, 3, 24, 25]). This chapter has concentrated upon practice in the criminal court, and the discussion applies equally to the civil court. However, there are important differences. The civil court is far more complex than its criminal counterpart. Each jurisdiction will have its own CPR. Psychiatric experts familiar with work in the criminal court will, when undertaking occasional expert reports in the civil court, be relative novices and need to thoroughly familiarize themselves with court processes and the stringent requirements of civil proceedings. If coming to the civil court for the first time, it may be prudent to prepare reports under supervision from an experienced colleague. Adversarial bias is a particular hazard in civil proceedings.

Important differences in England and Wales include:

- The burden of proof is at the level of balance of probabilities, rather than the more stringent test—beyond reasonable doubt—in the criminal court.
- Civil actions have multiple stages governed by different rules (preliminary reports, pre-action stage, claim). Preliminary reports are for the sole use of the legal team, and not subject to CPR, while reports at the claim stage are subject to the specific and stringent CPR.
- The CPR encourage the appointment of single experts.
- Where more than one expert is involved, exchange of reports is mandatory, and case conferencing between experts with joint reports on areas of agreement/disagreements routine. While not covered specifically by CrPR, this is becoming common practice in the criminal court.

The psychiatric expert will need to take particular care to understand the questions asked of them and understand the case law applicable to the questions asked. The reliability of the expert's evidence, including evidence on standards of care in medical negligence, will be central to the court's assessment of the expert's evidence. In medical negligence cases, the opinion should be anchored to established codes of practice, clinical practice guidelines, and practice protocols applicable at the time of the medical event under scrutiny. Though the civil court does not have formal guidance on reliability in England and Wales, the guidance for the criminal court is equally applicable to the civil court (**Box 145.1**).

Civil jurisdictions

It is beyond the scope of this chapter to examine the expert's role in civil jurisdictions, which includes most of Europe, but some differences and common concerns can be recognized. Inquisitorial systems typically employ two stages: an investigative stage and a trial stage. The judge is an active protagonist in adducing the truth. The divide between both systems is not clear-cut; for example, in Scotland, the Procurator Fiscal directs an investigative stage in the most serious crimes, followed by a trial employing the adversarial approach.

In contrast to common law jurisdictions, the courtroom is not the setting for examining the scientific reliability of expert evidence and the expert's evidence is not subject to cross-examination at the trial stage. Issues of admissibility or reliability are not subject to formal criteria, but there is equal concern about these matters within the European Union [26]. The examining magistrate has wide discretion in what evidence is admitted at the trial stage.

Homicide

Matthew Large and Olav Nielssen

Introduction

Homicide is the killing of one person by another. This simple definition unites a wide range of motives, methods, and characteristics of both the offenders and the victims. Murder has been defined as the unlawful and intentional killing of one person by another, and psychological aspects of the motive for killing are central to the legal verdict of murder. All societies with recorded history have forbidden homicide, and an enduring fascination with homicide is reflected in our myths, plays, and fiction and the continued public appetite for stories about homicide.

Most homicides are committed by people with no identifiable mental disorder, and few people with a mental disorder will ever commit a homicide. However, homicide is an important topic in psychiatry, because people with mental disorders, especially schizophrenia, commit a disproportionate number of homicides. Psychiatrists have a role in assisting the court in determining the degree of criminal responsibility of mentally disordered homicide offenders and in providing long-term care and advice regarding the release of offenders to the community. Moreover, several notorious homicides involving people with mental illness have influenced the development of mental health law, policy, and services.

Definitions

Homicide is a type of unnatural death, along with fatal accidents and suicides [1]. Deaths from military conflicts are not usually considered to be homicides, although those resulting from civil unrest, mass killings of civilians by governments, and deaths from terrorism are included in the definition. This chapter is mainly concerned with intentional homicides, defined as ‘unlawful death purposefully inflicted on a person by another person’ [1]. Non-intentional homicide (such as in motor vehicle accidents) and lawful killings (in self-defence or during law enforcement) are not considered. Intentional homicides can be divided into primary, or interpersonal homicide, when the death or injury of a particular victim was the aim of the offender, and secondary homicide which is the result of other criminal activities [1].

Without wishing to understate the importance of deaths due to military conflict, civil unrest, terrorism, negligence, and lawful

killings, or any overlap between primary and secondary homicide, the focus of this chapter is on primary or interpersonal homicide, particularly homicide committed by people with a mental disorder.

An equivalent to the commandment ‘Thou shalt not kill’ can be found in the lore of all ancient societies [2]. Most legal classifications of homicide have developed around the offender’s motive and the degree of mental responsibility for their behaviour. For example, in Anglo-Saxon law, at the time of the Norman Conquest, ‘slaying by stealth’ was distinguished from ‘slaying openly’; the former was punishable by death, and the latter could be remedied with compensation to the victim’s family [3]. More modern definitions of criminal homicide emerged in twelfth-century England when ‘slaying with malice aforethought’ was distinguished from justified homicides, such as the killing of a thief caught in the act, and excusable homicides such as accidental homicide and homicide in self-defence [3, 4]. The perceived intent and the capacity to form the requisite intent to kill have become central to modern legal determinations. A clear-minded intention to harm or kill is what distinguishes murder from deaths resulting from dangerous acts committed without the specific intention of causing death. In most jurisdictions, there are provisions that recognize the effect of mental disorder on the ability to form the rational intention to kill, together with mechanisms for diversion for treatment and supervision of mentally ill offenders.

Epidemiology of homicide

In 2012, almost half a million people died by homicide [1]. Most homicides are single homicides committed by one person, and therefore the rates of death by homicide and homicide offending are generally similar. The global homicide rate is about six per 100,000 people, but there is marked variation in homicide rates between regions, countries, and communities (Table 146.1). In the Americas, the rate of death by homicide was over 16 per 100,000 in 2012; in Africa, it was over 12 per 100,000, while rates of homicide in Europe, Oceania, and Asia were about three per 100,000. The homicide rate in Russia in 2012 was over nine per 100,000, whereas in England and Wales, as in most other countries in Western Europe, it was about one per 100,000. In Canada, the rate of homicide was 1.6 per 100,000; in the United States, it was 4.7 per 100,000, and in Honduras, it was over 90 per 100,000 per annum.

Table 146.1 Homicide rate and proportion of male homicide victims in the ten most populous countries, England and Wales, Canada, Australia, and New Zealand

Country	Homicides per 100,000 per annum	Proportion of male victims
China	1.0	78.1
India	3.5	59.2
United States	4.7	77.8
Indonesia	0.6	80.3
Brazil	25.2	89.8
Pakistan	7.7	76.7
Bangladesh	2.7	63.3
Russian Federation	9.2	75.5
Japan	0.3	47.1
England and Wales	1.0	70.3
Canada	1.6	69.8
Australia	1.1	67.3
New Zealand	0.9	48.8

Being male is one of the most stable and well-established risk factors for homicide, and about 95% of homicide offenders are male, a proportion that does not vary much between countries or according to the rate of homicide. About 80% of homicide victims are also male, although the ratio of male-to-female victims varies more than that of offenders, and in a small number of countries, including Germany, Japan, several Nordic states, and New Zealand, the number of female victims exceeds the number of male victims [1].

Homicide offending by children is rare, and the rate of offending is highest between the ages of 15 and 29 and declines steadily with age. The age distribution of homicide victims varies between regions. In the Americas, 15- to 29-year-old men and women are most at risk, whereas in Europe, males aged 30–59 are more likely to be the victims of homicide than younger men.

Rates of homicide have declined in most economically developed countries in the last 20 years, for reasons that may include ageing of the population, better policing, changes in patterns of substance use, and a decline in the number of domestic homicides [5]. Improvement in emergency treatment of trauma victims might also have influenced the measured rates of homicide, especially in the United States [6]. Changes in homicide rates in low- and middle-income countries have been less uniform but appear to be related to economic development. For example, the greatest decline in the rate of homicide in South America has been in Chile, a country that has enjoyed consistent economic progress [7].

There is no complete explanation for the wide variation in homicide rates. Differing patterns of weapon availability and substance use are two of the most frequently cited reasons. Worldwide, more than 40% of homicides are committed using a firearm; higher rates of firearm ownership are associated with higher rates of homicide [1, 8], and being a gun owner is associated with an increased probability of committing homicide, compared to non-gun owners from the same community [9, 10]. There is clear evidence that measures to regulate gun ownership can have an impact on homicide rates. For

example, in the wake of a mass killing in Australia in 1996, stricter licensing and storage requirements and compulsory government buy-back of automatic and semi-automatic weapons was followed by an accelerated decline in firearm homicides and a marked reduction in the number of mass killings [11].

High homicide rates can be found in some areas with low levels of gun ownership, mainly in places with high-per-capita alcohol consumption. There is a well-established association between alcohol intoxication and homicide at the level of the offender [12], and there is an association between changes in national alcohol consumption and fluctuations in homicide rates [13]. There is also an association between more broadly defined rates of substance use and homicide [14], an association that might be explained by the criminal activity associated with illegal drug use and possibly even the mental effects of abuse of illegal drugs, especially stimulants. In regions with very high homicide rates, such as South Africa and some Central and South American countries, there is often a combination of ready availability of weapons, hazardous patterns of substance use, drug crime, economic deprivation, and weak law enforcement.

Homicide and mental disorder

The two main methods of examining the association between crime and mental disorder are by psychiatric evaluation of offenders and by linking criminal and health registers. Both methods have advantages and disadvantages. The examination of offenders is liable to sampling bias, as not all offenders are the subject of a detailed examination and because those evaluations are retrospective. To date, only a few countries have had the benefit of centralized health information in order to perform large-scale data linkage studies. This method relies on the reliability of primary health diagnoses and overlooks the presence of mental illness in offenders in the first episode of an illness and those who avoided contact with health services. However, both types of study provide strong evidence for an association between schizophrenia and homicide [15]. The association between homicide and mental disorders other than schizophrenia is less clear and might well be explained by other factors such as comorbid substance use [16, 17].

Homicide and schizophrenia

People with schizophrenia are overrepresented among samples of homicide offenders. Meta-analyses suggest that those with schizophrenia are about 20 times more likely to commit a homicide than other members of the community [18] and make up about 6.5% of all homicide offenders [15]. The population rate of homicide by people with an established diagnosis of schizophrenia appears to be about ten per 100,000 annum [19], although there is some variation, and the rate of homicide by people with schizophrenia is higher in regions with high total rates of homicides [15]. A meta-analysis found that about 40% of those homicides occur in the first episode of psychosis and the absolute risk of homicide by people during the period of their first episode of psychosis, regardless of how long the illness had been untreated, is more than ten times the annual risk of homicide after treatment [19].

Homicides by people with schizophrenia are often committed in response to frightening delusional beliefs [20]. The importance of delusional beliefs and positive symptoms of schizophrenia is

supported by the association between delusions and non-lethal violence [21], the apparent fall in the homicide rates after initial treatment [19], and the decline in homicide by people with schizophrenia following the development of community mental health services in England and Wales in the 1970s [22]. However, other factors contribute to the association between schizophrenia and homicide, especially after initial treatment of the illness, including the high rates of substance use among people with schizophrenia, the emergence of schizophrenia among young males, a group already at greater risk of violence, and the association between social disadvantage and both violence and schizophrenia. The importance of factors other than delusional beliefs in homicide is evident in the finding that rates of homicide by people with schizophrenia are strongly correlated with rates of other homicides, rather than with the epidemiology of schizophrenia. One interpretation of this finding is that people with schizophrenia are vulnerable to the social factors that determine the overall rate of homicide [15].

Homicide and other mental disorders

The proportion of homicide offenders with mental illness varies widely between studies. A nation-wide study from New Zealand found that fewer than 10% of all homicide perpetrators were determined to be 'mentally abnormal' by the courts [23]. In contrast, a national study of Swedish homicide offenders found that only 10% had no mental health diagnosis [14]. The association between homicide and mental disorders other than schizophrenia has also been studied by the psychiatric evaluation of offenders and by linking health and criminological data. Any study of the homicide rates among people with mental disorders is likely to have been affected by the proportion of homicide offences that result in the identification of an offender, whether the study was conducted by clinical interview, co-registration of criminological and health data, or research interviews. Studies that include substance use disorders and personality disorders in the definition of mental disorder are also likely to report a higher proportion of mentally disordered offenders than studies that exclude those diagnoses. It has been suggested that places with a higher homicide rate have a smaller proportion of mentally ill offenders because of a dilution effect [24], although this is disputed [25].

There is evidence for an association between substance use disorders and homicide. A case linkage study from Sweden found that 20% of homicide offenders had been identified to have a substance use disorder prior to the homicide [14], whereas a study conducted in Australia using similar methods found that 5% of homicide offenders had a previous substance use disorder [26]. Studies based on the psychiatric evaluations of homicide offenders after the offence also vary in the proportion of offenders with a substance use disorder, with studies from the United States [27], Finland [28], Austria [16], and New Zealand [23] reporting rates of substance use disorder of 47%, 12%, 1.4%, and 0.7%, respectively.

There is marked variation in the proportion of homicide offenders considered to have a mood disorder. Case linkage studies from Australia [26] and Sweden [14] both reported that about 2% of homicide offenders had been treated for depression prior to the offence, whereas studies relying on the clinical examination of offenders have reported varying proportions of offenders with mood disorders. Studies from Singapore [29] and the United States [27] both reported that 9% of homicide offenders had a diagnosis of depression. Studies from other regions have

reported lower rates of depression, including 5% in Finland [28], 4% in England and Wales [30], 1.4% in Austria [16], and 1% in New Zealand [23].

There is an obvious association between antisocial personality disorder and violent crime, in part because a pattern of impulsive behaviour and criminal conduct is part of the definition of the condition, but few population-based studies of the psychiatric diagnoses of homicide offenders have specifically reported the proportion of offenders with the diagnosis of personality disorder. A Swedish case linkage study found that almost 30% of homicide offenders had been diagnosed with personality disorder prior to the homicide [14], and a recent study from the United States found that 23% of homicide offenders met the criteria for at least one personality disorder [27]. The reported rates of organic mental disorders, epilepsy, or brain damage among homicide offenders also vary. A Swedish case linkage study reported no cases of organic mental disorder [14], whereas a case linkage study from Australia reported that 7% of homicide offenders had a pre-existing organic mental disorder, most commonly a history of traumatic brain injury [26]. The reported rates of intellectual disability among homicide offenders range from 2% in Finland [28] and the United States [27] to under 1% in New Zealand [23] and Sweden [14].

Types of primary homicide

Domestic homicide

Domestic homicide includes the killing of an intimate partner, the killing of one's own children (filicide), the killing of parents (matricide and patricide), and the killing of siblings (fratricide). In England and Wales, about 20% of all homicides are classified as domestic homicides, 80% of which involve the killing of current or former partners [31]. Like other homicides, the offenders are mostly male and have a mean age in the late thirties. Unlike other forms of homicide, the victims are overwhelmingly female. In the United States, the pattern of male perpetrators and female victims in domestic homicide is similar, although a higher proportion of deaths involve a firearm [32]. In regions where firearm ownership is less common and total homicide rates are low, kitchen knives are the most common method [33]. Domestic homicides are often a form of fatal domestic violence, in which there has been an escalating pattern of violence in the relationship before the killing. Less common forms of domestic homicide include homicide by a mentally ill family member and homicide-suicide.

Homicide of strangers

Stranger homicide can be defined as the killing of a person who is not known to the perpetrator until shortly before the offence. In the United Kingdom, as many as one in five homicides are stranger homicides, usually involving young men who become involved in a fight in a public place while affected by alcohol [34]. Stranger homicides by people with mental illness are very rare. A meta-analysis of data from England, Germany, Denmark, Finland, and Australia estimated the population rate of stranger homicide by people with schizophrenia to be about one in 14 million people per annum [35]. Stranger homicide offenders with psychosis are often homeless, have a history of violence, and are acutely psychotic at the time of the offence, often without any previous psychiatric treatment [35].

Neonaticide, infant homicide, and infanticide

About half of child homicide victims are under one year of age [36]. Neonaticide is the killing of a child in the first 24 hours of life and is typically committed by disadvantaged and psychologically distressed single women who concealed their pregnancy and kill their children by abandonment or neglect [37]. Infant homicide is the killing of a child below the age of one and includes neonaticide. The most common cause of infant homicide is fatal child abuse, usually by male partners [36, 38]. Rates of infant homicide are correlated with rates of both homicide and other violent offending [39, 40].

In some jurisdictions, infanticide is a separate category of homicide offence and refers to the killing of a child less than one year of age by the mother during a post-partum mental illness. Mothers with mental illness commit a small proportion of infant homicides [36, 38]. In jurisdictions without specific infanticide laws, the role of maternal mental illness on criminal responsibility is determined in the same way as that of other forms of mental illness. Societal attitudes to the killing of infants influence the types of verdicts and the penalties imposed [41].

Child homicide

Over 5% of homicide victims are under 15 years of age. About half are killed as a result of fatal physical abuse, and about 20% are due to parental mental illness, usually involving the child's mother [38]. Other causes are fights between teenagers, and children being caught up in criminal homicides or homicide–suicide by parents [42]. Despite the publicity that follows the offences, sexually motivated homicides of children are rare.

Homicides by older people

People over 60 commit a small proportion of all homicides, although this proportion is likely to increase with ageing of populations around the world. Homicide by people in advanced old age is extremely rare [43–45]. Studies of older offenders emphasize the role of cognitive impairment and morbid jealousy associated with long-term alcohol use [46].

Many older homicide victims are intimate partners of a similar age to the perpetrators. Homicide of the elderly also includes homicides committed in the course of a robbery, intentional neglect, and physical abuse of a frail elderly people, and altruistic homicide of chronically ill and terminally ill partners, for example those with dementia [47].

Homicide–suicide

Homicide that is closely followed by the suicide of the perpetrator is known as homicide–suicide or murder–suicide. Worldwide, almost one in ten homicides are followed by the suicide of the offender [48]. Most homicide–suicides are by men who kill their partners, and sometimes their children, and familial ties between the offender and the victim make suicide after homicide more likely [49]. Establishing the motives for homicide–suicide is difficult because of the death of both parties. A quantitative review of 49 international studies of homicide–suicide found that rates of homicide–suicide are strongly associated with rates of homicide, which is understandable, given that the initial event is a homicide [48]. There is less evidence for an association between rates of suicide and those of homicide–suicide, suggesting that, in most cases, homicide–suicide

should be considered to be a form of homicide, rather than ‘extended suicide’. However, altruistic homicide of a sick or infirm partner, followed by the suicide of older offenders is a well-established pattern of homicide–suicide.

Medical killings and euthanasia

A full discussion of euthanasia is beyond the scope of this chapter. However, two points are worth noting. The first is that deaths classified as euthanasia occur on a spectrum from legal and ethical decisions not to resuscitate or continue medical care of a terminally ill person to the use of terminal sedation, assisted suicide of people with varying degrees of competence, to premeditated killings by health practitioners. An increasing number of jurisdictions permit physician-assisted suicide for terminally ill people, and the responsibility for determining capacity to give consent often falls to psychiatrists. At the other end of the spectrum, physicians played a role in the state-sponsored killing of disabled patients in Nazi Germany, and England's most prolific serial killer was a trusted local doctor Harold Shipman [50].

Homicide in institutions

Suicides and deaths from natural causes in institutional care far outnumber homicides, and state-sanctioned execution is probably more common than homicide as a cause of death among prisoners worldwide. Homicides do occur among inmates of prisons and include cases of mentally ill inmates killing their cellmates. Homicides in secure hospitals and other psychiatric hospitals are rare events. A study of homicides in Australian and New Zealand psychiatric hospitals found that all of the 11 homicides were by people with schizophrenia, and ten of the victims were fellow patients. The rate of homicides per bed day was estimated to be similar to that of the wider community, although the victims would not have been placed in danger had they not been detained in hospital [51].

Mass killings, spree killings, and serial killings

Mass killing is variously defined as the killing of more than three or, in some studies, four people at one time. Mass killing is distinguished from spree killings, which are random killings of more than one person in a short time, sometimes in company, and from serial killings, in which a series of homicides are committed, usually by one person, over a longer period.

Mass killings have been described as a relatively modern phenomena, although there are historical accounts of random mass killings [52]. Mass killings include multiple homicides of a family by a family member, often followed by the suicide of the perpetrator, and mass killings of strangers or colleagues and acquaintances by disturbed men, often with an automatic or semi-automatic weapon. A proportion of mass killings are committed by people with mental illness, often with emerging or untreated psychosis [53].

Homicidal ideation

The incidence of thoughts or plans to commit homicide among members of the general community has never been reported. Further, the extent of any association between homicidal ideas and actual homicide is not known. Two studies of psychiatric patients have reported the rates of homicidal ideation. One study found 22%

of 517 unselected psychiatric outpatients reported previous homicidal ideation, that 7% had persisting homicidal thoughts or a homicide plan, and about 4% had made an attempt to kill another person [54]. Gender, race, marital status, and the diagnosis of schizophrenia were not associated with homicidal ideation, but those with schizophrenia and homicidal ideation were more likely to have been violent. Another study of 223 adult patients with chronic schizophrenia found that 15% had 'severe or extreme homicidality' and that homicidal ideation was associated with the presence of mania, psychotic symptoms, and impaired social function [55]. Another study followed up 613 people who had been convicted of threatening to kill another person found that 44% were convicted of a violent offence in the next 10 years, including 3% who were charged with homicide [56]. Although this study suggested a possible link between homicidal ideation and homicide, it should not be forgotten that homicidal ideas must be several orders of magnitude more common than homicide in most patient groups.

The relationship between homicidal ideas and homicide was the subject of one of the best known legal cases in psychiatric history. In 1967, Prosenjit Poddar met Tatiana Tarasoff while they were both university students in California. Poddar was rebuffed by Tarasoff who subsequently sought psychiatric treatment. In the course of counselling, Poddar disclosed homicidal ideas towards Tarasoff, and some time later stabbed her to death. The court later held that treating doctors owed duties not only to the patient, but also to warn and protect members of the public who might be endangered by the actions of their patients [57]. Although the duty to warn after Tarasoff only applies in some states in America, it has influenced the laws and claims for negligence internationally.

Attempted homicide

The two elements of murder are death and the intent of the offender to kill. However, even when there is a clear intention to kill, injuries inflicted are not always fatal, and the victim fighting back, the intervention of bystanders or medical care, might prevent death. Hafner and Boker's landmark study of homicide and mental disorder in West Germany between 1955 and 1965 included cases of both homicide and attempted homicide [58]. Their study found similar numbers of attempted and actual homicides, and few differences between the offenders in each group. A recent Australian study suggested there were few differences between mentally ill homicide offenders and mentally ill people who committed serious non-lethal violence [59]. Assaults by mentally ill people that result in a serious injury are rare, compared to other less serious types of assault. For example, in a recent meta-analysis, pooled estimates of the proportion of patients with first-episode psychosis committing any violence, serious violence, and violence resulting in serious injury were 34.5%, 16.6%, and 0.6%, respectively [60].

Legal proceedings and inquiries after a homicide

Several notorious homicides by people with mental illness have resulted in changes in the way in which people with mental illness are regarded and treated. An early example was a trial following the attempted shooting of George III by James Hadfield in 1800, which

led to the emergence of both the verdict of 'not guilty by reason of insanity' and of legislation to regulate the treatment and control of mentally ill offenders [61].

Homicides are usually followed by police investigations to determine the cause of death and who might be responsible. The 'clearance rate' is the proportion of homicides in which either the killer is identified or a conviction is obtained. About 60% of homicides worldwide result in an arrest, a proportion that varies markedly between jurisdictions, mainly according to the number of homicides to be investigated [1]. For example, in countries where the homicide rate is less than one per 100,000, the clearance rates are mostly above 90%. Clearance rates fall to below 80% in countries with homicide rates of between one and ten per 100,000 and below 50% when the homicide rate is above ten per 100,000 [1]. Clearance rates can affect the results of studies of the epidemiology of homicide by the mentally ill, because it may be that homicides by the mentally ill are more likely to be detected.

Criminal proceedings after homicide offences initially involve establishing that the accused person committed the homicide. However, if the facts of the offence are clear, a conviction for the most serious form of intentional homicide can depend on the motive and state of mind of the accused person. When the accused has a mental illness, the question before the court is the extent to which the mental illness reduced the defendant's degree of responsibility. Defences on the basis of mental infirmity have been described since Roman times [61]. In common law tradition, the defence of mental illness depends either on the person being aware that the killing was legally wrong or, in some places, morally wrong, from the perspective of the mentally ill offender. The most influential precedent in assessing criminal responsibility in the presence of mental illness were made by the House of Lords after the acquittal of Daniel M'Naghten for the 1843 killing of Edward Drummond, who M'Naghten had mistaken for the then British Prime Minister Robert Peel. In the M'Naghten Rules, as they came to be known, a verdict of not guilty by reason of insanity required that it be 'clearly proved that at the time of committing the act the party accused was labouring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing, or as not to know that what he or she was doing was wrong' [62].

Many jurisdictions have partial defences to murder on the basis that a psychiatric disorder may cause an offender to have reduced ability to form the required intent to commit murder or to control their actions (Box 146.1). A finding of diminished responsibility in the UK [63] reduces the verdict from murder to manslaughter, with a lower range of sentences and often an order for secure hospital treatment.

In addition to criminal proceedings, homicides are often the subject of civil inquests and proceedings on the basis of alleged negligence. In the UK, homicides by known patients are routinely examined in a process of confidential inquiry [64]. Coroners sometimes conduct inquiries to determine the cause of homicides that did not result in immediate criminal charges. Several well-publicized homicides by patients have resulted in more wide-ranging public inquiries, for example, the enquiry into the care and treatment of Christopher Clunis who killed a young man standing with his family on a London railway station [65], which produced recommendations for wide-ranging changes in clinical practice.

Homicides by patients with mental illness deserve close scrutiny to establish whether future tragedies might be prevented. However,

Box 146.1 Approximate legal definitions of homicide in English law

Homicide: a broad term for the killing of one human by another, sometimes restricted to unlawful killings.

Murder: an unlawful death inflicted with the intent to kill or seriously injure, and in the case of felony murder, a killing that takes place in the course of committing a serious crime, even if the killing was not intended.

Manslaughter: an unlawful death inflicted without the intent to kill or injure, including killings where the offender's criminal responsibility is reduced because of the effect of a mental disorder.

Not guilty by reason of insanity: at the time of committing the offence, the offender was unable to appreciate the nature and quality or the wrongfulness of his or her acts because of the effect of a mental illness or condition.

Diminished responsibility: where a person kills or is party to the killing of another, he or she shall not be convicted of murder if he or she was suffering from such an abnormality of the mind (whether arising from a condition of arrested or retarded development of the mind or from any inherent causes or induced by disease or injury) as substantially impairing his or her mental responsibility for his or her acts and omission in doing or being party to the killing.

Infanticide: when a woman or girl who unlawfully kills her child (under 12 months) under circumstances which, but for this section, would constitute wilful murder or murder, does the act which causes death when the balance of her mind is disturbed because she is not fully recovered from the effect of giving birth to the child or because of the effect of lactation consequent upon the birth of the child, she is guilty of infanticide only.

Homicide-suicide: when the homicide offender commits suicide shortly after the homicide, sometimes defined as within a week of the homicide.

homicide is a very rare event that is not possible to meaningfully predict [66, 67]. Decisions regarding the release of mentally ill homicide offenders should take into account the cognitive biases that influence the interpretation of catastrophic events, including the tendency to hindsight bias in apportioning blame. The rarity of homicides by the mentally ill, and the absence of identified factors associated with a greatly increased probability of homicide, means that it is not possible to predict which patients might go on to commit homicide or when a homicide might occur.

Homicide recidivism

Homicides committed by people after the conclusion of proceedings for an earlier homicide offence are known as recidivist homicides. Schizophrenia has been reported to be a risk factor in recidivist homicide [68], but in most advanced countries, recidivist homicide by people with schizophrenia is rare or unknown, probably because of long-term secure hospitalization and effective systems for ensuring long-term care after release [69].

The role of mental health professionals in homicide prevention

People with mental illness commit a minority of homicides, and only a small proportion of homicide offenders are in contact with

mental health services at the time of the homicide. Hence, treatment of mental illness can only ever have a small effect on the overall rate of homicide. However, mental health professionals do have a role in the prevention of some homicides, particularly domestic homicide, homicide by people seeking treatment for substance use, and homicide by people with emerging or established psychotic illness. Because domestic homicides are a common form of homicide, the most important role health professionals can play is in the detection of domestic violence and in interventions to protect the victim and treat the perpetrator. Domestic violence victims present with a range of emotional disorders and seek help from a range of services, often without disclosing their situation [70]. Health professionals can assist domestic violence victims by notifying the authorities and referral to respite and support. In many jurisdictions, there is now mandatory notification of violence involving children. Mental health professionals may also have a role in notifying licensing authorities about the emergence of mental illness or the presence of domestic violence among gun owners.

Improvements in the overall management of substance use disorders, in particular alcohol use disorders, and of comorbid substance use among people with mental illness could be expected to reduce the incidence of violence, including homicide, among those seeking care.

Health services can also play a part in reducing the incidence of violence by the mentally ill, by developing systems to ensure early treatment of psychotic illness and by ensuring the continuity and standards of ongoing care.

Threats of homicide warrant careful evaluation. Warning of potential victims and notifying authorities can be an acceptable breach of patient confidentiality, if the information that has become available to the clinician indicates the presence of a real threat to another person's safety.

While it is likely that good clinical care can prevent some homicides, the benefit of interventions is not apparent or easy to demonstrate. Most clinicians will never have a patient who commits a homicide. Psychiatrists do have a more tangible role in providing care to both mentally ill homicide offenders and a much larger number of people who have experienced the trauma and grief of the loss of a relative by homicide.
